[a] In addition to the notation of the Symposium: T = time, in hours; $t = 60\, T$ = time, in minutes; q and σ are in inches per hour; q_a = flow at the end of 20 min; y is in inches; y_a = depth at the end of 20 min; and K is in (hours-inches)$^{-1}$. [b] The following constant conditions apply to each curve in this example: $K = 0.85$ per hr-in.; $q_a = 2.116$ in. per hr. [c] Initial value. [d] For all curves except 1 and 8, T and t are measured from point A ($t = 20$ min). For curve 8, t and T are measured from point B ($t = 40$ min). [e] $\sigma < K\, y^2_a$.

Fig. 27.—Comparison of Runoff Rates and Drainage Requirements as Derived by Mathematical and Graphical Methods

These curves and examples raise the question as to whether or not the curves used by Mr. Hathaway properly allow for the infiltration which certainly must continue after the storm ceases as long as the ground is submerged. The effect of subsequent infiltration is shown clearly by curve 6, Fig. 27.

Why does not the mathematical method yield precisely the same results as does the Hathaway method for a given intensity and duration of rain? To be specific—why do curves 2 and 5, Fig. 27, differ so markedly? The lack of agreement seems to rest on the failure of the unit hydrograph method employed by Mr. Hathaway to apply to the case. His method assumes that the rate of flow out of a given area which comes from a particular portion of a rainstorm is precisely the same at a given time after that rain occurred, regardless of the amount or distribution of rain that might have followed. Thus, according to this view, the flow rate out of an area from a 40-min-long rain of 4 in. per hr rate of supply would be the sum of two flow rates: (1) The flow rate that did occur during a like storm from this area 20 min after the beginning of that storm; and (2) the flow rate that would occur at a certain time from that area as the result of a storm which lasted just 20 min but which ended 20 min before that time.

This assumption would be a valid one if at the end of the first 20 min an artificial roof, with hydraulic characteristics the same as those of the ground, were suddenly placed over the area. Under these conditions the two flows could not influence one another, and the Hathaway method of adding the two known independent flow rates would be correct.

The actual situation is different. The rain from the second 20 min of the storm finds itself, so to speak, flowing on top of the rain from the first 20 min of the storm. Each layer increases the velocity of the other. (Since the depths are greater at corresponding points on the area, and at corresponding times on this area, than in the hypothetical "double-deck" area, the velocities are greater.) One might first suppose that this increased velocity would not necessarily increase the rate of runoff, since the depths might decrease correspondingly, but, when the depths decrease, the amount of storage also decreases. As a consequence, a greater amount of runoff must have occurred in a given period of time.

From these considerations it appears that the mingling of the two flows, the one from the first 20 min and the other from the second 20 min of the rain, produces rates of runoff which, for a time, are greater than the sum of what each would be if the other were not present. Thus the principle of superposition should not be used with this type of flow.

Of course, the total quantities of runoff, plus storage and infiltration, must check the total volume of supply. The writer has made sure that the areas under each curve conform with this basic requirement. The function $\int q \, dT$ is readily determined mathematically for each of the curves in Fig. 27.

Curve 9, Fig. 28, is the rate-of-supply hydrograph that would yield the Hathaway runoff hydrograph, curve 2, Fig. 18, which is also shown in Figs. 27 and 28. Curve 10, Fig. 28, is the rate-of-supply hydrograph that would yield the Hathaway runoff hydrograph, curve 7, Figs. 27 and 28. These rate-of-supply hydrographs have been obtained by the differential equation:

$$\sigma = K\,y^2 + \frac{2\,dy}{3\,dT} \qquad \text{(8)}$$

Values of $K\,y^2$ are the ordinates to curve 2 which, of course, was plotted by the Hathaway method—that is, by subtracting appropriate ordinates of curves like curve 1 from one another. Since values of $K\,y^2$ are known, corresponding values of y, and also values of $\frac{2}{3}\,y$, may be computed. These have been plotted as curve 11, Fig. 28. (Curve 12, Fig. 28, was plotted similarly, employing as a basis the ordinates of curve 7, Fig. 28.) Then the slope of curve 11 was determined graphically. These slopes constitute the values of the third term in the differential formula, Eq. 8. The last two terms in this equation were then added—with due regard to sign—and plotted as σ. The values of σ are the ordinates of curve 9, Fig. 28. (The ordinates of curve 10 were similarly obtained, using the slopes of curve 12.)

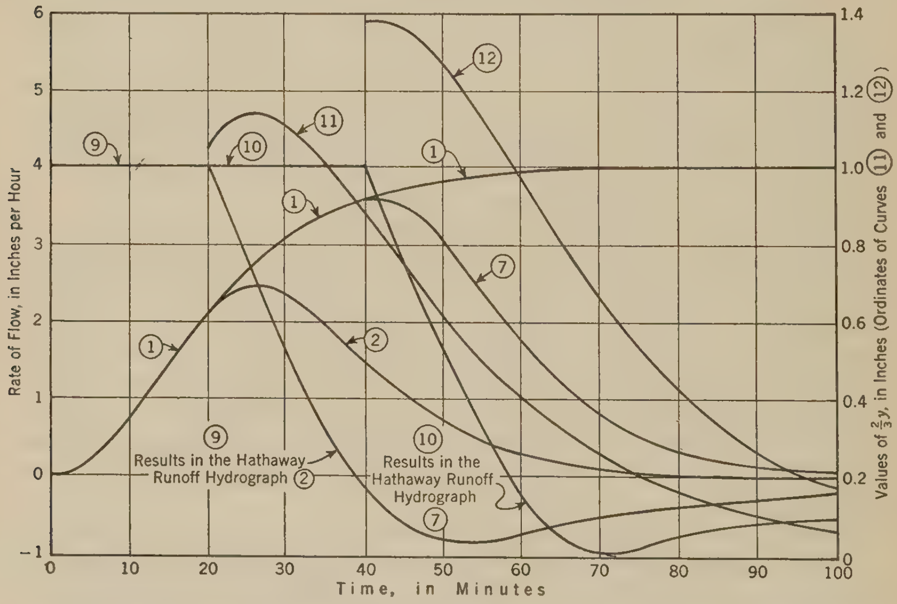

FIG. 28.—RATE-OF-SUPPLY HYDROGRAPHS (CURVES 9 AND 10) WHICH WOULD RESULT IN THE HATHAWAY RUNOFF HYDROGRAPHS (CURVES 2 AND 7)

Such hydrographs of rate of supply—namely, curves 9 and 10—might just as likely occur as perfectly rectangular hydrographs, one of which is represented in Fig. 27. Rains do not stop suddenly, but diminish slowly in intensity after their period of high rate, and sometimes are followed by a period of negative supply (or predominant percolation) somewhat as these curves might indicate. Thus the runoff hydrographs in Mr. Hathaway's paper appear correct for certain plausible rate-of-supply hydrographs which might occur, although not for the simple rate-of-supply hydrographs which Mr. Hathaway seems to have assumed.

To obtain the runoff hydrograph for any arbitrary rate-of-supply hydrograph on the basis of the Horton differential formula, Eq. 8, two methods for analysis of the behavior of flood retention reservoirs are available: (1) The mass curve method presented by H. G. Payrow, M. Am. Soc. C. E. (26); and (2) the method (27) developed by the Miami Conservancy District, Dayton, Ohio.

David S. Jenkins,[8] Assoc. M. Am. Soc. C. E.—That part of the Symposium on airfield drainage, to which this discussion is largely devoted, is a major contribution from the science of hydrology to the advancement of both civil and military aviation. Mr. Hathaway provides the airport engineer with two important new tools for the design of storm drainage systems. First, by the use of Mr. Horton's (18) equations of overland flow as applied by W. W. Horner, M. Am. Soc. C. E. (27), for related purposes, an ingenious consolidation of Mr. Yarnell's (15) rainfall data into one very useful set of curves, and some bold assumptions concerning infiltration, a greatly improved method for calculating storm runoff from airfields is devised. Second, a simple and urgently needed procedure is presented by which the actual quantities of temporary pondage in areas between runways are computed from the established hydrograph. The correct application of these two methods requires certain highly specialized knowledge of hydrology. As the airport engineer engaged in a variety of general civil engineering duties cannot reasonably be expected to acquire this specialized information on short notice, delay in the adoption of these improvements should be expected. If the Hathaway paper were to have no other immediate value than the stimulation of widespread interest in the application of hydrology to airport drainage, much will have been accomplished. Furthermore, the occasional application of the tools will be of great and immediate value in the design of the airports to which they are applied.

Differences in requirements of drainage systems for civil airports and military airfields might be expected because of the different basic purposes of the two establishments. For obvious security reasons, the military airfield must be made serviceable on short notice and must offer minimum delay from flooding, but the commercial airport may be rendered unserviceable by flooding for longer periods with only economic loss. Counterbalancing the need for greater serviceability on the part of the military airfields is the demand for greater safety in civil airports arising largely from the factor of financial liability for passengers and cargo with which the military engineer is not confronted. Because of these compensating requirements, the writer believes that the five general criteria for design of the drainage system stated by Mr. Hathaway may be substantially adopted for civil airports. Postwar economic studies of aircraft movements, cargo values, and fuel reserves are needed to provide a more adequate basis for the design, not only of drainage structures but also of pavements and other airport facilities as well.

The method developed by Mr. Hathaway for calculating storm runoff from airfields is a definite improvement over the rational method, the Burkli-Ziegler equation, and other similar formulas which have little scientific foundation.

---

[8] Senior Airport Engr., Civ. Aeronautics Administration, Washington, D. C.

That part of the rainfall which does not appear as runoff is quantitative and specific, and is not a ratio of the rainfall, as represented by a coefficient. As this truth has been well established, the subject is no longer controversial. However, the new method, like the old, requires a personal estimate of critical factors based on judgment and experience. Although separate evaluations of two or more unknowns will doubtless result in greater reliability than a collective estimate of the several, as embodied in the runoff coefficient, it is questionable whether the airport engineer is sufficiently familiar with the phenomenon of infiltration and with the roughness factors applicable to overland flow to make a correct estimate of them without additional guides. Mr. Horner (24*a*) states that possibly as many as 100,000 controlled experiments are available in the records of the Department of Agriculture from which infiltration capacities and overland flow characteristics are derivable. The practical application of these data to essential uses such as the design of military and civil airfields opens a new field to those familiar with these experiments. A contribution of practical value would be made, for example, if a table were prepared from these data showing the range in infiltration capacities for different soils and cover. The data could also be used in preparing a set of photographs showing grass covers representative of the ranges in the roughness coefficient n, similar to visual guides for channel roughness proposed by C. E. Ramser, M. Am. Soc. C. E. (28). If these suggested aids are not adopted, the data should be prepared from infiltrometer tests made on a representative group of airports.

In regions of high rainfall intensity where infiltration may constitute only a small fraction of the rainfall, large errors in estimating its value may result in only minor errors in design; but in regions of medium and low intensities this is not true. In the example given in the paper, Mr. Hathaway assumes an infiltration capacity of 0.6 in. per hr. This value is within the range of infiltration capacities—from 0.5 to 1.0 in. per hr—recommended in the *Engineering Manual* (a more detailed version of the Hathaway paper (23*a*)). From the writer's personal field observation of several thousand watershed rainstorms and the measurement of these and the runoff therefrom, together with the study of similar rainfall-runoff records and infiltrometer determinations, this range appears to be too narrow and its lower limits may be too high. Much greater emphasis could be placed on the influence of grass on infiltration.

TABLE 6.—TYPICAL TERMINAL INFILTRATION CAPACITIES, IN INCHES PER HOUR

Grass cover	MERITA CLAY LOAM		ABILENE SILTY CLAY LOAM		REAGAN SILTY CLAY LOAM	
	Range	Mean	Range	Mean	Range	Mean
Poor.......	0.07 to 0.35	0.15	0.05 to 0.21	0.12	0.12 to 0.20	0.16
Good.......	0.20 to 0.70	0.38	0.23 to 1.64	0.73	0.22 to 2.65	1.26

Unpublished infiltrometer records show wide variation in terminal infiltration capacities, but define a trend indicating that the infiltration capacity of a given soil having a good turf cover is roughly twice that of bare ground and that the over-all average of all terminal infiltration capacities on bare soil is roughly 0.2, with a range from 0.02 to 1.00 in. per hr or higher. Also unpublished are the results of numerous infiltrometer tests on high-plain prairie soils of very low slopes, comparable to slopes of airports. Three of these are given in Table 6 to illustrate the broad range of infiltration capacities on some soils which may be expected by the airport engineer. The average time required to reach constant capacity in each case was as follows:

Soil	Time, in minutes
Merita clay loam	47
Abilene silty clay loam	76
Reagan silty clay loam	63

Since many airport engineers consider that the method proposed by Mr. Hathaway is not usable unless a guide for estimating infiltration capacities is provided, the tentative values in Table 7, for use in airport drainage design only, are suggested. The writer is fully aware that these values are subject to revision and that infiltration rates are influenced by many variables, but the use of Table 7 in conjunction with the Hathaway method should result in fewer and smaller errors than if no guide at all is followed. The values in Table 7 for dry antecedent conditions should be considered in regions where high rainfall intensities occur only as summer thundershowers and where wet antecedent conditions will probably not prevail at the time of the design rainfall.

TABLE 7.—ONE-HOUR INFILTRATION CAPACITIES, IN INCHES PER HOUR
(For Use Only in Design of Drainage Facilities for Airfields)

Character of entire soil[a] profile	DRY ANTECEDENT CONDITIONS		MOIST ANTECEDENT CONDITIONS	
	Dense grass	Poor grass[b] or bare	Dense grass	Poor grass[b] or bare
Tight plastic clays and silty clays	0.4 to 0.6	0.2 to 0.4	0.05 to 0.2	0.02 to 0.1
Porous loams and fine sandy soils	0.8 to 1.2	0.5 to 0.7	0.4 to 0.8	0.2 to 0.4

[a] Gravels and coarse sands not included. For pavement use zero. [b] To a small degree these values for bare soil will vary inversely with intensities. This is not true for dense turf.

In calculating airport runoff to be used in designing the drainage system, an important source of error arises from the necessity of assuming in advance that a certain grass cover will ultimately be established on the area. No opportunity is afforded therefore to examine the grass cover on which the infiltration and roughness values—or the runoff coefficient—must be based. Airport turf is generally not well established until about the end of the first year, and in many cases not for two years following the completion of grading. During these two years which represent one design rainfall cycle, the land is relatively bare, runoff is high, the erosion of pavement shoulders advances rapidly, and the silting of drain lines may be serious. For this reason, the conservative results obtained by the Hathaway method seem further justified for the protection of the installation during this initial period, which may represent as much as 20% of the life of the pavements.

The practice of subtracting the infiltration capacity from the rainfall curve without a downward adjustment of the frequency is questionable, as it implies that the resulting supply curve retains the frequency of the original rainfall. Ground moisture conditions productive of the 1-hr infiltration capacity will not prevail at equal frequency and simultaneously with the design rainfall, although that is the interpretation generally placed upon the supply curve. A factor of safety is thereby introduced, the magnitude of which varies geographically. A similar interpretation is usually applied to other runoff formulas and probably accounts for the fact that some small and apparently inadequate airport drainage systems based on the 2-yr rainfall have not been overtaxed in eight or ten years of service. If the engineer desires to base airport drainage design on the frequency of flooding (as must eventually become standard practice) and, if this design flooding frequency is two years, the selected design rainfall frequency will need to be increased, perhaps to one or even two storms per year, for all but the most important airports. Meanwhile, studies of the frequency of occurrence of selected infiltration rates and probabilities of groups and combinations of individual rainfall events should also be made from the wealth of available data previously mentioned. In any event, if an adjustment of the safety factor is necessary, it should be accomplished by revision of the selected frequency, and preferably not through modifications of other factors that might be misleading.

It is regrettable that the runoff methods proposed cannot be used for the many large intermediate airport areas having effective lengths of overland flow exceeding 600 ft, and there is some question whether the Horton equation would hold true on graded airport slopes 500 ft or 600 ft long. For applicability of that equation the surface (and adjacent surfaces) must be a true plane of such shape as to avoid channeling or accumulations of flow. Furthermore, as the relationship between length and critical time is very nonsensitive for the longer slopes, great refinement of results should not be expected in this range. For the larger areas a correct application of the rational method may be necessary, if indeed it is possible to apply that method correctly. Recent trial studies indicate that the Snyder Synthetic Unit Graph (29) may be adaptable to small watersheds of this type. Considerable success has also been achieved by numerous investigators in applying to small watersheds the "Modified Rational Method" as developed by Merrill Bernard, M. Am. Soc. C. E. (30), and others.

The method of determining the maximum volume of available pondage is not entirely clear although it is stated that this quantity depends upon land slope and permissible grades. General recommendations (31) for commercial airports of the three higher classes require that longitudinal and transverse grades should be limited to 1.5% maximum slope, and that the maximum change in grade at any point shall not exceed 2%. On the basis of these recommendations, in general, negligible pondage can be created along one drain line parallel to a runway when the longitudinal grade is greater than about 0.8% if the transverse grade is 1.5%. Fig. 26 affords favorable opportunity for the use of pondage as the longitudinal grades of the three runways are all less than 0.15%. For use as a guide in determining the maximum pondage requirements, the total runoff for each inlet can be obtained directly from Cols. 23 and 25 of Table 4(*b*).

Care should be taken to avoid the creation of ponding areas where the geologic structure is of such dip and character as to convey water from the pond to the pavement subgrade. A slight dip toward the runway with porous material outcropping in the pond and underlain by less pervious material presents a perfect opportunity for ponded water to reach the pavement base and subgrade. Borings made with this in mind will reveal such a condition if it exists.

Under "Computations of Storm Drain Capacities, Assuming Supplemental Ponding," Mr. Hathaway states:

> "It is desirable to maintain the hydraulic grade line as near as practicable to the top of the drain pipe during the design storm."

This important statement is not further emphasized, and, although this requirement has apparently been satisfied in the example, the procedure by which it is accomplished in the case of ponds has not been clarified. If the hydraulic gradient is permitted to rise to the elevation of one of these ponds, discharge from the pond will cease. Backwater will occur from the drain line into the pond if the gradient is raised further. Fig. 26 shows rectangles beside each inlet which are not discussed, but other than these the only limitation placed on the discharge rate of each pond appears to be the flow capacity of the inlet grating.

To compute the runoff for storm drainage design (32), an adaptation of a rational method (33) is used by the Civil Aeronautics Administration which has successfully pioneered in the field of airport design:

$$Q = \frac{A\,I\,R}{T + t} \quad \text{.........................(9)}$$

in which Q = rate of runoff in cubic feet per second; A = area to be drained, in acres; I = percentage of imperviousness of the area; R = maximum average rate of rainfall over the entire drainage area, in inches per hour, which may occur during the time of concentration; T = duration of rainfall in hours (assumed to be 1 hour in airport design); and t = time allowed for removal of rainfall after the end of the storm (assumed as 2 hours in airport design). The value of R is the 1-hr, 2-yr rainfall intensity for all inlets.

As this method has been used in the design of many large airports, a brief comparison of the results obtained from it and from the Hathaway method is of interest. For this comparison two of the drain lines, C and D, of the midwestern airport in Fig. 29 have been investigated. These lines were selected because they are isolated, or branch, lines carrying neither water from other inlets nor "foreign" water from outside the airport. All computations for line D, including those of pondage, exclude any provision for future grading of the unfinished area to the west. The pondage along line D used in the application of the Hathaway method is the maximum that could be provided with the given inlet elevations. Because of the high longitudinal slope, no pondage can be created along line C. The high infiltration capacity of 0.9 in. per hr was selected to correspond as closely as possible for this rainfall region to the value 0.20 for "imperviousness" used in the method followed by the Civil Aeronautics Administration (33). The roughness factor represents average grass cover. The comparison shows the runoff computed by Mr. Hathaway's method to be appreciably greater, even with ponding, than that computed by Eq. 9. Since the soil surveys indicate that the area is quite sandy, the smaller quantities shown in Table 8 are apparently adequate. If the transverse grade along line D were to be increased to about 1%, pondage sufficient to contain the total design runoff for each inlet could be provided.

Neighboring property interests must be considered in connection with drainage. These interests, which may be seriously affected by the drainage system, may in turn affect the design. The possibility that the artificial conveyance of the water from the airport and vicinity may alter the natural regimen of the outlet streams by either increasing or decreasing the quantities and rates of flow, may cause inundation of rural or urban areas, or otherwise may damage private or public property should be investigated thoroughly before work is started. In his introductory remarks Mr. Hathaway indicates

TABLE 8.—COMPARISON OF RUNOFF COMPUTATIONS FOR DRAIN LINES D AND C, FIG. 29

Inlet No.	USING[a] EQ. 9						USING HATHAWAY METHOD[b]				
	Area (Acres)		Discharge Q, in Cubic Feet Per Second				Discharge Q, in Cubic Feet Per Second				Volume of pondage (1,000 cu ft)
							Without Ponding		With Ponding

that the problem of diverting water from adjacent areas will be discussed. This water from neighboring lands can usually be disposed of most economically by interception in open channels located outside the area of operations. Then, the quantity of water reaching the final outlet channel under natural conditions should be calculated. As the results may ultimately be used for various purposes, including litigation, the runoff for the 5-yr, 25-yr, and 100-yr rainfall should also be computed and a permanent record made of all assumptions and estimates. The elevations of flood water in the final outlet channel under the natural condition should be computed by using the estimated quantities together with a simple application of the backwater method (34) introduced by the late H. R. Leach. Of interest in this connection is a recent case of an airport in the arid West where, because of neighboring property interests, it has been proposed to construct on the airport property a shallow reservoir of large area with sufficient capacity to collect and evaporate the total annual runoff.

Where snow is cleared into a mound along the edge of the runway, the normal path of overland flow is blocked. The trapped water collects on the runway creating a dangerous operational hazard. Among the numerous means for disposing of this small discharge, a pre-cast concrete pipe of rectangular shape with removable lid and numerous surface inlets has proved satisfactory.

The California bearing ratio (CBR) is being used extensively in its original or modified form in the design of airport pavements. Nevertheless, there is a rather widespread misunderstanding of its purpose. As a result airport drainage is considered by some to be of little or no importance because, it is argued, flexible pavements will be designed on the basis of a saturated subgrade by the use of the CBR, and, therefore, flooding will cause no damage. This Symposium with its discussion of CBR, coupled with its emphasis upon airfield drainage, should aid in correcting this misunderstanding. For further clarification: First, the soaking procedure of the CBR does not necessarily produce saturation. Second, there is a vast difference between saturation and the surcharging of the subgrade through flooding. The construction of a stable pavement on a fluid subgrade would be virtually impossible regardless of the base course thickness, and the CBR does not anticipate this condition. Third, the principal cause of subgrade and pavement instability is the intermittent change in moisture conditions with the accompanying destructive alterations in volume and density. No better method than adequate drainage has yet been devised to minimize that change. Engineers may continue to build thicker and costlier pavements, but, regardless of thickness, strength, and cost, these pavements cannot be successfully floated on fluid subgrades or on those found where airport drainage is inadequate, which are swelling, shrinking, and frost active.

The drainage and pavement designs discussed in this Symposium as well as the plan shown in Fig. 29 are for the better classes of military and municipal airports. There is an urgent and rising demand for economy in airport construction, not only for the several thousand smaller cities but for the numerous smaller airports which will environ larger cities in the postwar era. To satisfy this demand the engineer will be compelled to seek less expensive runways and drainage facilities. The open channel will undoubtedly be used extensively for both surface and subsurface drainage, but an understanding of its limitations as well as of its usefulness is essential. The open channel may be widely adaptable if supplemented where necessary with small closed drains to remove those long depression flows that create dangerous, and frequently obscure, soft areas. Through the developments discussed in this Symposium and the current work of the Civil Aeronautics Administration and other agencies, engineers have or are obtaining much information needed for the design of pavements and drainage facilities to accommodate heavy craft at the large airports. They now must meet requirements for economy—on the smaller fields for the private flier—and to this end much investigational and development work remains to be done.

William E. Rudolph,[9] M. Am. Soc. C. E.—The engineer who has followed the development in airplane landing fields must be impressed by the thorough manner in which the Corps of Engineers has solved the two important problems of paving and drainage, as described in this Symposium.

Colonel Stratton outlines the wheel loadings (as high as 60,000 lb) on which designs of pavements for military airfields are being based. Under the heading, "Loading Criteria for Military Airfields," he states: "Loadings greater than 60,000 lb may be anticipated in the near future, but no design provision is being made yet for such loadings." The writer would raise the question: How will the pavements designed for present loadings be converted to future loadings, when and if such increased loadings are adopted? Recent news items indicate that Idlewild Airport in New York, N. Y., may have runways designed for 300,000-lb plane loads—wheel loads more than double those for Class I airfield pavements. Thus, another and even more important question applying to lengths of runways as well as loadings should be asked: When and where is the limit to be established on increases in design requirements for airfields?

Somewhere the writer has read that development in airplanes generally has been ahead of airport and airport facilities. This statement is doubtless true, but for a reason. After all, the civil engineer has had the continuous task of keeping up with the airplane designer, providing airports and facilities for the landing and the taking off of larger and heavier types of aircraft at ever-increasing landing speeds. Because early aircraft had no brakes, the airfield builder had to provide a large number of runways for landings into prevailing winds. As wing loads and operating speeds increased, he had to lengthen these runways to provide for longer take-offs and landing runs. The resulting field became more and more cumbersome. As wheel loads reached the stage at which turf fields were no longer appropriate, the engineer had to give more attention to soil stability, paved strips, and expensive drainage systems. It is small wonder that throughout the history of aviation, after several years of service, landing fields became obsolescent—too small for the kind as well as amount of air traffic using them.

Will the airfield continue to be laid out and built to fit the airplane, or will the airplane designer build his craft to fit the airfield? Economic laws will dictate the answer to this question. Already engineers are beginning to stress limitations on the size of an airport rather than increases in runway lengths and loadings. The development of catapults for aid in take-offs and of tricycle landing gear for cross-wind landings, as well as of better air and ground brakes, promises to keep the lengths of runways within the limits mentioned by Colonel Stratton; however, wheel loads might be destined to increase further as the cargo plane replaces the bomber in the postwar world.

---

[9] Eng. Dept., Anaconda Copper Mining Co., New York, N. Y.

Colonel Stratton mentions the current rule by which runway lengths are increased 500 ft for every 1,000 ft above sea level. This necessity seldom involves important increases in airfield dimensions within the United States, but it does create problems in South America, where the mining regions and their population centers are generally located at altitudes above 7,000 ft (many above 12,000 ft). South America is far more dependent on air services for cargo, not to mention passenger and mail, transport than is the United States. Its railways and highways have not been developed to any extent in most sections, and the obstacles of rugged topography and rainy season stream flows make construction very expensive. The European interests which earlier played an important part in developing South American aviation have now been removed, and the engineers of the United States face the task of furnishing the "know how" in completing this development, particularly as applied to postwar cargo transport. The cost of landing fields with the extremely long runways required at high altitudes, located necessarily in regions of rugged topography, presents a problem which must be solved by the civil engineer and the airplane designer working together. The writer recalls an experience with airfield location in Bolivia about 1936, when serving on a committee entrusted with the task of recommending an airfield site near the City of Potosi. Two sites appeared appropriate, one at an elevation slightly below 13,000 ft, the other at one somewhat above 11,000 ft. The higher site had greater advantages—or, more exactly, fewer natural disadvantages—than did the lower, but the army officer making the final decision was interested only in the lower site. Here the additional runway length required at the higher elevation, although relatively small, was the governing factor against this location, available space within the narrow valley being scant for take-off and landing requirements in either case.

A consideration not mentioned by Colonel Stratton in connection with the choice of airfield site is concealment. The writer has read with interest a recent book (35) on this subject by Merrill E. De Longe, in which it is stated that hard surface runways are invariably the most conspicuous features of an air base. Undoubtedly the Corps of Engineers has given serious consideration to reducing such runway visibility.

RAYMOND L. IRWIN,[10] Assoc. M. Am. Soc. C. E.—The procedures recommended in this Symposium by Mr. Hathaway for the design of airfield drainage facilities are impressive. The applications of the more advanced theories on drainage, particularly those concerning infiltration and surface runoff, are, in themselves, valuable contributions toward future drainage studies and computations.

---

[10] Engr., U. S. Engr. Office, Columbus, Ohio.

There is an apparent need for further research to determine the basic data, which play so important a part in the development of the computations and curves. In this connection, attention is invited to the following items which are ordinarily considered essentials in drainage studies and designs: (*a*) Rainfall intensity and frequency data; (*b*) procedures for the determination of rainfall infiltration rates; (*c*) effects of surface detention storage; and (*d*) roughness coefficients applicable to anticipated grass cover.

Available records show that the runoff resulting from an excessive storm is not usually in proportion to experienced rainfall intensities. An intense rainfall which normally occurs during the summer season ordinarily provides less runoff from a given area than a storm of corresponding intensity which occurs during the winter season. There is also a perceptible difference in the intensities of rainfalls with seasonal changes. A comparison of rainfall frequency-intensity data taken for the entire year, as against frequencies and intensities experienced for the six months, November to April, was made by the writer on the basis of data obtained from rainfall records for Pittsburgh, Pa., Cincinnati, Ohio, and Cairo, Ill. For each of these stations, at least seventeen summer rainfall occurrences of 1-hr duration have exceeded the highest winter rainfall intensity for one hour, during the 35-yr period from 1905 to 1939, inclusive. It is an accepted fact also that infiltration rates for summer rainfall occurrences should ordinarily be considered greater than those for storms occurring during the winter seasons. Since infiltration rates and rainfall intensities vary with the seasons of the year, recognition of these factors might be contained in the construction of runoff frequency curves.

The values of runoff used for construction of the curves might be obtained by subtracting the infiltration rate to be applied during a given period, say, a month, from the intensity of the rainfall to be expected during that month. The data could then be combined on a yearly basis if so desired. In this manner it would be possible to refer to the frequency of rainfall contributing to runoff, which is the factor more indicative of the capacity for which protection and design are desired.

The methods for determining infiltration rates have not advanced sufficiently to furnish reliable values for use in design. After establishing infiltration rates based upon careful tests and studies, it has been found by experience that soils which appear porous sometimes are quite susceptible to clogging from the fines and vegetable matter contained in top soil and transported by the surface runoff. This action has been noted to occur particularly where the ground surface is disturbed by grading operations, prior to the establishment of a protective turf covering. The results of such experiences indicate the advisability, even for soils with high infiltration rates, of providing pipe or ditch drainage systems capable, eventually, of disposing of apparently unforeseen surface ponding.

The problem of grading to specified take-off and landing grades for all-over type airfields, although apparently more desirable for plane operations, often has the disadvantage of creating areas that result in surface detention pockets. This is usually caused by uneven settlement of ground in areas where slight slopes are constructed. In most cases, these areas are not harmful in themselves, although basic formulas utilized in drainage computations are disturbed. It seems unreasonable to demand that a contractor maintain surface grades in agreement with theoretical grades within as much as 0.1 ft or 0.2 ft. For fields where grading was considered quite satisfactory, topographic surveys have indicated the existence of these irregularities, which usually have no effect upon plane operations. On steeper slopes care should be exercised in maintaining the proper grades. Slight differences in slope may tend to collect the flow along a given line. This condition might result in channeling, which will tend toward higher velocities and erosion. As a consequence, shorter concentration periods will be applicable. If large ponding areas are involved in the process of overland flow, the concentration time of so-called overland flow apparently would be reduced because of the nearly negligible friction coefficient involved in traversing the ponded areas. Therefore, a greater peak outflow would result.

Various types of soils are encountered in airport construction. Some of these are more responsive to the growth of turf than others. To avoid unnecessary expense in treating the soil, types of grass are grown on some fields which are not practical for other fields. It has been suggested that, if the ground will not grow grass, weeds should be grown to obtain a protective covering. The writer is not familiar with any specific project in which the planting of weeds was found necessary.

For the various conditions of grass cover, which differ widely in structure and texture, difficulty will occur in the evaluation of the roughness coefficients. The Manning formula, used for determining flow, indicates that, for a given depth, the discharge varies inversely with the roughness factor. The roughness factors recommended by Mr. Hathaway range from 0.2 to 0.8. The corresponding discharge values for a given depth, other factors remaining constant, would therefore have the ratio of 4 to 1. Roughness coefficients are frequently selected under the guidance of judgment and experience. Therefore, the values selected might be considered questionable until sufficient supporting data and a dependable procedure are made available for practical application.

Experiments by W. O. Ree (36) on shallow flows over grassed slopes indicate that, after depths of flow of 2.5 in. were exceeded with certain grass cover, the roughness coefficient tended to decrease with increase in depth. At a depth of approximately 5 in., the roughness was less than 80% of that at 2.5 in. (Since runoff velocities for grass are very low, the aforementioned depths are feasible for long slopes.) The change in roughness may be caused by arrangement of the grass blades or reduction of the wetted perimeter by the force and weight of the water. A finer type of grass apparently will be quite sensitive and will cause appreciable changes in discharge at shallower depths. Here again experimental information seems necessary before adequate data can be secured to permit accurate reproduction of profiles for overland flow.

The rates of overland flow corresponding to standard supply curves, Fig. 19, do not represent the absolute maximum rate of runoff for a storm of a given frequency if the rainfall sequence is disturbed. Mr. Hathaway states that the curves of Fig. 19 are not hydrographs, but represent the peak rates of runoff from individual storm events of various durations, all of which have the same average frequency of occurrence. At the beginning of the design storm, which is of uniform rate, the ground surface is free from flow; therefore, storage for overland flow does not exist. This does not represent the usual condition experienced preceding high rainfall intensities. Runoff occurring from the lighter rainfall immediately before the design intensities will often displace a part of the surface detention storage.

In the interest of determining the maximum rate of runoff that could be obtained for a hypothetical storm containing runoff intensity values corresponding to a given supply curve, the writer made the following analysis: Rainfall intensity values corrected for infiltration were obtained from the standard supply curve 1.6 for 5-min periods, and their values were arranged in ascending order. These values were routed graphically through the storage occupied in overland flow, by the method suggested by W. W. Horner, M. Am.

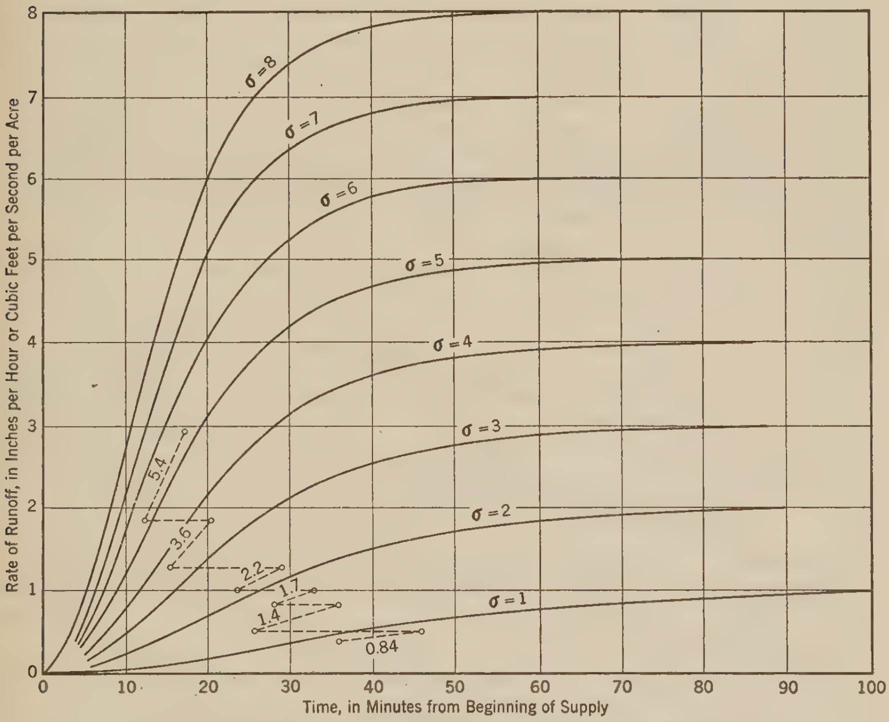

FIG. 30.—ROUTING WITH INCREASING EFFECTIVE RAINFALL RATES

Soc. C. E., and S. W. Jens, Assoc. M. Am. Soc. C. E. (24), using the relation $q = K y^2$. In brief, on the rising side of the hydrograph, the volumes of surface detention or storage for two different but uniform net rainfalls are considered equal, when the runoff rates are equal. Therefore, when changing from a lower to a higher rainfall rate, the discharge rate obtained at the end of the time for the first selected rainfall intensity is proportional to the storage and can be transferred to apply, at an equal discharge rate, to the second rainfall supply curve. This curve is then paralleled for the desired interval of time to obtain the runoff at the end of time for period two. Fig. 30 indicates the steps taken for routing with L = 400 ft and the intensity values obtained from the 1.6 supply curve. The maximum runoff rate obtained by this method was 2.9 in. per hr as compared to a maximum value of 1.75 in. per hr, furnished by Mr. Hathaway's procedure. Fig. 19 indicates a maximum runoff rate of 2.3 in. per hr for supply curve No. 2.0 and L = 400 ft. Although the former value of 2.9 in. per hr represents an extreme condition, but not necessarily the result of a true frequency, it was presented to demonstrate the wide deviation in results possible from the same indicated frequency storm with a different arrangement of the rainfall. Since storms of lower intensity occur more frequently, they should produce a runoff of, say, 1.75 in. per hr where the true frequency would apparently be less than indicated by Mr. Hathaway. There is a greater possibility that the runoff intensities are higher for the shorter lengths of overland flow than for conditions involving travel over the longer lengths. The extreme for minimum flow could be reached by reversing the rainfall distribution, under which condition a value of approximately 1.2 in. per hr would obtain. A careful study of critical rainfall distribution deserves investigation to determine critical conditions for the area under consideration.

A graphical solution used by the writer to determine storage and drain-inlet capacity may be of interest. Where the storage is very small, the rainfall distribution is arranged for maximum conditions as stated in the foregoing paragraph, using descending values of intensities. The method proposed is approximate only and consists essentially of the following:

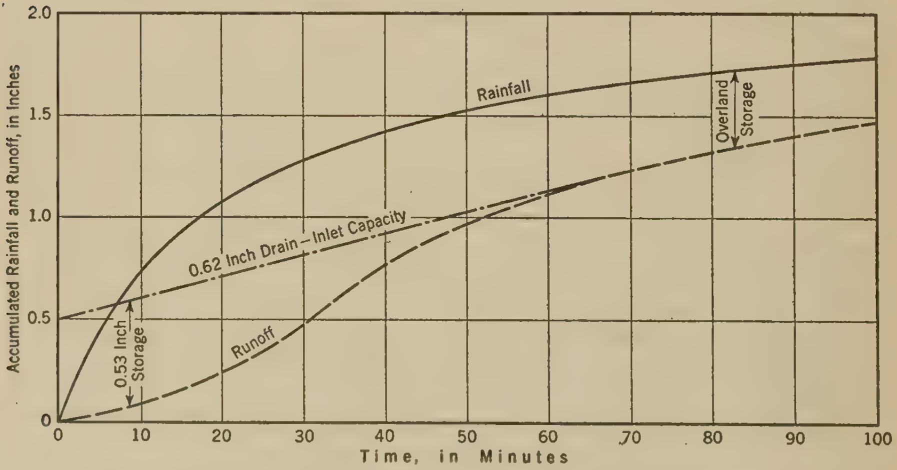

FIG. 31.—GRAPHICAL SOLUTION FOR DETERMINATION OF DRAIN-INLET CAPACITY, FOR STANDARD SUPPLY = 1.6; L = 400 FT

(*a*) Construct a mass curve of rainfall versus time corrected for infiltration rates (see Fig. 31). The rainfall intensities for short intervals of time are taken from the supply curve of Fig. 15 and are arranged in descending order to obtain minimum overland flow storage at the time of maximum ponding.

(*b*) An outflow hydrograph is constructed in accordance with the method previously outlined for the rising side of the hydrograph. When the outflow reaches a peak by this procedure, it is assumed that the outflow or net runoff for the recession side of the hydrograph is equal to the rainfall rate minus the infiltration rate.

(*c*) The storage for overland flow is then obtained from the relation $q = K^2$, in which the symbols are the same as in the Symposium.

(*d*) The instantaneous storage produced by overland flow is subtracted from the mass rainfall. (The outflow hydrograph was not constructed to balance the inflow graph.) The procedure gives a mass runoff curve which is somewhat conservative.

(*e*) By the method of rate lines similar to those used for the solution of water-supply storage problems, the slope of the tangent to the mass curve indicates the drain-inlet capacity. The required storage value is given by the greatest vertical distance from the rate line to the runoff curve.

If accepted, the overland flow curves developed by Mr. Hathaway may be used advantageously in combination with the well-known rational method to determine the flow not affected by ponding. A differential of 10 min or even 20 min in the application of the overland flow curves for the longer lengths of travel is indicated by this method to differ only slightly from values obtained by the procedure developed by Mr. Hathaway. This is true provided the error is on the long side of the time or somewhat past the t_l-value. For the 1.6 supply curve and lengths ranging from 150 to 600 ft, an error of 20 min will not affect the results of computations by more than 16%. In view of this fact, the flow at junction chambers might be obtained accurately enough by direct addition of the critical branch-line values, with adjustments for runoff from paved areas, provided that the entire drainage system is relatively short. In terms of distance a 10-min interval considered for time of flow through a closed conduit, with an average velocity assumed as 3.3 ft per sec, would constitute a travel distance of 2,000 ft. Following this procedure with consideration for junctions of long lines the design capacities can be computed or checked quite rapidly.

At some of the more recently constructed airfields, recording raingraph and recording hydrograph instruments have been installed to furnish accurate records and to present a sound basis for comparing design values with those actually obtained in nature. It will be quite some time before sufficient data are collected, and before satisfactory explanations concerning runoff can be attempted. However, strides are being made in what appears to be the proper direction toward better design for airfield drainage.

G. G. GREULICH,[11] M. AM. SOC. C. E.—As repeatedly indicated in this Symposium, the effects of moisture changes have a great influence on the subgrade soil and base courses. Moisture accumulation, in particular, affects subgrade deformation, remolding, pumping at joints, and density or volume changes due to frost, heaving, and thawing. Deterioration from these influences makes the determination of subgrade ratings by plate bearing or California bearing ratio (CBR) tests a matter of guesswork where year-round performance predictions are necessary.

These factors seem to indicate the need for more attention to subsurface drainage systems. Lowering the ground-water level by adequate drainage may give greatly improved performance at much less cost than can be obtained by thickening pavements and base courses and by compacting the subgrade. Every one is familiar with the crushing strength of dry, as compared to saturated, soils.

Accumulation or ponding of water during construction should be prevented as much as possible. Water seeping through pavement joints should be able to flow readily to subgrade drains. This will prevent excessive moisture accumulations in the soil at points where the surface slabs are weakest and where the greatest relative vertical movement of adjacent slab edges and attendant reworking or churning may result.

In mountainous or foothill country, and even in gently sloping plain country, there may be subsurface flow or seepage of ground water which normally does not approach the surface near enough to affect stability or carrying capacity of the upper soil layers. However, during wet seasons, this flow may occur very near to, or even emerge at, the surface. Under such conditions, during or immediately following the wet season, subsurface drainage will take care of most of such flow and prevent serious changes in the moisture content of the subgrade soil.

Under the preceding conditions, the most excellently designed and functioning surface drainage systems cannot prevent saturation from subsurface flow originating at points that may be remote from the airfield. Infiltration of water in surrounding areas may also accelerate flow under the surface of the airfield.

Whereas inadequate surface drainage may hamper operations only for a limited time, inadequate subsurface drainage may reduce the usefulness of a field for a long period and may even render it completely unserviceable, particularly as more planes with Class I wheel loading come into service.

An extension of the subject of subgrade drainage in the closing discussions would provide a most welcome contribution to general engineering knowledge on the design of military airfields.

HIBBERT HILL,[12] ASSOC. M. AM. SOC. C. E.—The influence of load repetition on the life of pavements is emphasized by Colonel Stratton. This effect is very evident in the accelerated traffic tests described in his paper. In these tests a pavement characteristically will show no distress whatever during the first passages of the load, and yet may fail completely (and progressively) after a relatively small number of passages. The same phenomenon is a matter of common experience to paving engineers, although not usually so readily observed in practice, because of the length of time involved, as in tests.

---

[11] Cons. Engr., Specialty Div., Sales Dept., Carnegie-Illinois Steel Corp., Pittsburgh, Pa.

[12] Lt. Col., Corps of Engrs., Deputy Chf., Eng. & Development Div., Office, Chf. of Engrs., War Dept., Washington, D. C.

The accelerated traffic tests progress from the condition of newly completed construction to total failure in a matter of days or weeks. The condition of the pavement base and subgrade is thus substantially "as built" during the course of the test. On the other hand, perhaps a runway will not be subjected to an equal number of stress repetitions for years. During this time, and in addition to other time effects, moisture conditions in the base and subgrade may have changed, frost may have acted on the base and subgrade, and the paving itself may have deteriorated because of factors other than load stresses.

Thus, in translating accelerated test data into terms of runway pavement life, two questions at once arise: (1) To what actual number of stress repetitions will the runway pavement be in fact subjected? (2) What is the relation between the effects of rapid repetitions of load in an accelerated test and the effects of the much more widely spaced (in time) repetitions to which a runway will be subjected in operation?

Existing data and calculations clarify the first question considerably. The second question can be disposed of rapidly. The answer is not known at the present time. It can only be assumed, on the basis of general experience, that repetitions in one case are approximately equal in effect to repetitions in the second case—that is, if under accelerated conditions a pavement fails at the end of one thousand load repetitions taking place in say ten days, it will also fail at the end of one thousand load repetitions spaced over a much longer period.

In accelerated traffic tests, a load is made to pass repeatedly over a lane of given width in such a manner that the wheel tracks uniformly cover the surface of the lane; for example, assuming a 5-ft lane and a tire imprint width of 1 ft, the first passage is in the 1-ft strip along one edge of the lane, the second passage is in the strip between 1 ft and 2 ft from the edge of the lane, and so on, until, in five passages of the wheel, the entire lane has been covered. If the tire imprint is narrower or wider than this example, a greater or lesser number of passages is necessary to cover the lane. Such a series of passages has been regarded, in the tests, as one coverage, or one maximum load repetition. Load repetitions are reported in terms of number of coverages in lanes of a given width.

Thus, if, in the case of an operating runway, a longitudinal element of the 10-ft-wide runway is considered and it is known that this 10-ft element has been traversed one hundred times by a wheel with a 6-in.-wide footprint, then it can be assumed that the 10-ft strip has experienced five coverages, or five maximum load repetitions. Such an assumption is only valid if the 10-ft strip can be considered as a small element of the entire width. The same assumption could not be properly made in the case of a taxiway, where the narrow pavement would force traffic into narrower lanes.

The usual military runway is 150 ft wide. On such a runway it may be assumed that the pilot will plan to land the center line of the plane on the runway center line and that deviations from this plan will be accidental in a statistical sense. Thus, the distribution of landings over the runway width will approximately conform to the normal law of error, and the maximum number of coverages will be on the central element of the runway.

A study of the possibilities leads to the conclusion that from 16% to 24% of the landings (center line of the plane) will be on the center 12.5-ft strip of a 150-ft-wide runway if there are no constant factors tending to channelize the traffic. Fig. 32 shows the actual distribution of landings on a particular runway used exclusively by fighter planes. These data were obtained by counting tire marks on a concrete runway after about six months of service. Since it is presumed that there are two tire marks per landing, the percentages of landings and of the tire marks are approximately equal. Actually, the tire marks may exceed twice the number of landings, since the plane may bounce in a poor landing, leaving two or more sets of marks.

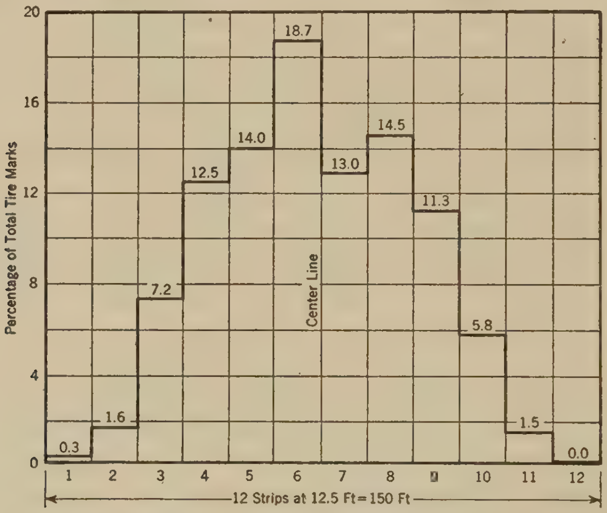

FIG. 32.—PERCENTAGE OF TOTAL TIRE MARKS IN EACH STRIP WITHOUT RESPECT TO LONGITUDINAL DISTRIBUTION

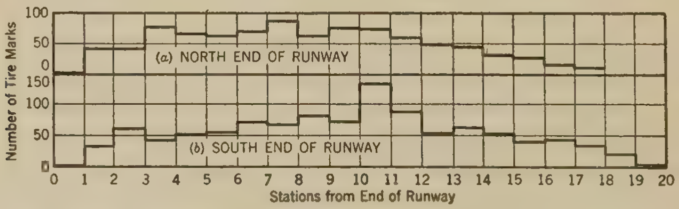

FIG. 33.—NUMBER OF TIRE MARKS IN EACH TRANSVERSE SECTION BETWEEN STATIONS

The total number of tire marks counted to obtain Fig. 32 was 2,010. Of these, 1,132 marks were counted at the south end of the runway and 878 marks at the north end. Longitudinally (Fig. 33) the marks are rather well distributed over about 1,500 ft of each end of the runway, but with a maximum point about 1,000 ft from the end.

Each landing loads two points on the pavement, one point under each wheel (the nose or tail wheel load is small and may be neglected). The total number of load repetitions is therefore twice the number of landings. Fig. 34 represents one hundred landings distributed over a 150-ft-wide runway in accordance with the normal law of error,

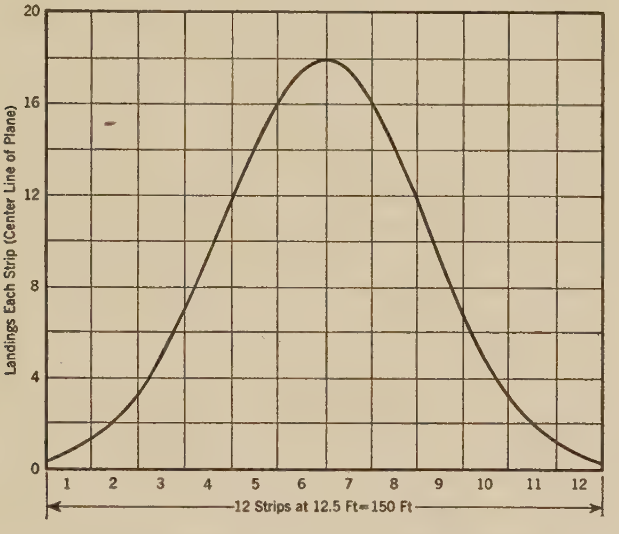

FIG. 34.—DISTRIBUTION OF ONE HUNDRED LANDINGS

$$y = K e^{-h^2x^2} \qquad (10)$$

in which $h = 0.1$. The curve represents the locations of the center line of the plane during the various landings. The wheels of the plane are displaced from its center line by an amount in general dependent upon the size of the plane. In Fig. 35, this displacement is assumed to be 12.5 ft (25-ft spread between wheels), representing a large plane. The number of wheel passages in a given strip then is the sum of the ordinates of the two curves in Fig. 35, representing the individual wheel positions. The maximum ordinate of the resultant curve is less than twice the maximum ordinate of the base curves, varying with the magnitude of the wheel spread. This difference increases as the wheel spread increases and is in general significant only for the largest planes. In the example shown (Fig. 35) the maximum ordinate of the resultant curve is 10% less than twice the maximum ordinate of the base curve.

The most frequently loaded strip will be at the center of the runway, and, for practical purposes, the number of passages over a given width of center strip will be twice the number of landings on that strip. The number of load repetitions (coverages in the sense of this discussion) will be the number of passages over the strip multiplied by the tire imprint width and divided by the width of the strip considered. The latter factor is of great importance. The width of the imprint of a fighter plane is about 8 in., and that of a bomber is about 16 in. The bomber, therefore, occasions about twice the number of load repetitions that the fighter causes during the same number of landings.

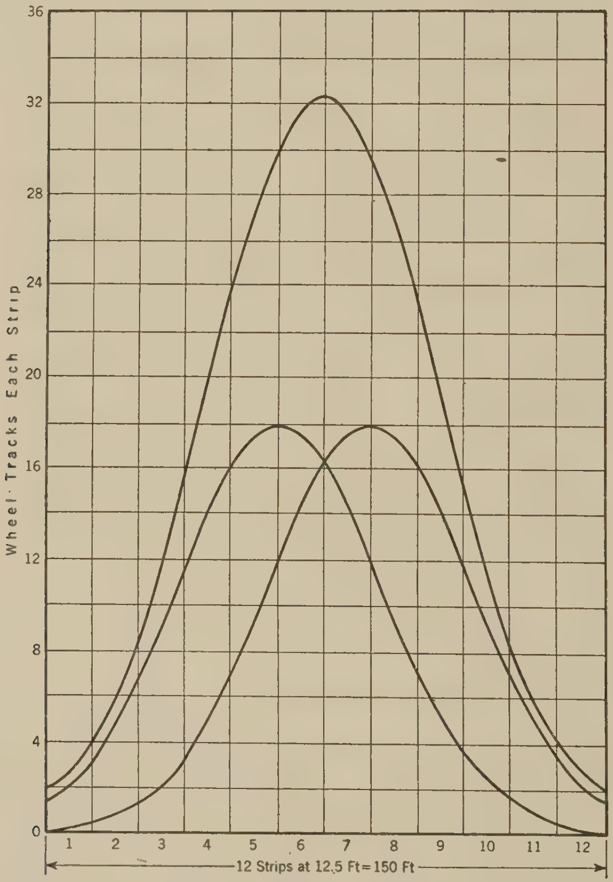

FIG. 35.—DISTRIBUTION OF WHEEL TRACKS; ONE HUNDRED LANDINGS

This discussion relates entirely to landings. Similar considerations will apply to take-offs. Probably take-offs, being more closely under the control of the pilot as to location on the runway, will tend to channelize to a greater extent than do landings. Other factors being equal, the take-off will be approximately along the center of the runway. However, the latter statement would not apply to wide runways; nor does it apply to small planes, which will tend to take off along the side of the runway that is first reached from the taxiway. Thus, local conditions, such as the location of the taxiway exits, will tend to channelize traffic on take-off. Fighters taking off in formation will deliberately use the sides of the runways. At night the pilot will follow the side (left side for large planes) of the runway where he can guide himself by the runway marker lights.

A plane on landing ordinarily first touches the pavement within the first thousand feet of runway. At this point, and for perhaps 1,000 ft beyond, the plane is substantially air-borne, and therefore does not cause maximum load on the runway. The maximum load on the pavement will not be felt until the speed has reduced to that of taxying, and this load will be imposed on a length of runway dependent on the location of the exit taxiway. Similarly, a plane taking off will be substantially air-borne after about 1,000 ft of run. Therefore, the take-offs cause maximum stress to the runway only at the end of the runway from which they occur and the landings only at the opposite end. Each end thus receives 50% of the stress repetitions due to the total operations, regardless of the wind rose. This can be seen readily in the extreme where all operations are in one direction. In such a case one end of the runway will be stressed to the maximum by every landing, but by no take-off, whereas the opposite end will be stressed by every take-off, but by no landing. Dependent, again, on the field layout and on the conduct of local operations, a central part of the runway will receive only accidental and occasionally maximum stresses.

The foregoing considerations have not much influenced airfield pavement design to the present time. As Colonel Stratton states, however, designs of the Corps of Engineers have been influenced to the extent that heavier pavement is provided on taxiways and on aprons (where taxying or standing traffic is channelized) than on the runways proper. The Corps of Engineers considers the effect of repetitions on the life of the pavement in designing advanced airfields for temporary operation. Since such considerations may have considerable economic importance in connection with the heavy construction required for present and future large airplanes, they should receive increasing attention.

JACOB FELD,[13] M. AM. SOC. C. E.—Solutions for practically every design and construction problem which arises in the performance not only of military but of commercial airfields are given by Colonel Stratton in this Symposium. A few comments from the construction point of view are made not as a criticism of the material in the paper but as a possible explanation for the manner in which the design problems have been solved within the limitation of construction feasibility.

In standard sections of concrete pavement, most of which (because of the priority regulations affecting the use of steel reinforcement) are practically devoid of any steel, the thickening of edges has introduced difficulties. Construction of an airfield is always a large-scale operation. The preparation of the subgrade and the application and the compaction of the sub-base—both must be done in large areas if uniform results are expected and if the work is to be done economically. The requirement that the subgrade of the concrete be shaped to provide for thickened edges, especially if the thickened edges occur adjacent to the forms, introduces a new operation which disturbs the compacted subgrade. If the compacted material is removed by the blade of a power unit or even if it is removed by hand, the area must be extended sufficiently to provide space for setting up forms. It is impossible to cut away a wedge-sectioned strip of a compacted sub-base without some disturbance. It is almost impossible to reroll or recompact the irregular shaped subgrade to a density equal to that of the undisturbed adjacent material. In addition, when the concrete is being placed, the vibration required adjacent to the forms to eliminate honeycomb further disturbs the density of the subgrade. Such disturbance may be the cause of honeycomb often found in concrete in the vicinity of the forms, since the reduced density of the subgrade tends to absorb and remove the mortar from the concrete placed on it. Except, of course, for the necessity for hand work in shaping the subgrade, the thickened edges at joints transverse to the direction of the forms are less objectionable from the point of view of the aforementioned difficulties.

---

[13] Cons. Engr., New York, N. Y.

In scheduling the concrete pavement, there is always a difference in opinion as to sequence of lane pouring. Alternate lane construction has the advantage that it releases the forms faster, but as Colonel Stratton states it has some serious disadvantages because of the disturbed subgrade and the possibility of ponding of rain water between completed strips. These objections are overcome by pouring around completed strips, and, if the length of the strip is properly correlated with daily progress, a satisfactory schedule can be maintained. By permitting a time gap after the first strip, used to fill in other concrete operations, continuous operation in placing additional strips can be scheduled by adding strips to the first one poured in a continuous and circular sequence. If the length of the strip is made equal to a 2-day capacity of the unit used for placing concrete, no time loss will occur. After the second strip is started (the concrete being properly set up to support the finishing machine), the operation is away from the completed concrete at all times, and subgrade preparation is never fenced in by completed work.

Under the heading, "Pavement Design for Frost Action," Colonel Stratton states: "* * * the combined thickness of pavement and base material not subject to frost action is made equal to the average depth of frost penetration as determined from local records." This statement should be modified by considering the different heat transmission coefficients of materials like coarse sand or gravel which are ordinarily used for base course, as against the much finer and more easily saturated local materials displaced by the base course.

The writer has noticed that the compaction of added base-course material to specified densities, greater than the natural densities of the immediately underlying material, presents a temporary condition of unbalance which proves a weakness under the impact of traffic. Sudden change in density within the soil body seems contrary to natural conditions and should not be specified. The tendency to readjust density with time is aggravated by traffic vibration when adjacent horizontal layers are of different densities. There is a very similar, and to some extent more serious, adjustment when trenches dug in the natural soil are backfilled to a specified density greater than the density of the undisturbed soil. Such backfilled drainage ditches form a network of relatively hard intrusions in the natural soil condition and almost always cause trouble in the finished pavement.

Fig. 36 is plotted from data taken from Fig. 5, and shows a linear correlation between percentage of unit supporting value and the ratio "perimeter: area" of the test bearing plates smaller than 30 in. in diameter.

In the part of Colonel Stratton's paper on drainage, the entire discussion of subsurface drainage is based on the assumption that the pavement is perfectly impervious. If any rain water seeps through the joints or through cracks into the sub-base or if the underlying base course is saturated and at times possibly below ground-water level, a positive subsurface drainage should be provided. In installations where a porous sub-base is installed on an impervious soil, ponding-of-water accumulation in the sub-base would cause failure of the pavement by its effect on the subgrade material.

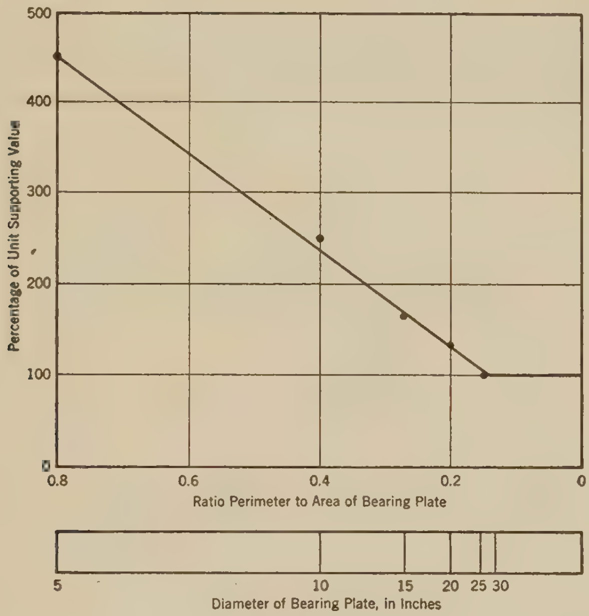

Fig. 36

The system shown in Fig. 8(*b*) for the base-course drainage is a specified finished product which, under the usual construction schedules, is impossible to build. Analyzing the various stages of the work, such an installation would require:

Either—	or—
1. General excavation to the top of pavement level.	1. General excavation to the level of the base-course subgrade.
2. Trench excavation from the top-of-pavement level to the necessary depth for placing the pipe.	2. Trench excavation by hand since the use of the "backhoe" or similar tool is not feasible with the step-in level at the trench, partly at original grade and partly at general excavation level.

Either—	or—
3. Pipe placed and trench backfilled with filter material to the top-of-pavement level so that the excavation for the necessary thickness of pavement and the base course will not seal up the filter material.	3. Pipe placed and the remainder of the work completed as shown in Fig. 8(*b*).

In the first procedure, trench excavation volume increases with consequent reduction in general excavation and loss of filter material which is first placed and then removed. The second procedure specifies much slower operation of trench excavation by hand, which in normal progress schedules would be a bottleneck. A solution of all these difficulties is shown in Fig. 37. This method permits excavation by machine and at the same time introduces an extension of the filter material to help eliminate the sealing up of the filter material by the adjacent soil during heavy rains or from subsurface drainage flow.

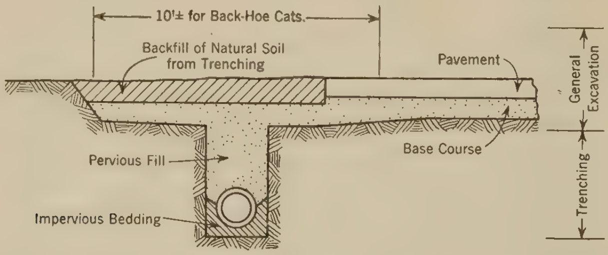

FIG. 37.—BASE-COURSE DRAINAGE DETAIL TO PERMIT MACHINE EXCAVATION

The foregoing comments agree with Colonel Stratton's statement in the "Summary" that "Good designs may be vitiated by poor construction * * *," but good designs must also take account of construction methods, tools, and labor available for the work.

ROBERT HORONJEFF,[14] JUN. AM. SOC. C. E.—As stated by the author, the design of concrete pavements is generally based on the formulas developed by Dean Westergaard. The modulus of soil reaction "*k*" is measured in the field. With a known *k*-value and an assumed working stress for concrete, the required thickness of a slab for any desired wheel load can be computed by substitution in the Westergaard formula. The question in the writer's mind is whether the Westergaard analysis is adequate for determining thicknesses of concrete pavements laid on marshy ground. The load deformation curve (Fig. 4) of a plate 30 in. in diameter placed on a subgrade underlain by mud varying in depth from 40 to 60 ft is considerably different from the curve shown in Fig. 4. When the subgrade consists of mud covered by select material not exceeding 2 ft in depth the load-deformation curve is very flat, indicating that very little load is required to deflect the slab a large amount. In fact, in many cases it is not possible to load the plate with a total of 60,000 lb (Class I airports) without pushing the slab into the mud. With average subgrade conditions the general practice has been to limit the size of individual slabs (by means of dummy joints) to an average dimension of 12.5 ft by 15 ft. The argument presented is that by limiting the size of the individual slab the stresses produced by shrinkage and warping are reduced to a minimum, thus reducing the formation of cracks.

---

[14] Asst. Chf., Civilian Engr., U. S. Engrs., War Dept., San Francisco, Calif.

It is the writer's opinion that this argument cannot be applied to construction of pavements on marshy ground. The individual slab sizes should be increased so that a greater bearing area is provided. It would take a larger load to push a 25-ft by 25-ft square slab into the mud than it would to push a 12.5-ft by 15-ft slab. The next questions that arise are how one can be assured that the larger slab will distribute the concentrated wheel load and how the tensile stresses produced by warping will be taken care of. These conditions can be met by proper distribution of reinforcing steel through the slab. At the top the reinforcing steel should be concentrated at the corners and at the edges and at the bottom toward the center of the slab.

The method of computing the size of reinforcing steel is still an unknown factor. It is true that reinforcing steel may not prevent initial cracking of the slab but it will prevent the enlargement of these cracks and it will certainly prevent the complete severance of a portion of the slab from the parent slab, such as is the case with a plain concrete slab. Reinforcing steel has a definite place in the design of concrete pavements on marshy ground.

The transfer of wheel loads of from 60,000 lb to 75,000 lb by means of ordinary steel dowels is somewhat questionable. There is not sufficient surface area in the dowels to transmit the load to the concrete without crushing the concrete. There is a due need for a satisfactory load transfer device that is practicable to install in the field.

Another problem that is constantly arising in airport work is the strengthening of existing concrete pavements by "second-storying." "Second-storying" means the placing of a new slab over an existing slab and separating the two by means of cushion course. The thickness of cushion course will vary depending upon the particular conditions at the airfield involved. Thus, if the strengthening is required around existing hangars, the finished grade of the new slab has to be maintained as close as possible to the grade of the existing hangar floors, which results in the use of a minimum cushion course of from 1 in. to 2 in. between the two slabs. On the other hand, on a runway the grade of the new slab is not limited by existing structures and the cushion course can be as thick as 2 ft.

A study to determine the behavior of slabs placed on existing slabs with various thickness of cushion course and subjected to moving wheel loads up to 75,000 lb has been undertaken by the San Francisco District in conjunction with the staff of the Engineering Materials Laboratory of the University of California, at Berkeley. The aim is to determine the stresses in the slab at such critical points as those on the edges and corners by measuring internal strains in the concrete. The subgrade reactions and surface deflections are also to be measured. From this study it is hoped that some information will be obtained as to the effect of the thickness of cushion course on the structural behavior of the slab. Various thicknesses of slab both reinforced and unreinforced will be studied in the test section.

Another point that usually is given little consideration in the design of airfields is the radius of the fillets applied to runways and taxiways. Present standards are inadequate to a certain extent. These standards set up by the Civil Aeronautics Authority are as follows:

Angle of intersection	Radius of fillet (ft)
0°–85°	25
85°–115°	50
>115°	100

At a number of airfields designed by the writer the using service has arbitrarily increased the radii of the fillets because most of the planes were "cutting the corners." A number of people attribute this condition to "pure carelessness on the part of the pilots," but it is a known fact that, at a number of airfields used both by large transports and single-seat pursuit aircraft, a sincere effort has been made by the pilots to "stay on the pavement." For large transports the difficulty seems to arise from the fact that the ratio of the wheel spread to the paved width of the taxiway is quite large. Therefore, when a pilot is confronted with the need for making a turn on the taxiway the plane veers off from the center line of the taxiway just enough to throw one of the wheels off the pavement. Pursuit aircraft seem always to taxi at fairly rapid speeds and, therefore, in order to maneuver sharp turns the pilots run off the pavement. The writer recommends that the minimum radius of fillets for airfields to be used by fairly large planes be established at 75 ft.

Clarence S. Jarvis,[15] M. Am. Soc. C. E.—Of untold value is the record in this Symposium on the logical development of both construction and design problems, together with the solutions permitted under the strict limitations imposed by the expanding, ever-changing, and accelerating activities of wartime. Colonel Stratton's interesting notes relating to subgrade support and the various methods of stabilization by compaction, or by the addition of base courses suitably rolled, recalled some of the writer's early construction experience. In addition to the usual provisions for both surface and subdrainage, it was sometimes necessary to insure against both lateral and upward flow of compressible and plastic materials. One of the most satisfactory methods was the placement of crushed slag or stone in trenches for compaction under pile-hammer impact. The virtual interlocking of the angular fragments accomplished in this manner seemed to make such footings react very similarly to plain concrete slabs. Unquestionably the inertia of such heavy masses among the footings accounts in part for their remarkable stability under varying applications of live load and required dead load.

The writer vividly recalls the announcement in the division of design of a federal bureau concerning proposed thickened edges of pavement strips to replace either the prevailing uniform thickness, or even the heavily crowned road pavement, with edges of concrete thinned by the amount of rise in the crown. No less startling was the introduction of dowels to extend across all construction and expansion joints, thus preventing the uneven settlement that had proved so destructive to concrete under heavy metal tires.

---

[15] Senior Civ. Engr., Intelligence Div., Office, Chf. of Engrs., Washington, D. C.

Colonel Stratton's frequent references to traffic distribution, repeated stresses, and fatigue of pavement materials indicate his familiarity with, and his practical application of, the basic principles disclosed by the experiments of the late J. L. Van Ornum, M. Am. Soc. C. E. (37), and others. How else could any one justify the departures from previous practices described under the heading, "Concrete Paving: Allowable Working Stresses for Concrete Pavements"? The use of a safety factor of 1.75, corresponding to 57% of the 28-day flexural strength of the pavement, or even the use, for limited operations, of a safety factor of only 1.40, representing 71% of the stress ordinarily required to cause failure with a single application of loading to destruction, is entirely logical in view of the increasing strength after 28 days and the wide dispersion of traffic, as well as the wing lift accompanying the landing of planes. Who could have foreseen that the vibratory strains of the taxiways and the warming-up aprons, rather than the stresses due to landing impact, would govern both current and future design?

Summarizing the conclusions that may be drawn from the Van Ornum series of tests, application of 50% or less of the loading that would normally cause failure may be repeated indefinitely without appreciably decreasing the resistance of reinforced concrete columns, beams, or slabs; but, for a 75% loading or greater, only a few such applications should be tolerated because of the definite tendency toward fatigue of materials, accompanied by a measurable reduction of ultimate strength.

The observed variation in behavior among individual test specimens employed by the writer in a research conducted in 1905 and 1906 (38), and also among the more numerous samples subjected to the more elaborate tests of the Van Ornum series, would occasionally becloud the results. For example, a loading of 85% would cause failure with a single application, and the next specimen would withstand a similar loading 100 or more times.

In the light of all available tests to date, it is difficult to improve on the range indicated in Colonel Stratton's treatment of allowable working stresses—57% of the ordinary 28-day strength of resistance, or for limited operations, 71%.

Although there are valid objections to the use of concrete pavements as thick as 10 to 14 in., because of the attendant temperature stresses and also because of the difficulty in securing the required compaction and density, there appears to be no practicable limit on the base-course thickness of stone or slag, duly compacted. In the writer's experience, it has been demonstrated repeatedly that a base course of rubble or of quarry stone, with interstices mostly filled with fragments, would support a lightly reinforced pavement of 3-in. thickness plus whatever penetration was attained by keying into the stone base, with better results and at less cost than would plain concrete of double or treble the pavement thickness, and without base course.

Mr. Hathaway deals with noteworthy accomplishments in a broad field that seems to have awaited a well-organized, vigorous, clear-sighted, and analytic approach. Some other attempts have fallen far short of the goal because of the lack of required basic data. However, additional material has been supplied in recent years through the cooperative efforts of various federal departmental representatives including, notably, Mr. Hathaway and Merrill Bernard and N. C. Grover, Members, Am. Soc. C. E., their administrative supervisors and technical staffs, legislative committees, and, finally, the great mass of enlightened citizenry who favored liberal support of hydrometeorological and related research. In addition to this financial and scientific support, the development of fundamental procedures as exemplified by the Symposium certainly required the wholehearted assistance of specially qualified members of the technical staffs in various field offices under the Chief of Engineers, as well as of those men immediately under Mr. Hathaway's direction, as tacitly implied or expressed under "Acknowledgments."

If attempts were made to include in the "Bibliography" such technical papers and other publications as have contributed vitally to the background and to the fundamental knowledge of airfield engineering (including meteorological, infiltration, runoff, and related phenomena), the list would be too long and cumbersome for practical purposes.

The writer realizes that any constructive suggestions for either amplification or clarification of concepts may be mistaken for criticism, no matter how helpfully intended. However, passengers on maritime vessels or on other transportation units, who fail to communicate vital information that may be beyond the range of regular lookouts (an open port too near the water line, signs of shallows or impending collision—anything endangering the common interest) thereby partly forfeit their claims to safe passage. The writer is deeply concerned about the field of hydrologic and related scientific research, particularly regarding,

(*a*) Thorough utilization of existing basic data;
(*b*) Expansion of procurement programs to broaden their scope;
(*c*) Recognition of patterns among natural phenomena, capable of affording guidance in supplying reasonably close approximations of missing basic data; and, finally,
(*d*) Simplification of procedures whereby the divergent factors may be made to yield an integrated, logical, and conclusive result, capable of withstanding repeated practical tests consistently and satisfactorily.

The writer's first glance at Fig. 14 disclosed what appeared to be a break in the continuity of the series between the curves for 30 and 120 min. Obviously, a 60-min curve (intermediate yet not quite midway between the adjacent graphs) should have been included in Fig. 14. This would appear as a straight line connecting the origin of coordinates with the abscissa value of 4.5 at the top margin. By the very nature of this relation, numerical values of ordinates and abscissas at all intersections on the grid for the 60-min curve will be equal. The fact that the hourly rainfall intensities are displayed along the vertical axis was not overlooked.

An additional curve that might well be drawn in Fig. 14 concerns the 24-hr period. Assuming that the only rainfall during such a period occurs within the 240-min (4-hr) interval which the curve represents, the average hourly intensity would be $\frac{4 \times 4.5}{24} = 0.75$ in. Therefore, the new curve or straight line would connect the origin of coordinates with the point on the top margin corresponding to abscissa 0.75, representing the extreme limit toward the vertical axis. Allowing for the gradual increase of precipitation prior to the beginning of the 4-hr period of high intensity and for a corresponding decrease later, as well as for the associated showers which combine to make up the 24-hr maximum for each designated frequency within the series, the final position of the graph would connect the origin with the value of approximately 1.0 along the top margin. This result is logical because 24-in. rainfall depths have been attained rarely, if ever, within the scope of officially accredited records in the United States. The most outstanding example to be found in the writer's investigation (first reported in 1930), covering a period of some five years but dealing with several times as many stations as were included in the final tabulation (39), was the record at Taylor, Tex., of 23.1 in., associated with a maximum hourly rate of 4.25 and a monthly maximum of 25.9 in. Similar maxima recorded for Austin, Tex., in another tabulation of more recent date are 19.0, 4.38, and 20.8 in., respectively (40).

If maximum observed values are desired for some of the world's outstandingly high rainfall stations, one must include 24-hr depths of 21.9 and 28.7 in. for remote stations in Hawaii and Jamaica, British West Indies, respectively, and 25.0 in. for Madras, India, and 40.0 in. for Cherra Punji, India, associated with hourly maxima of somewhat less than 4.0 in. and with daily and monthly maxima of 42.8 and 360.1 in., respectively (39)(40).

Similarly, for the Baguio Station, high among the mountains of Luzon, Philippine Islands, the maximum hourly rate was nearly 4.0 in., whereas the maxima for daily and monthly periods were recorded and published as 46.0 and 133 in., respectively. Obviously, the curve for century-frequency maximum intensities that includes all known values should connect a point on the top margin with abscissa nearly equal to 2.0 in. per hr with the origin; it would therefore lie slightly to the right of the curve of Fig. 14, representing the maximum 4-hr intensities within the United States. The last-described curve, dealing with world maxima, should preferably be excluded, since it would disturb the orderly march of the series developed for the United States.

As far as the writer was able to determine, much of the concept relating to rainfall patterns was new when it was published in 1930 (39). Two illustrations (39*a*)(39*b*), a table (39*c*), and textual references pertaining to all three incline toward the establishment of a nearly straight-line relationship for the series. For many of the stations listed (39*d*), comprising 820 of the principal station-records throughout the world in summarized form, the writer reported that the mean annual rainfall divided by the average number of rainy days per year would represent the maximum rainfall depth to be expected within a 3-min period (39*e*). Obviously, this curve would lie somewhat to the right of the one in Fig. 14 and might well serve as an envelope of the plotted values below the graph for a 5-min duration. Inasmuch as the majority of the stations listed by the writer (39*d*) for world-wide distribution had no data for periods shorter than one day, the intermediate values between the 3-min period and the 24-hr period had to be determined by interpolation. For this purpose, the writer determined by trial that curves for the 15-min and 60-min durations practically trisected the space between the 3-min and 24-hr maxima. For that reason, principally, the 30-min rainfall intensities were purposely omitted, as being less significant members of the series than were those retained. Other members of the plotted series of rainfall data (39*a*) were maxima for both monthly and yearly rainfall depths. Differences in lengths of records for the respective periods, from a day or less to months and years, were inclined to disturb the true relationships. It was not uncommon to find only a decade or so of rainfall intensity records for a day or less, whereas the monthly and yearly values as published covered half a century or more, thus calling for some adjustment to reduce such data to a basis of comparable frequencies.

Under the heading, "General." Mr. Hathaway states:

> "A study of rainfall intensity-frequency data for a large number of precipitation stations indicates that there are fairly consistent relationships between the average intensity of rainfall for a period of 1 hr and the average rates of comparable frequency for shorter intervals, regardless of the geographical location of the stations or frequency of 1-hr rainfall."

This terse statement is of far-reaching importance and somewhat startling on first reading, as it links hourly and shorter intensities regardless of geographical location and frequency of each series. It proves to be almost axiomatic in the light of further study. In fact, it is a part of the concept of rainfall patterns which the writer sought to express in 1930 (39) and earlier. In an effort to define the essential similarities inherent in precipitation intensities or total depths for varying periods of time from 5 min to a year, the writer expressed all these quantities as percentages of the mean annual depth of rainfall. Thus, the maxima for a 5-min period ranged from 0.17 in. at Juneau, Alaska, to 0.91 in. at Denver, Colo., or to 1.05 in. at Tampa, Fla., or to 1.15 in. at Terre Haute, Ind., representing the maximum officially reported and observed depth in the United States. Reduced to percentages of annual mean rainfall depths for the respective stations, the maxima become 0.2%, 6.4%, 2.1%, and 3.0%. Some other stations have established claims for somewhat higher records but have not fully qualified them as official data. Undoubtedly still higher values have occurred for tropical storms, although official observations are lacking.

Isohyetal Maps.—For several years after the publication of technical reports, including the volume entitled "Storm Rainfall of Eastern United States" (41), by the Miami Conservancy District, many hydrologists considered that the Great Plains and Western States were not susceptible of the same treatment. The reason for this opinion was related to the erratic and unpredictable rainfall occurrence, amount, intensity, and areal extent, as well as to the dominant influence of altitude over latitude. In the face of such professional opinion, the writer undertook to extend a series of isohyetal lines representing not only daily but also monthly maxima throughout the United States (39*f*) (39*g*), and then completed the maximum monthly isohyetals for such parts of the various continents as were covered by officially published records. Mr. Yarnell (15) adopted scales that precluded the portrayal of local effects, such as are associated with topographic forms, rain shadows, normal paths of air-mass movements, and the orographic barriers to be surmounted. To overcome this difficulty in part, Mr. Yarnell introduced special maps on a more generous scale, covering the Pacific Coastal States, with regard to 24-hr rainfall depths for various frequencies, from 5 to 100 years. Lack of data had been noted on the Pacific Coastal strip for some of the shorter periods—namely, 16, 8, and 4 hr—and by implication for still shorter periods.

The writer's experience in the construction and drainage of arsenal and airfield facilities lead him to offer the following observations:

(*A*) No matter how liberally one may interpret the series of isohyetals on the small maps of Fig. 13, there is urgent need for either supplemental maps of the Pacific Coastal region on scales permitting the portrayal of the pronounced local variations, or a special note of caution concerning the practical certainty that the indicated limit of 1.25 in. per hr has been and will be greatly exceeded within 25-yr periods of record.

TABLE 9.—SUMMARIZED RAINFALL RECORDS OF THE PACIFIC COASTAL REGION

Item No.	Station	Altitude (ft)	Maximum[a,b]			Annual Rainfall[b]		
			Hour	Day	Month	Minimum	Mean	Maximum
	Washington:							
1	Tatoosh Island..	86	1.44	5.91	25.8	49.6	83.5	114.3

[a] Parentheses enclose unofficial or estimated quantities. [b] All units are in inches. [c] Northwest.

(*B*) A study of the selected station-records in Table 9 (which were chosen intentionally to represent the upper bracket of observed intensities, inasmuch as most of the actual maxima of high mountainous regions are unrecorded) indicates that the influence of latitude is subordinated to that of altitude combined with windward exposure.

(*C*) The seaward slopes of the coastal ranges extending from the Olympic Peninsula in Washington to San Diego, Calif. (and probably even farther) and from the western slopes of higher ranges farther inland (such as the Cascade Range and the Sierra Nevada) are capable of developing a fair approach to the series of intensities plotted around the Gulf Coast. These intensities approach about 4 in. per hr at outstanding stations, although they are ordinarily limited to roughly half of that depth for available periods of hourly record.

(*D*) In Table 9, the rainfall patterns disclosed by neighboring stations are used for practical purposes to estimate appropriate values of the missing items of basic data. All these are enclosed in parentheses to indicate their unofficial character. These estimated values may be subject to uncertainties of approximately 20%.

(*E*) Both limiting and periodic intensities for selected rainfall stations seem to vary with the square root of the number of minutes in the respective time intervals considered, as has been stated in official publications (42)(43). Thus, the envelope of conceivable intensities—perhaps far beyond the attainable limit for most of the outstanding stations of high rainfall—would have depths for respective periods as follows:

Minutes	Inches
1	1.00
5	2.24
10	3.16
15	3.88
30	5.48
60	7.75
240 (4 hr)	15.50
1,440 (24 hr)	37.90
43,200 (month of 30 days)	207.4
525,600 (year of 365 days)	725

Some of the foregoing depths have been attained or even exceeded—for example, the daily, monthly, and yearly depths at Cherra Punji and the daily and monthly depths at Baguio. Some have been either attained or closely approached at several stations in India and the tropical islands of the Pacific Ocean. During seven of the fourteen years of available record for Cherra Punji (1905 to 1919), the maximum daily rainfall depths were in excess of 20 in.; and three of these exceeded 30 in., as follows: 33.00, 31.05, and 32.35 in. during 1910, 1914, and 1915, respectively. Desert regions may attain a much greater proportion of the short-period rainfall intensities, say, for less than an hour, than should be expected for days or months. Otherwise, they would cease to be classified as deserts, inclining more toward the humid in character. Patterns for most stations will follow more or less closely some proportion of the foregoing envelope depths.

Runoff Formulas.—In the interest of simplified procedure and computations, Mr. Hathaway has wisely made a number of assumptions, some of which are admittedly only approximations to cover variable conditions and behavior. (Either compensating or cumulative errors may result for a given problem.)

Among these are the assumed constancy of rainfall, infiltration, and resulting rate of supply for overland flow during a specific storm. Inasmuch as the assumed rectangular form of pluviograph is seldom if ever attained and an alternate form of isosceles triangle on the same time base but with its altitude double the height of the rectangle would enclose an equal area and would measurably alter the proportions for infiltration and supply volumes, this alternate form of pluviograph may bear investigation. Although it would still be an approximation, it would occupy a mean instead of an extreme position.

Mr. Horton's equations for overland flow, as presented by Mr. Hathaway, as well as a single page of textual material in Mr. Yarnell's notable bulletin (15), employ the so-called "rational equation" for runoff, $Q = C\,i\,A$, which expresses runoff Q in cubic feet per second, representing some percentage or decimal fraction (C), the ratio of runoff to rainfall for the critical period, times the product of rainfall intensity i in inches per hour and the number of acres A in the drainage area. The infiltration capacity is likewise expressed in inches per hour; as, for example, 0.6 in. per hr adopted by Mr. Hathaway for turfed areas. Similarly, the allowable pond storage of 2,000 cu ft per acre in the example used by Mr. Hathaway may be expressed as a depth of 0.55 in., since an acre-inch is $\frac{43{,}560}{12} = 3{,}630$ cu ft.

For the example solved by Mr. Hathaway according to the rigorous procedure recently developed with discharge to the inlets of the drainage system given as 2.1 in., from a rainfall intensity of 3.6 in. per hr, C is equal to $\frac{2.1}{3.6} = 0.583$, or 58.3%. Evidently, the surface storage outside of ponds was 0.35 in., which added to $0.60 + 0.55 + 2.10 = 3.60$. Only that portion of the surface storage (10% of the total rainfall) is subject to estimation; it could not be seriously in error; if neglected entirely, the error would be only 10%.

Perhaps it is just plain coincidence, but it is interesting to note that the X-ratio value derived graphically by Mr. Hathaway is 59% (compare with 58.3%), representing the ratio of drain-inlet capacity to peak rate of runoff, the difference being absorbed in pond storage.

The impressive array of well-chosen tables of basic data and related computations, together with the charts and diagrams on which the illustrative solutions of typical problems are readily traceable, and the clear-cut, logical treatment of the entire procedure in the accompanying text by Mr. Hathaway leave but little to be supplied in discussion. It is gratifying to know that the design procedures have already been incorporated in the Engineering Manual of the Construction Division, Office of the Chief of Engineers (23).

The susceptibility of the entire analysis and rigorously derived results to comparison and expression in terms of the so-called "rational formula," as demonstrated herein, should insure their incorporation in professional practice much more widely than would have been possible without such a popularly established device. This formula results in closing a survey circuit well within the tolerance limits, when results derived, or capable of derivation by both methods, are found to be in substantial agreement. Mr. Hathaway's paper represents a noteworthy accomplishment and progress in the field of hydrometeorology.

D. D. McGuire,[16] Esq.—A splendid method for rational design of drainage capacity is contained in Mr. Hathaway's paper. The engineer is given a measuring stick by which he may correlate the effect of the storm deemed critical for a particular installation with the airport topography and the drain capacities necessary for the required use of the airfield. Such a collection of concise data and workable information is appreciated by the drainage engineer.

Proper use of subgrade drainage may often simplify surface drainage facilities. Where extensive flat areas are involved, a better over-all solution of the problem may sometimes be obtained by a combination of several methods. The following analysis and comments give some reasons for serious consideration of subgrade drainage facilities.

The 1-hr infiltration value subtracted from the 1-hr rainfall quantity identifies the standard supply curve and forms the basis for succeeding computations. In the example quoted in Mr. Hathaway's computation of storm drain capacities assuming supplemental ponding, the design storm chosen presumes 2.2 in. of rainfall per hour. The 1-hr infiltration capacity for turfed areas is assumed to be 0.6 in. per hr and represents 36.7% of the rainfall quantity. Surely this is important enough to warrant further investigation and more accurate data on infiltration capacities. The pertinent factors are many and their interrelationship apparently vague. Problems presenting greater difficulties have been solved previously through research.

If 36.7% of the rainfall quantity may be disposed of through infiltration, why not either dispose of the water quickly through subdrainage facilities and thereby reduce the amount of ponding, or, by lowering the adjacent water table, create a ponding area below the surface and away from traffic.

The possibilities of subdrainage pipe seem wide and valuable. Quick disposal of filtered water will reduce overland flow and minimize surface erosion. The subdrainage system creates a storage area below the plane of traffic, thereby reducing the number of required inlets with their attendant safety hazards.

Lowering the water table reduces the damaging action of frost on subgrades under runways and aprons and, through better stabilization, can reduce the cost of surface treatment. A proper subdrainage system will make available for landing outside of runways areas which might never attain a usable condition if the entire disposal depended on inlets and storm sewers.

In view of the many facets of the subdrainage problem, it is hoped that the same clear, usable type of analysis described by Mr. Hathaway for storm sewer disposal systems may be evolved for the design and efficient use of subdrainage pipe.

E. D. Parmer,[17] Esq.—The engineer who is in any way connected with the design or construction of airfields, whether for military use or civilian use, should find this important and timely Symposium indispensable. It contains many sound principles of utmost value to the designer of airfields, presented in a simple, straightforward, and stimulating manner.

---

[16] Asst. to the President, United Steel Fabricators, Inc., Wooster, Ohio.

[17] Capt., Corps of Engrs., Army of United States, and Commandant of the Army Soils Control School, Graduate School of Eng., Harvard Univ., Cambridge, Mass. (formerly Junior Resident Engr., Texas State Highway Dept., Beaumont, Tex.).

In connection with airfield design and construction problems, the Corps of Engineers has proceeded quietly and systematically in designing, constructing, and testing, to meet adequately the demands of the airfield war construction program. Although greater and greater wheel loads have been predicted, comparatively little information has been published on methods proposed to meet such an airfield problem.

Suitability of Base-Course Materials.—In discussing base courses for concrete pavements, Colonel Stratton uses the term "high-quality base materials" without sufficient definition. Because of a common misunderstanding as to what constitutes a "high-quality base material" and because of the belief of many engineers that clay should be added to granular materials for use as a base course (simply because the satisfactory performance has been observed of well-graded sand or gravel mixtures containing clay when used as surface courses exposed directly to light wheel loads without the use of substantial pavements), it should be stated that, in general, clean, well-graded granular base materials with a minimum of "fines," say, not over 4% or 5% passing No. 200 mesh, make the most desirable high-quality bases for both rigid and flexible pavements.

Only 3% by weight finer than 0.02 mm in a well-graded granular material used as a base course in northern areas may cause troublesome frost action—breaking of concrete due to irregular heaving in winter and insufficient support due to softening in the spring.

In southern regions, natural clayey gravel or sand-clay mixtures may give satisfactory results if placed in a properly compacted, homogeneous condition. However, the deliberate addition of clays to clean, well-graded granular materials for use as base courses should be discouraged, not only because of the difficulty, expense, and length of mixing process, but also because of the inherent increased sensitivity to moisture control for proper compaction, as well as because of the increased potential susceptibility to subsequent moisture changes.

Design of Concrete Pavements.—War conditions have restricted the use of steel which in turn has caused the revision of concrete pavement sections. More than one good engineer pleaded that the reinforcing steel be left in pavements, and especially those which had to be placed directly on poor subgrades without the benefit of intermediate base courses.

There is no question about the necessity for thickening the edges of concrete pavement as is done in the revised sections if the pavement is placed directly on a poor subgrade. However, it would be very desirable to make additional investigations as to the necessity for thickening any edges when the pavement is placed on a high-quality, well-compacted base course, considering the minimization of differential settlement, together with the loading frequency and the natural traffic distribution on airfields. Is it not probable that the effect of disturbing the base course in shaping for thickened edges counteracts many benefits obtained from the thickened edges?

Control of Frost Action.—In discussing pavement design for frost action, Colonel Stratton states that the most generally accepted method of insuring pavement or base-course stability over a potential frost-action soil is the provision of sufficient thickness of insulating material.

The writer would question the mere use of "insulating material" over a potential frost-heaving soil to insure stability unless the term "insulating material" were defined as a granular material containing no more than a small percentage of material finer than 0.02 mm. Without such a restriction, one can well imagine a granular material with, say, 10% finer than 0.02 mm which, if it were possible to keep dry, would act as an insulating material but which, because of its high percentage of "fines" and high potential capillarity, might cause serious damage from frost heave if used to cover another potential frost-action soil in contact with a water supply. Therefore, in using soils as insulating materials, it is necessary to place a limit, not necessarily on the grain-size curve itself, but on the allowable amount of soil finer than a certain size, unless the soil can be entirely separated from a water supply either by using an intermediate impervious course or by so selecting the soil that the limit of capillary rise will not fall within the zone of frost penetration.

Subsurface Drainage.—In the past much time and money have been wasted in installing subsurface drainage systems which, as Colonel Stratton states, could frequently have been eliminated by providing an adequate and properly designed surface drainage system.

A subsurface drainage system is referred to herein as a system installed primarily for the purpose of removing water from pavement base courses or subgrades—some form of improvised "French drain," a system of open-jointed pipe, or an assemblage of well points.

When studying subsurface drainage, it is expedient to classify soils in one of the three following groups: (*a*) Well-draining soils such as clean sands and gravels; (*b*) Poorly-draining soils like the slightly plastic organic and inorganic silts; and (*c*) Impervious soils—for example, homogeneous clays. (These remarks on drainage are based on lectures by Arthur Casagrande, M. Am. Soc. C. E., on the "Control of Soils in Airport Construction," delivered at the Graduate School of Engineering, Harvard University, Cambridge, Mass.)

Colonel Stratton states that "* * * where the ground water is above the frost line or causes soft, boggy conditions in areas where soil stability is required, subsurface drainage is necessary." It should be noted, however, that (*a*) lowering the water below the frost line may or may not prevent frost heave, depending on the height of capillary rise, and (*b*) it may be much easier and more practicable in some cases to lower the water table by using circumferential ditches or by providing drainage through an underlying impervious stratum when such a favorable condition exists.

For clean well-draining granular materials, subsurface drainage can often be eliminated altogether, or at least reduced to a minimum by providing circumferential ditches to intercept ground water from surrounding areas and by sealing off the surfaces to reduce the infiltration of water into underlying courses or subgrades. In other words, the water should be kept from entering the base courses, but, if some does penetrate, the perviousness of these courses should be advantageous in removing the water. If the well-draining materials contain an appreciable amount of fines, then, to prevent possible serious damage from frost heave, it will be necessary to keep the water table not only below the frost line but at a distance below the frost line greater than the height of capillary rise for the particular soil.

In a strict sense, the statement that poorly-draining soils are "drained" with a subsurface drainage system is incorrect. The height of capillary rise in such soils is usually great, and as long as the water table lies within the height of capillary rise the soil will remain saturated by capillary water. If the frost zone comes within this zone of capillary water, there may be danger of serious frost heave. Therefore, there is no advantage in attempting to use subsurface drains to eliminate danger of frost heave in poorly-draining soils, unless the drains can be placed at such depths that the piezometric water table will be lowered to a distance below the frost line greater than the height of capillary saturation. For some soils, this is impracticable or impossible. However, benefits can be derived from using subsurface drains in poorly-draining soils. By their use soft soils can be consolidated and thereby their bearing value can be increased.

In using subsurface drains for consolidation purposes the following should be emphasized:

(*a*) Since any benefits of consolidation are obtained from capillary forces (that is, as long as the soil remains completely saturated), the deeper the drains can be placed within the zone of capillary saturation, the greater will be the force producing consolidation.

(*b*) The closer the drains can be placed for a given depth, the less time is required to consolidate the soil between the drains.

(*c*) To function properly the system must be so designed that water can be removed as fast as it collects. It may be possible to accomplish this with a gravity system in certain favorable locations, but, more often, it will be necessary to use pumps in sumps. Pumps are also needed when well points are used.

(*d*) Drain pipes for such a system may be very small since the actual amount of water moving through them may be no more than a "trickle." (The overlying soil remains saturated by capillary water so that the greater part of water from that source will be only that which is squeezed out by consolidation.) Since the soil by nature drains poorly, only a small quantity of water can be expected from infiltration and ground-water movement.

(*e*) The ideal situation would be one in which the poorly-draining soil is underlain by a pervious layer, in which case water could be removed from the pervious layer by means of well points or circumferential ditches. The action of a subsurface drainage system in homogeneous clay is so extremely slow that it is of little value for improving the condition of the clay.

Construction Methods.—Good designs may be vitiated by poor construction, and it should be stressed that high-quality construction control and inspection are essential to many types of construction.

The value of "engineered" subgrades and bases is more and more apparent. An excellent pavement may deteriorate on an inferior base and subgrade, whereas a second-grade pavement on a properly designed and constructed foundation may give excellent service. An engineered foundation requires proper control from design through completion. It requires careful selection and placing of materials, proper moisture control, and adequate compaction—the real value of which cannot be overstressed. Many of the defects of settlement, swelling, and shrinking, so often blamed on the pavements, can be traced to the foundations and could have been minimized by proper compaction control.

Remarks on Training of Soils Engineers.—In teaching Army courses on "The Control of Soils in Military Construction," the writer stresses particularly the value of identifying soils correctly because thereby the possibility of making a major mistake may be eliminated. After a soil is correctly identified, the properly trained soils engineer and his inspectors should know how to improve that type of soil, how to judge its drainage characteristics, how to decide the degree of moisture control necessary for efficient compaction, and how to determine what method should be used for compaction.

In prewar days, too little attention was given to the proper training of field men and inspectors for all types of highway and airfield construction. Frequently proper control and inspection was sacrificed for impressive looking plans. If the postwar period is to bring extensive highway and airfield construction with ample available man power, as is anticipated, then surely something will have to be done to assure not only the proper utilization of experienced personnel returning to civilian work, but also the provision of ways and means for the training of additional men. The time to consider these problems has already arrived.

A. CASAGRANDE,[18] M. Am. Soc. C. E.—The construction of transportation facilities—roads, bridges, railways, and waterways—has been an age-old source of problems to the civil engineer, and now the construction of airports, with a scope undreamed of only a few years ago, may well be making an important new chapter in civil engineering. When such rapid developments take place, reliable published information often lags far behind. This Symposium is a fortunate exception.

The following discussion deals primarily with the first paper of the Symposium. Colonel Stratton has succeeded remarkably well in summarizing all pertinent information and essential considerations on this subject, with particular emphasis on the many important contributions which the Army Engineers have made to the design and construction of airfields for heavy plane loads. Although restricted in scope to military airfields, it should be emphasized that most of the Symposium also applies to the commercial airfields of the future. In fact, almost all of the extensive research on the design and construction of airfields, conducted under the direction of Colonel Stratton, will be of inestimable value for the postwar development of commercial air facilities to serve the air liners of the immediate future. Therefore, it is hoped that this paper will be followed by others describing the results of the large-scale traffic tests which have been undertaken by the U. S. Engineer Department, the results of which will be indispensable to every engineer designing pavements for heavy planes.

---

[18] Associate Prof., Civ. Eng., Graduate School of Eng., Harvard Univ., Cambridge, Mass.

Design of Flexible Pavements.—The design procedure adopted by the Office of the Chief of Engineers is based on the empirical method developed by the California State Highway Department. As stated by Colonel Stratton, the design curves of Fig. 3 have been confirmed by large-scale traffic tests.

It may be well to explain why it has not yet been possible to develop a successful theoretical approach to the design of flexible pavements, based on the theory of elasticity. Perhaps the most important reason is that the coarse-grained materials, of which pavement and base courses are generally composed, do not follow Hooke's law. Therefore, the distribution of stresses in the subgrade will show considerably greater concentrations than that computed by the theory of elasticity. In addition, most flexible pavements do not have enough tensile strength to resist the considerable tensile stresses which develop, according to the theory of elasticity, for large ratios in the modulus of elasticity of pavement-plus-base over that of the subgrade. Even if no tension cracks develop, the computed stresses in the subgrade would be on the unsafe side because the deformation of the pavement in tension is much greater than that in compression; in other words, for practical purposes the pavement cannot take tension. These remarks are not intended to discourage further attempts at theoretical studies of the design of flexible pavements, but merely to emphasize difficulties which are often overlooked and which can lead to conclusions very much on the unsafe side.

Stabilized Versus Compacted Base.—Much confusion still prevails on the value of admixture of "fines" or "binder" to a clean coarse-grained material in the construction of base courses. To cite two extremes: (1) Excellent concrete pavements have been built in Long Island on hydraulically placed, clean, beach sand, without even an attempt at compacting the sand; whereas (2) in a different place, well-graded, fairly clean, glacial gravel (the best base material next to crushed stone) was "stabilized" by adding 15% material passing No. 200 mesh, thereby changing it into a frost-heaving material. Even where there is no frost action, the addition of a plastic binder to gravel has often resulted in a type of base which, in a condition of capillary saturation (evaporation from its surface prevented by the overlying pavement), was much less resistant to deformation than the coarse material without the binder. Not only is it costly to mix a binder with coarse material, but it is difficult to make the mixture uniform. Even a small excess of clay binder may cause local destruction of a pavement, which would not happen if the admixture of such binder were omitted.

Instead of paying for the admixture of fines, time and money should be directed toward very thorough compaction of the base-course materials. Although it has been emphasized, far too little attention is paid to proper compaction. In fact, some engineers really believe that a uniform sand cannot be compacted; that it always remains loose. (Perhaps this belief is due to the ambiguity of the term "loose," which is also used to designate grains with no cohesion.) The writer foresees the development of compaction equipment which by means of vibration will produce degrees of compaction of coarse-grained soils unattainable with any methods now used, and at little or no additional cost.

The importance of thorough compaction is best illustrated by the fact that a well-compacted sand has about three times more resistance to deformation and bearing capacity than the same sand in its ordinary loose condition (not bulked). For a well-graded gravel this ratio may be as high as fifteen. The large increase in resistance to deformation of gravel surfaces exposed to constant traffic is well known. Such surfaces may not be satisfactory unless traffic compacted. Does this not prove that it is possible to compact such materials far better than by ordinary construction methods? What can be done by traffic can be accomplished by vibration equipment especially designed for the compaction of sandy and gravelly soils.

Considering that the cost of compaction is only a fraction of the cost of the material itself, particularly where long hauls are necessary, it is only logical to improve the material by compaction to the utmost limit. Manufacturers of construction equipment would do well to pay attention to this problem and to its partial solution already attained before the beginning of World War II (44).

Design of Concrete Pavements.—Colonel Stratton advances pertinent arguments for restricting the thickness of concrete pavements to about 8 in., and for providing the necessary support on poor subgrades by an appropriate increase in the thickness of the gravel base. Success of such a design will depend on the uniformity of subgrade support. When dealing with nonuniform support such as results from irregular subgrade conditions, soils subject to swelling and shrinkage, or nonuniform frost action, in spite of a good base at times there may be little support, and corners may break under the design load, or even less load. For such unfavorable subgrade conditions, the use of thicker slabs with steel reinforcement cannot be avoided. Warping stresses might be controlled by a sufficiently small size of the slabs, say, 12 ft by 12 ft for a pavement 12 in. thick. The wire mesh reinforcement will preferably be used in two layers, spaced about 3 in. from the top and bottom of the slab. Some additional reinforcement in the top of the pavement should be provided at the corners. In such a design the steel would actually participate in carrying stresses, instead of acting merely to tie broken slabs together.

In thick pavements even greater attention will have to be paid to the design of the joints for very heavy loads. The most desirable solution would be to make all joints alike, each one permitting a slight amount of expansion. A trapezoidal tongue and groove design could be used with premolded asphaltic boards, about 3/16 in. thick, containing enough air voids (for example, in form of admixture of cork particles) to permit a compression of about 1/16 in. Thus, the total expansion possible for 100 ft of pavement, assuming a 12-ft spacing of the joints, would be about 1/2 in. This allowance is ample in view of the uniform distribution of this expansion and the greater assurance that all joints will remain operative, as compared with the standard, wide expansion joints that have been known to become partly inoperative with time. Heavy, short steel dowels should be provided, painted with asphalt and having a thin compressible disk glued to each end, to allow for the necessary slight amount of movement. If vertical steel pins are used to hold the premolded boards in place (piercing the trapezoidal tongue and being driven into base or subgrade), the section inside the tongue may require a sleeve or cover to allow movement between this part of the pin and the concrete.

A uniform joint construction, distributing expansion uniformly over all joints, would aid greatly in solving many undesirable features in the concrete pavements of the past.

Insulation for Frost Protection.—One of the feasible methods for protection against frost action is the use of an insulating material beneath the pavement, of such thickness as to prevent frost penetration into the subgrade. Where cheap timber is available and gravel scarce, timber deserves serious consideration, because a thickness of 3 in. will offer the same protection as 18 to 30 in. of gravel.

Another material which the writer has seriously considered for this purpose, ever since he became acquainted with it in 1929, is a porous concrete made from a mixture of cement mortar and foam. This Danish development has been used in Europe and South America for heat insulation and other construction. Fracture surfaces have the appearance of slag. It can be manufactured in different unit weights and insulating characteristics, and has the important advantage that it can be mixed in the field and poured like concrete. This, or some other cheaply made material full of air voids and having a compressive strength of at least 300 lb per sq in. (which will not soak up water into the air voids when submerged), poured either in place or in pre-cast slabs, would solve the problem of frost action in cases where the necessary thickness of gravel would be prohibitive in cost. In areas of permanently frozen ground such insulating materials could serve to protect the frozen ground under pavements from melting.

Wheel Loads of Airplanes.—Airplane designers should realize that placing the entire weight of the heaviest planes on only two wheels, or on two pairs of dual wheels with little space between the dual tires, creates the necessity of very expensive airfield pavements and limits the number of airfields on which such planes can land safely. For the heaviest planes the load should be spread over four wheels, with the dual tires spaced at least 6 ft apart. For further increase in plane load to 150 tons, the writer foresees the necessity of spreading the load over two four-wheel carriages, resembling perhaps the wheel carriages of railroad cars. With such an eight-wheel landing gear, a 150-ton plane would have the enormous advantage that in an emergency it could land on an ordinary commercial airfield without danger of breaking through the pavement and of serious consequences for plane and passengers. Civil engineers specializing in airfield construction should be consulted in connection with the design of the landing gear of air liners.

Closing Remarks.—The writer takes this opportunity to express his appreciation of the broad application of soil mechanics to the design of earthworks, foundations, water-front construction, and now to airfields, which the Army Engineers have followed during the past decade, and in which Colonel Stratton has played a leading rôle. The Army Engineers have contributed more to the advancement of applied soil mechanics than any other governmental or private organization.

HARRY E. COTTON,[19] M. AM. SOC. C. E.—The Corps of Engineers, with which the two authors (Colonel Stratton and Mr. Hathaway) of the Symposium under discussion are connected, has contributed much to the various problems of airport design and construction—especially base and subgrade design, proper backfill for subdrains, and runoff criteria for the design of storm drains.

Backfill for Subdrains.—The design of base-coarse drainage in Fig. 8(*b*) of Colonel Stratton's paper shows the perforations placed up which is contrary to good practice especially if proper backfill (filter material) is used. This suggests that a discussion is in order on backfill, the proper design of the infiltration area (perforations), and the amount of infiltration area required.

The chief enemy of subdrains is clogging either of the pervious trench backfill or of the pipe itself or of both. This problem has been solved in an investigation undertaken by the U. S. Waterways Experiment Station at Vicksburg, Miss. (45). The function of a subdrain is to remove ground water from a water bearing zone. Such zones are of previous material—silts, fine sands, coarse sands, and gravel. To prevent the entrance of the fine soil particles into the trench backfill, the investigation shows that the backfill should be not coarser than that in Table 10.

TABLE 10.—MAXIMUM SIZE FOR FILTER MATERIAL

A clean backfill having a grain-size curve between the curve of grading in Table 10 and that of a medium sand (No. 60 sieve) will be satisfactory. This is a radical departure from the usual state highway specification for material mostly between 2 in. and 1/2 in. Some states allow 0 to 10% passing a No. 4 sieve and some allow material as large as 6 in. The idea that a coarse backfill is needed with a pipe subdrain probably originated with the requirements for a "French" drain (without pipe) in which large voids are necessary for lateral flow. The vertical flow capacity of medium sand is ample for all ordinary subdrain conditions. The pipe provides lateral flow.

Such fine grained backfill is not only necessary to prevent clogging but, in many localities, more economical. However, it is necessary that the drain pipe be designed to eliminate the entrance of the backfill and yet allow for the entrance of water.

Because most of the recommended backfill material is of a smaller grain size than the perforation diameter, it drops through the holes by gravity action when the perforations are in the upper half of the pipe. This fact was demonstrated in the Vicksburg tests as well as in all other similar tests previously conducted. Therefore, instead of the perforations being up, as shown in Fig. 8(*b*), they should be down, or in the upper part of the lower half of the pipe. Also, to prevent the backfill from entering, due to side pressure, the upper row of holes should not be higher than 22.5° below the horizontal axis of the pipe as shown in Table 11.

---

[19] Drainage Engr., Culvert and Pipe Sales Div., Am. Rolling Mill Co., Middletown, Ohio.

There seems to be an undue concern among engineers regarding the loss of water once it has been collected inside the pipe. There are few instances in subdrainage work where such concern is justified. For the usual condition of lowering a water table in a saturated soil (section (b), Table 11), the zone under the pipe is already saturated and therefore no loss of water will occur. However, for landslide and terrace bank drains, to collect seepage that may be flowing on top of a thin impervious zone, the bottom of the pipe may lie in a pervious soil and precaution should then be taken to prevent loss of water by methods such as those shown in section (a), Table 11. For these cases and for base drainage, the quantity of water to be collected is small and two rows of perforations are more than adequate. When drain pipes are installed adjacent to pavements in impervious soil zones for base drainage and also for intercepting

drains, an impervious trench bottom, as shown in section (a), Table 11, and Fig. 38, is advisable to insure complete removal of free water collected in the trench. The backfill or "filter material" over the top and sides should be a tamped mixture of sand and gravel not coarser than the grain-size curve of material in Table 10 but having a permeability sufficient for runoff.

Required Infiltration Area (Perforation Area).—The hydraulics of subdrainage is not an exact science. The engineer may be guided by research on ground-water flow, but the answer is largely based on judgment and experience. (Typical of such research are the runoff tests by the Engineering Experiment Stations of Iowa State College at Ames and the University of Minnesota at Minneapolis. Also the Darcy formula may be used:

$$Q = A\,k\,i \qquad (11)$$

in which k = coefficient of permeability, i = hydraulic gradient, and A = cross-section area of flow.) The ground-water flow is seldom sufficient to fill a 6-in. pipe within a 1,000-ft run. Even for the most severe seepage condition encountered in highway and railway cuts, 6-in. pipe has sufficient capacity in the first 400 to 500 ft of the run. A change of pipe size in the run (for example, 6 in. to 8 in.) is required to carry the accumulated interception but not because of increased ground-water flow to the drain per linear foot. Therefore, the larger drain pipes need no more infiltration area (perforations) than is required in a 6-in. pipe.

Little is known about the infiltration capacity of perforations in a pipe surrounded with sand or sand and gravel. One such test with a metal pipe gave an approximate answer of 0.009 cu ft per sec per sq in. of perforations (1/4-in. holes) for a condition in which little or no head was assumed above the top of the pipe. On this basis, a 6-in. pipe, on a 1.0% slope with perforations as specified in section (b), Table 11, could fill itself in less than 30 ft. When consideration is given to the fact that the area of perforations in a run of 16 ft as specified in section (b), Table 11, is equal to the end area of a 6-in. pipe, it is self-evident that the infiltration area is many times larger than is necessary; in other words, a large factor of safety is provided. When too many rows of perforations are specified in pipe, requiring the top row to be at or near the spring line (horizontal axis), solids are likely to enter. To prevent such entrance is one of the requirements of a well-designed subdrain pipe.

Impact.—Colonel Stratton's discussion of loading criteria leads the reader to conclude that impact is not a factor in the design of runway pavements and may even be construed to infer that impact does not occur. The subject of impact has probably received more discussion than any other one item in connection with airport design. The justification for designing runways for wheel loads without impact seems to be based mostly on the observation that runway pavements show less damage than apron pavements used for warming airplane engines. The writer is of the opinion that the apron failure is not due to increased load, but mostly to the failure of the foundation, which becomes puddled by vibration, creating a condition similar to that of beach sand when tapped with the foot.

It can be assumed that there is no impact at the instant of a perfect landing but, to this date, published data indicate definitely the existence of impact for the average landing. R. D. Evans, of the Goodyear Tire and Rubber Company, has stated (46):

> "In connection with this work [landing tests to determine the efficiency of tires in landings on a variety of soils and surfaces], we used two planes, one in the 3,000-lb. class and one in the 5,500-lb. class. They were equipped with a recording accelerometer whereby the actual impact factors developed during landing could be determined. As a result of this work, we arrived at the following conclusions: Ordinarily our typical landings made on hard surfaces developed impact factors ranging from 1.25 to 1.75 *g*. Anything less than 1.25 *g*. would be rated as an easy or soft landing and one above 1.75 or 2.0 *g*. would be called a hard landing. The hardest landing which we ever experienced in all this series of tests was 3.4 *g*. The design factor in both of these planes was, as I recall, 6.5 so that we still had quite a ways to go before approaching the limit of impact values which the planes were designed to withstand. In this connection, it may be of interest to point out that all types of airplane tires, if operated at recommended values of load and inflation will not 'bottom'; that is, deflect down to contact with the rim until the impact load reaches 3.5 to 4.0 times the static load xx."

In contrast to the Goodyear impact tests with light planes, the Douglas Aircraft Company conducted tests (47) on a DC-4 weighing 63,000 lb. The normal landing impact factor was 1.43 and the extreme landing impact factor was 3.5. Although there was a wide difference in the weight of planes used, the impact factors developed in both tests are in close agreement.

As a basis for the design of the primary airplane structure, the Civil Air Regulations (48) require, in addition to a factor of safety, depending on the part considered, a limit load factor for level landings and three-point landings. For planes as heavy as 2,000 lb gross weight this factor $n = 4.33$, whereas for planes heavier than 2,000 lb,

$$n = 2.8 + \frac{9,000}{W + 4,000} \qquad \text{(12)}$$

in which W = the gross weight in pounds. For a 74,000-lb plane (37,000-lb static wheel load) the factor n becomes 2.91, to which is added a factor of safety.

In summing up this impact question, it should be remembered that the ground reaction is the sum total of the forces causing tire deflection, shock absorber travel, and stresses in the chassis. Also, whenever the tire deflection or the shock absorber travel is greater than that under static load, impact must exist.

The California bearing ratio method is now used extensively for the design of airport pavements and pavement bases. This method is empirical, based on California highway experience, and no doubt contains an impact factor for highway traffic, the existence of which was so definitely proved by tests conducted at the Iowa Engineering Experiment Station. In these tests trucks moving as fast as 20 miles per hr were used, and transmitted loads were scale weighed. The resulting recommendation for the design of highway structures, including culverts, was that impact factors from 1.5 to 2 should be used. Therefore, it would seem preferable to state that impact is allowed for in the California method rather than that no impact is used, or to infer that normal landings create no impact.

The time factor is another item that has received considerable discussion. The contention by some engineers seems to be that a load applied and removed suddenly does not produce the same transmission effect on the pavement foundation or on a buried structure as would a static load or a slow moving load. Whether this is true, or to what extent the transmitted load may be lessened by a supersudden load, as compared to just a sudden load, is not known. Observation has shown that mud pumping occurs from slab deflection under fast moving trucks as well as under slow moving trucks. Also the deflection of a large flexible culvert under a heavy railroad loading with 3 ft of earth cover has been observed. In this case a distinct deflection occurs with the passing of each of the front and rear group of wheels and with a deflection recovery between the application of these loads, thus indicating the speed with which moving loads are transmitted through earth.

Surface Drainage.—Mr. Hathaway's criteria for surface drainage is based entirely on catch basins or inlets. Two methods have been adopted for the collection of surface water—the catch basin (or inlet) and the surface intercepting drain. On some airports a combination has been used. Experience has shown that both methods have their advantages and disadvantages.

The "surface intercepting drain" was devised because of the apparent difficulty of concentrating surface water at one point without the use of pronounced gutters or ditches, which are objectionable on airport surfaces. The idea is to intercept the surface water without changing the uniform sheet flow to a piled-up flow; and, when properly functioning, these drains do just that. The two chief difficulties have been silting of the top layer and displacement of the top layer by traffic. These difficulties are not the fault of the idea, but are due to improper use and construction. Silting will occur when the surface water carries silts and fine sands; and, therefore, when used as indicated in Fig. 38, all turf areas should slope away from the drain. Regarding displacement, the tendency is to use too little bitumen. The correct amount can be determined best by making tests with the particular stone to be used. Contrary to the opinion of asphalt technicians, the claim is sometimes made that if enough bitumen is used to stabilize the surface, porosity is lost. This problem needs and deserves much more research work.

Catch basins (or inlets) function more satisfactorily on sumped areas than any other type. Those of ordinary size are not efficient in collecting water from valley surfaces where warping is limited as on airports. This fact is recognized by those who use extra long grate-top inlets across valleys in runway pavements. These valleys are generally located in the outer part of the pavement as shown in Fig. 8(*c*) to collect the runoff from the runway and thus prevent erosion and softening of the shoulder. Catch basins are even less efficient in collecting surface flow in turf valleys. A combination of the catch basin and surface intercepting drain system as shown in Fig. 39 would insure much better interception. For this use, the intercepting drain backfill up to the surface should not be coarser than the grain-size curve of the filter material in Table 10. On newly graded fields, silting may, and probably will, occur, but, by using the recommended backfill, the silt and fine sands, carried by the surface water, will be stopped in approximately the upper 1 or 2 in. This can be bladed off and replaced with clean filter material. Under ordinary sod-growing conditions, such replacement will not be required more than once or twice.

FIG. 39.—COMBINED CATCH BASIN AND INTERCEPTING DRAIN IN TURF VALLEYS

Combined Surface and Subdrain (*or Base Drain*) *Systems.*—The combined system, shown in Fig. 38, has received criticism on the ground that moisture may be introduced into the subgrade, or water may be forced into the pervious base, if and when the intercepting drain becomes full of water. For storms greater than that for which the drain pipe is designed (frequencies of 1 year, 2 years, 5 years, etc.), the trench backfill may become full of water, but theoretically only once in the design frequency period and then only for a few minutes. In considering this question, one must remember that water follows the line of least resistance and will not enter the pervious base unless under a head—a condition so infrequent as to be negligible. As for the introduction of moisture into the subgrade by capillary action, the design provides for complete removal of free water in the trench, and the remaining moisture will probably be no more than is normally contained in the subgrade soils.

For economic considerations of backfill, etc., the accumulated water in the intercepting drain pipe is usually diverted into a main sewer when a pipe larger than 18 in. is required.

The realization of the need for pervious bases and base drainage is increasing. The proper place for a base drain is at the edge of the pavement. Also, to prevent damage to runway shoulders, the proper place to intercept surface water is at the edge of the pavement. A combined drain that performs both functions is usually more economical than a separate system. However, as in other engineering problems, the conditions must govern the decision as to whether the combined system or separate systems are to be used.

Runoff Computations.—The computation of runoff from various types of sizes of drainage areas has always been an unsatisfactory task. No two engineers working independently will arrive at the same answer. This fact is probably due more to the values selected for the variable factors than to the formula used.

Most runoff formulas contain a "runoff factor" which is expressed as a percentage of rainfall. The Horton formula (Eq. 2) applies this factor (σ) as the rainfall less detention. This seems to be a step in the right direction as it is self-evident that for like surface conditions (soil, vegetation, slope, etc.), the percentage of runoff would be greater for a 2-in. rainfall than for a 1-in. rainfall. On the other hand, the engineer is confronted with the task of assigning a value for hourly detention on which there seems to be little information.

Mr. Hathaway has done a commendable job of simplifying the Horton formula computations by the use of charts, but the solution is still more laborious than by most other formulas. However, after sifting out the essential steps, Mr. Hathaway's solution is less difficult than it appears at first.

The writer has not made a sufficient number of computations to support a definite statement on runoffs obtained by the Horton formula as compared with runoffs obtained by other formulas, such as the Burkli-Ziegler and the rational formulas. In many cases the answers are in close agreement provided the same runoff factors are used.

D. O. Murray,[20] Assoc. M. Am. Soc. C. E.—The designing engineer will find, in this Symposium, considerable valuable information, presented in convenient form. He should bear in mind, however, that differences in hydrological features of widely separated regions will necessarily modify some of the standards proposed.

For example, Australia lies closer to the equator than the United States and, although snow falls on the tablelands and mountains of the southeastern part of Australia, trouble from frost is rare. For the most part, airdromes are so located that loss of subgrade support due to moisture-content increase is not a probability. Some airdromes have been constructed on poor subgrades. One site, abandoned before the war by the civil authorities, was later used because of the exigencies of war.

In Australia, particular care is taken to avoid conditions that will assist capillary moisture to rise under the surface. This precaution is most essential because of the thin bituminous surfaces typical of Australian airfields. Difficulty in procuring supplies has been a sufficient cause in itself for this procedure. Also, during past years, the various road authorities have paid particular attention to the construction of thin bituminous coats. In prewar days, under favorable circumstances, shire engineers were able to obtain as much as a year's service from a surface that had received only a heavy primer. The same treatment has now been given to a few airdromes, generally those in Class III.

Because of the confidence of designers in Australia that there will be no trouble from moisture in the subgrades, the opinion is gaining favor that the combined thickness of pavement and base can be 80% of the values given by Colonel Stratton in Fig. 3.

Surface treatment requires the use of the heaviest primer that the surface will take. If necessary, trial lengths with different grades of primer may be laid down to determine the heaviest that can be used satisfactorily. The rate of application of primer is limited to a maximum of about 0.25 U. S. gal per sq yd. The binder is usually bitumen fluxed to 85–100 penetration, the rate of application being about 0.3 U. S. gal per sq yd. The surface is then covered with screenings not exceeding a 0.4-in. gage. Only a sufficient quantity is spread so that there will be a minimum of loose material. Some engineers favor the use of tar instead of bitumen for surfacing areas upon which gas or oil may be spilled because of the greater stability of tar in the presence of these oils.

---

[20] A Prin. Engr., Headquarters Base Section, U. S. A. S. O. S., South West Pacific Area.

The rainfall intensity curves for rainfall on the eastern coast of Australia conform closely with the curves given by Mr. Hathaway in Fig. 15. Table 12(*a*), containing data presented by G. B. H. Sutherland (49), indicates the close conformity with the curves shown in Fig. 15 (compare with Table 12(*b*)).

TABLE 12.—COMPARISON OF RAINFALL INTENSITIES

Probability (years)	Curve No. (Fig. 15)	Length of Duration of Storm in Minutes							
		10	20	30	40	50	60	120	240
(*a*) Data Presented by G. B. H. Sutherland

30	....	6.8	5.3	4.3	3.6	3.15	2.8	1.65	0.95
10	....	6.2	4.8	3.8	3.2	2.75	2.45	1.4	0.75
3	....	5.3	4.0	3.2	2.6	2.3	2.0	1.15	0.6
(*b*) Data Presented by Gail A. Hathaway (See Fig. 15)									
....	2.8	6.6	4.8	4.0	3.7	3.1	2.8	1.7	1.0
....	2.4	6.0	4.5	3.7	3.1	2.8	2.4	1.4	0.9
....	2.0	5.2	3.9	3.1	2.7	2.15	2.0	1.1	0.7

A common practice in municipal drainage design is to adopt the formula,

$$i = \frac{K}{\sqrt{t}} \qquad (13)$$

in which i = intensity of rainfall in inches per hour; t = time of concentration of rainfall (that is, the time taken by the rain water to reach the point under consideration from the extremity of the catchment area); and K = a constant so chosen as to give a curve corresponding to the desired probability.

It is a worth-while practice to calculate the value of K for heavy storms or to check with Fig. 15 so as to develop some idea of the relative intensities of various storms. In this way, a better appreciation of the appropriate number for the curve corresponding to a specific storm will be developed. The formula gives low results for storms of short duration and high results for storms of long duration.

Frequently, to drain an airdrome, the neighboring region will have to be serviced by the airdrome drainage system. If the area involves more than about 1,000 acres, the use of time contours will lead to economy in the design of the main drainage ditches. The total area will have to be subdivided according to its separate small catchment areas as determined by roads, taxiways, or natural or other features. Each of these subdivisions will have its own features which will control the design of its drainage. The places reached by the drainage water from each subdivision are marked on the map for equal lapses of time. Usually lapses of 10 or 20 min are suitable—the larger the areas the longer should be the time interval. In this way, it will often be found that drainage from one subdivision has passed before drainage from another subdivision arrives.

The time contours are not constant. They vary with the quantity of water. The quantity of water will govern the depth of flow, and the velocity of the flow will vary with the hydraulic radius of the ditch. The trial computations may be made with either greater or less intensities of design storms. The effects of the time taken for the storm to travel across the full catchment area in various directions may also be considered. Useful information will be obtained as to the possibility of an economical design for a higher design storm.

The use of time contours to allow for ponding is imperative and simple. The total discharge may simply be the addition of the various discharges from the contributing parts of the catchment area.

The need for further research is clearly indicated. However, the latter part of the Symposium dealing with the design of drainage facilities makes available an excellent tool for a diligent application of principles of hydraulics to these drainage problems. Thus, the designer can visit the works he has designed and find the system functioning reasonably well in conformity with his design.

THOMAS B. PRINGLE,[21] M. AM. SOC. C. E.—During 1941–1942 and 1943 the Corps of Engineers constructed many million square yards of airfield pavements. Now that the major construction program is complete, it becomes increasingly more evident that the problem of developing and maintaining the airfield system will be a tremendous task and that to complete this work will require careful planning. Colonel Stratton has emphasized the importance of the development of airfield pavement design to carry the loads in use since the beginning of World War II and has called attention to the importance of traffic and its effect on pavement service. He has also stated that it is too early to forecast the ultimate service behavior of airfields of recent construction. However, it is not too early to lay the groundwork and begin planning the airfield development of the future. This planning will require the collection of factual data which will be the working tools of the planner or forecaster.

The average lives of various pavement surface types can be estimated by carefully compiling data on every airfield in the United States and assembling these data into orderly statistical form, showing for each surface type the square yardage constructed each year and the yardage remaining at the end of the year. The various state highway departments in cooperation with the Public Roads Administration have made studies, known as "Road Life Studies," which have given very reliable data on average pavement lives of various surface types for the nation as a whole, for regions, and even for individual states (50). Although there is no reason to believe that the pavement life of airfields will be the same as that of highways, the procedure for estimating the life will be identical and the statistical records that must be compiled before any comprehensive study can be made will be similar. The method of design must be substantiated by the statistical records and known service behavior of pavements. All these data can be collected only through the orderly compilation of existing information, such as pavement condition, maintenance costs, and reconstruction. These statistics, when studied with traffic records from the time of construction to the death or retirement of the pavement, give factual data for the future development of airfields and for setting up maintenance and reconstruction programs, and they form a basis for handling many complex problems of airfield administration. The actual number of load repetitions is far more significant in the case of airfields than in the case of highways, since the highways must be designed for an unlimited number of load repetitions, whereas on airfields (even those used for capacity operation) the number of repetitions is much less than on heavy traffic highways. From the standpoint of economy it will be necessary that airfield designs be predicated on anticipated life, estimated traffic, and average maintenance costs. Anticipated life can be estimated with reasonable accuracy from the collection of necessary data concerning pavements and the maintenance of reliable records of service, installations, retirements, and inventories. Retirement data and survivor curves, similar to those developed by life insurance companies, will be the basis of determining the probable life of the pavement. This information, if used to guide the expert judgment of men who know pavements and their maintenance problems, should produce a reasonable answer. Purely statistical data will not give the correct solution to the individual problem. However, these data can be of inestimable value to the experienced paving engineer in determining construction and maintenance programs.

---

[21] Senior Engr., Office, Chf. of Engrs., Washington, D. C.

Data on traffic volume and character will be required. These data should include the number and distribution by weight of airplanes using the field; and, for planning purposes of peacetime, airfields should predict the distribution for the hours of the day. These data will show with reasonable accuracy what facilities are required to handle present and future traffic requirements and will help establish priorities for improvement and predict maintenance requirements for the various pavements at an airfield.

About 1915 highway departments thought in terms of new construction and the day when their system would be complete. These systems have been completed to a considerable extent, and their maintenance is as big or an even bigger item than the original construction. The same problems of increased maintenance will apply to airfields as years pass, together with the problems of reconstruction due to obsolescence and deterioration.

It is vitally necessary that an effective planning organization be established to collect the necessary data on service behavior of pavements, including traffic records by type and character, which should contain not only design weights of airplanes but data on actual pavement loading and the maintenance costs for various pavement designs and surface types. The present and future needs of each installation must be studied carefully in order that development can proceed according to the most feasible and economical plan that will utilize existing facilities to the greatest extent and require the least new construction.

Airfield planning and development as discussed herein are mainly problems that will come with peace and the development of the airplane for army and civilian peacetime needs. However, it is important that these questions are not completely overlooked, even during the stress of wartime. The Corps of Engineers has undertaken a study known as an "Evaluation Survey" which will form a nucleus of data that will be invaluable not only in formulating and proving pavement designs but also in planning efficient layouts and in guiding maintenance programs, and especially in planning airfield development for the future. The results of these evaluations must necessarily be held confidential until after the war emergency. Since the evaluation survey is being conducted only at airports of military occupancy, it is, therefore, not considered desirable to disseminate this information until after it ceases to be of military importance.

Colonel Stratton has most ably discussed the design method employed by the Corps of Engineers for airfield pavement construction. The method of design as now employed by the department was not in use during the early construction period and knowledge of the effect of the heavy wheel loads to which pavements are now subjected was unknown from actual experience. Unfortunately, some of the pavement in the runways, taxiways, and aprons of the hundreds of airfields constructed by the Corps of Engineers and other agencies were not built according to the designs discussed in Colonel Stratton's paper.

When the tremendous construction program was almost complete, it became obvious that many airfields had been constructed whose actual carrying capacity was unknown. For the Army Air Forces to set up a training program which would utilize all airfields most efficiently and economically and insure the least interruption, due to failure of pavements under heavy loads, it was necessary to determine the safe carrying capacity of each field. The increasing weights of airplanes and the necessity for designating fields to be used by certain type of aircraft made it essential to obtain a record of the evaluation of each airfield based on the carrying capacities of the pavements as actually constructed.

The field work investigation and preparation of reports are being done under the supervision and direction of the U. S. Engineer Department. For the purpose of this evaluation two kinds of operation are considered—namely, capacity and limited:

1. Capacity Operation.—Capacity operation is defined as the maximum traffic that can possibly operate on an airfield for a period of approximately 20 years. Daily operation may be assumed as varying from 100 wheel loadings for very heavy airplanes to 1,500 wheel loadings for very light airplanes.

2. Limited Operation.—Limited operation is defined as a few wheel loadings a day for a period of approximately 20 years (about 10% capacity operation) or as the maximum traffic that can possibly operate for a period of 2 to 4 years. However. the use of a pavement rated for limited operation by the

maximum traffic that can possibly be operated for a period of 2 to 4 years may require greater yearly maintenance than would an airfield rated for capacity operation.

The over-all evaluation as made is for the airfield as a whole and the runway system as a whole. These evaluations are termed field and runway evaluation:

(*a*) Field Evaluation.—Each airfield is given an over-all field evaluation based on the carrying capacity of the pavements or sections of pavements. The field evaluation is considered as the gross plane weight that may be operated at the field for capacity operation or limited operation without any hindrance due to excessive maintenance or reconstruction of any major pavement.

(*b*) Runway Evaluation.—Runways are evaluated separately from the field as a whole. The mechanics of evaluation are the same for the runway pavements as for field evaluation. Runway evaluation specifies the gross weight of plane that may be operated at limited and capacity operation on any runway without hindrance due to excessive maintenance or reconstruction except possibly at the end of runways.

The evaluation of each pavement is studied carefully, using all available information, and is determined either by actual tests or by estimation of the carrying capacity from design and construction data or other information. This leads to a unit evaluation of each and every pavement.

The evaluation is based on the design criteria presented in Colonel Stratton's paper. Instead of making tests of soil and construction materials, determining the results expected, and thereby determining the design requirements, the evaluation tests the in-place values and from the in-place values assigns the carrying capacity of the pavements. The principles of evaluation are the same as those for design except that they are applied in reverse order. For the evaluation of flexible pavements, the in-place CBR (California bearing ratio) values of subgrade and base courses are determined. This eliminates certain factors that must be considered in design, such as construction control and the possibility that the materials in the prototype will not conform with design values. Similar procedure applies to rigid pavements. The actual k-value or modulus of soil reaction and the flexural strength of concrete in place are determined. Consideration is given to possible frost action in connection with the evaluation of both flexible and rigid pavements and load carrying capacity is reduced because of probable frost action where justified.

The evaluation will be the beginning, and the basis, of service behavior data on airfield pavements. All investigations will be conducted under uniform procedure. The in-place or as-built pavements can be watched through their life, and from the known service behavior a definite relation can be established between theoretical design, as now advocated by the Corps of Engineers and described by Colonel Stratton, and the actual pavement performance. The present empirical curves developed from the results obtained from traffic tests, covering the entire United States, can be verified and corrected, if necessary, from the record of actual service behavior of many pavements constructed under all conditions with a variety of construction materials.

JOHN R. HASWELL,[22] M. AM. SOC. C. E.—Under the heading, "Drainage of Airfields: Subsurface Drainage Systems," Colonel Stratton aptly states that under certain conditions, with a properly designed surface drainage system, no subsurface drainage is necessary. However, the ground-water table is not fixed and a site that may appear satisfactory in a dry year, or even over a cycle of several years of low precipitation, may later develop excess moisture. Therefore, a single line of drains on each side of a runway pavement somewhat as shown in Fig. 8(*b*) would be a valuable precaution in many instances. There will be some seepage through the pavement that should be considered and provisions should be made for its removal. In heavy soils a "perched" water table may develop in the upper few feet of soil when the real ground-water table is somewhat deeper.

The second type of subsurface system likened to "a farm tile drainage system" prompts this discussion. For many years agricultural engineers have been working away from the old costly uniform grid and endeavoring to put the most drains where the wettest condition is encountered in the subsoil. On a reasonably flat field one would not look for seepage to be intercepted by cross drains, but a slope may occur in the subsoil strata or springs may come up almost vertically through a tough clay. Gravel layers or lenses may be tapped and may serve as laterals in some favored places.

The general subject of planning and constructing agricultural drainage systems in the United States is briefly covered in "Drainage in the Humid Regions" (51) and many state agricultural colleges have publications covering local land drainage probems.

The maintenance, where possible, of the old agricultural drainage, as part of the airfield development, has been treated by H. H. Nicholson (52). After quoting the Ninth Report of the Select Committee on National Expenditures dealing with Air Services, Mr. Nicholson writes:

> "It is to be noted that soil and drainage are mentioned last of the factors to be considered in choosing a site, but there can be no doubt that these two points exert a telling influence on the operational efficiency of an aerodrome.
>
> "Some of the special difficulties and possible sources of trouble in this sphere of drainage work can easily be envisaged. The need for an even surface of considerable extent means that pre-existing ditches must be piped and filled in; ridges and furrows must be obliterated; excrescences must be removed and hollows filled in. Existing land drains may or may not be broken in the process, especially where buildings are erected or runways laid down. Whatever is done by way of such operations, surplus water will continue to move along the tracks which it has followed in the past, and wherever the drains are broken or the underground drift of the water is interrupted, there will trouble arise, unless adequate measures are taken to forestall it."

The necessity for placing "natural earth backfill" as shown in Fig. 8(*b*), or "impervious bedding" as shown in Fig. 37, under the tile drain may be questionable. There are trenching machines of the digging wheel type, capable of making a satisfactorily graded ditch and leaving the bottom slightly curved to receive the tile. If the trench is dug in a haphazard manner as to grade, there is ample chance for enough variation in depth of fill, in tamping, and in kinds of soil, to cause sufficient differences in settling to ruin the grade. For most airfields, the placing of drain tile on the undisturbed subsoil, properly prepared to receive it, would seem far safer than the placing of drain tile on an uncertain backfill.

---

[22] Prof. in Chg., Agri. Eng. Extension, Pennsylvania State College, State College, Pa.

The use of "impervious bedding" would result in the loss of at least one half the diameter of the drain tile in the effective depth of the drains as related to the soil below the pervious fill. Surely some water may be expected to seep into the subsoil from the base course. The movement of such water is downward in the soil to about the tile level and then horizontal to the drain, rising up in the open joints and entering almost entirely at the under side. It is to be expected that in some cases more water will enter the drains shown in Fig. 8(*b*) through the bottom of the open joints than through the perforations on the upper side of the tile. The same practice persists in some highway standards where the engineer seems to consider the soil mass as so much impervious material and not as a structure with pores and various water-holding capacities.

W. J. Turnbull,[23] M. Am. Soc. C. E., and William H. Jervis,[24] Assoc. M. Am. Soc. C. E.—The problems encountered at the beginning of the war construction program undertaken by the U. S. Engineer Department are covered in this Symposium. Colonel Stratton and Mr. Hathaway are to be congratulated for their contributions. Rigid adherence to schedules set up for completion of the various airfields to fit in with military necessity made these problems much more critical than they would have been in normal times. The solutions described in the Symposium were remarkable, especially considering the speed with which they were made.

Since 1942 the California bearing ratio (CBR) as a tool for the design of flexible pavements has been the object of much discussion by many engineers connected with the design of airfields. The discussion of the CBR test has been about equally divided between favorable and critical comment. Those engineers who support the use of the CBR test as a design tool recognize the fact that it is comparatively new with the Engineer Department. However, these engineers feel that it is better than any previous method and further that at the present time there is no alternate procedure which is as good. The engineers who are critical of the test think that it is something new and untried and that the background of previous experience is a better criterion for designing and building military airfields.

The CBR test measures the shear strength of a soil and is not a classification test. Since the strength of any soil varies widely under different moisture and density conditions and often varies widely between the undisturbed and remolded states, any shear test, whether a CBR, triaxial, an unconfined compression, or a direct shear test, must be divided into two parts—the preparation of sample for test and the actual test. The secret of proper performance of any shear test depends largely on the proper preparation of the specimen so as to reproduce faithfully conditions in the field. If this is not done, the test results will be misleading and may lead to either underdesign or overdesign. With this in mind, the Engineer Department, through the Mississippi River Commission, U. S. Waterways Experiment Station, in Vicksburg, Miss., has been conducting an extensive investigation of the CBR test technique involved both in preparation of the specimen and in performance of the test. This investigation has been supplemented by studies from numerous other laboratories in the Engineer Department. As a result of these comprehensive studies, the CBR test technique has been developed to such an extent that reasonably accurate and uniform results can be obtained by the ordinary testing laboratory.

---

[23] Chf., Embankment, Foundation and Pavement Div., U. S. Waterways Experiment Station, Vicksburg, Miss.

[24] Engr., U. S. Waterways Experiment Station, Vicksburg, Miss.

Much of the adverse criticism originally directed against the CBR test as a whole was due, not to difficulties entailed by performance of the test, but to lack of knowledge of the effects on the test of certain variables introduced in preparation of test specimens. At the beginning of the investigation it was thought that the variables with the most effect on the CBR would be density, water content, and soil type. Later in the investigation it was learned that other variables existed, the principal one being water content at the time the sample is molded for test. The indications have been that this water content is extremely critical for the soaked CBR values determined on all materials except cohesionless soils and high swelling clays.

Several changes in the test technique as a result of the Engineer Department investigation have occurred since Colonel Stratton prepared his paper. As previously mentioned, many variables involved in the CBR test now seem evident and may be controlled and adjusted to such an extent that the CBR test can be used practically for design purposes. As with any other testing procedure, refinements and variations will be made as further studies in the laboratory and the field become available.

In connection with the development and continuation of the use of the CBR test, the laboratory design test and actual field behavior should be correlated. In other words, it is not known whether the structure of the soil specimen produced in the laboratory is similar to the structure produced in the field by the field compaction equipment generally in use. For a complete and intelligent use of the CBR test, it will be necessary to correlate laboratory and field results. This may be accomplished by either of the following two methods:

(1) Observations and laboratory and field investigations of airports which have been constructed; and
(2) A closely controlled test of field versus laboratory compaction supplemented by actual field observations at existing airports.

Either method should be equally good with the exception that the first one will take considerably longer and its success will depend to great extent on the available field records of water content and density at the time of construction.

As of 1944, a method of conducting field in-place CBR tests has been developed which appears quite satisfactory and which agrees reasonably well with laboratory tests on remolded and undisturbed samples when moisture, density, and soil structure effects are considered. The field in-place test has many advantages because it can be used directly for evaluation purposes without the necessity of considering the many variables which exist in the test on remolded samples for use in design. The main criterion of the field in-place test is that the engineer, using or making the test, must have knowledge of the condition of the subgrade or base-course material with respect to the probable ultimate condition of moisture and density which will exist over the period of the life of the airfield.

Under the heading, "Base Courses," Colonel Stratton states that "Base-course materials sometimes are stabilized with commercial admixtures such as portland cement, cut-back asphalts, emulsified asphalts, and tars." The stabilization of base courses by means of various commercial admixtures should be approached cautiously since it has been proved in several instances that essentially stable base-course materials have been weakened by the use of admixtures. The CBR test is an excellent tool for detecting any increase or reduction of strength in the natural material when admixed with any so-called stabilizing material.

Because improper drainage often may have been responsible for the failure of military airfields, the necessity for surface and subsurface drainage systems at airports cannot be overemphasized, birdbaths on the surface of runways, taxiways, and aprons, as a result of the combination of low transverse grades and consolidation of the base courses and subgrades, are believed to be extremely detrimental, since, if any cracks exist in the surface pavement, water will enter and a localized weakened condition in the base course and subgrade will result. Nonplastic base courses, compacted to a density equal to that obtained at optimum moisture by the AASHO Method, as modified by the Engineer Department, to a great extent, will eliminate detrimental consolidation.

The construction of military airfields has been a huge program and, due to the war emergency, has been completed in record time. In spite of the difficulties inherent in so hurried a program, the design methods which were adopted should in general prove themselves adequate. The CBR test, even though admittedly a new and unperfected tool, has contributed materially to the success of the military airfield program.

Ralph R. Proctor,[25] M. Am. Soc. C. E.—The description, by Colonel Stratton, of the failure of highway design and construction methods to meet the demands for increased subgrade loadings required for military landing fields is most interesting and has prompted this discussion.

Relationship Between Soil Loadings in Earth-Fill Dams and Landing Fields.—More use should be made of earth-fill dam design and construction methods in landing field construction; the soils in the foundation and lower part of a high earth-fill dam are subjected to greater pressures than any mentioned by Colonel Stratton and must withstand these pressures (about 1 lb per sq in. for each foot of height of the dam), without undue settlement or distortion. This condition of loading requires soil stability, secured from the coefficient of friction and cohesion, under greater loadings than those contemplated by Colonel Stratton.

---

[25] Field Engr., Dept. of Water and Power, Water System, City of Los Angeles, Los Angeles, Calif.

Uncertainty of Plate Bearing Test Results.—Plate bearing tests involve elements of uncertainty. Three separate soil conditions may be involved; the soil may be saturated at the start of the test, it may become saturated during the test, or it may not become saturated at all during the test. It is believed that no formula for evaluating the relationship of tests under these conditions can be developed for the three following reasons:

(*a*) A fully saturated soil has a modulus of elasticity determined by the soil and water during the time the water is being forced out of the soil by the applied load;

(*b*) An unsaturated soil is permanently deformed by consolidation, even under loadings of 5 lb per sq in., and develops some elasticity at the end of the consolidation period, but consolidates further upon application of a greater loading; and

(*c*) A soil that becomes saturated by consolidation passes through both condition (*a*) and condition (*b*) with an additional influence of compressed air in the voids of the soil when under loading.

These unpredictable variations in soil characteristics (conditions (*a*), (*b*), and (*c*)) led the writer to the conclusion that the best way to avoid such complications in earth-fill dam construction is to compact the soils used to dry weights and moisture contents that would permit full soil consolidation without involving saturation, with consequent reduction of the effective coefficient of friction from internal pressure.

Prediction of Soil Consolidation by Use of the Indicated Saturated Penetration Resistance.—Fig. 40 shows the mean measured soil consolidation, under various loadings, that was secured from 859 laboratory tests of compacted soils of practically all soil types. The solid lines represent the range of the tests and the dotted lines represent interpolated values. The consolidation of broken granite, from 1.5 in. to 2.5 in. in size, when hand placed in a layer 14 in. in diameter by 7 in. deep, is also shown; the compressive strength of the rock was 14,950 lb per sq in. It will be noted that the amount of soil consolidation to be expected from a given loading is shown in terms of the "indicated saturated penetration resistance" of the soil. Fig. 41 shows the method of determining this value. Point A shows an assumed moisture content and dry weight of the soil whose characteristics are shown by the dry weight and penetration resistance curves. Point B shows the moisture content at which the soil would become saturated at the dry weight shown at point A. Point D shows the indicated saturated penetration resistance of the soil at a dry weight represented by line AE. The indicated saturated penetration resistance is seen thus to be dependent on the relative dry weight of the soil.

Prevention of Internal Pressure Caused by Soil Consolidation.—This method of evaluating the relative density of a soil as compacted or as found in place has been used by the writer for the last 12 years. Fig. 40 has been in use (with revisions from time to time as more test results became available) since 1936 for predicting the consolidation of soils in earth-fill dams in order to provide room

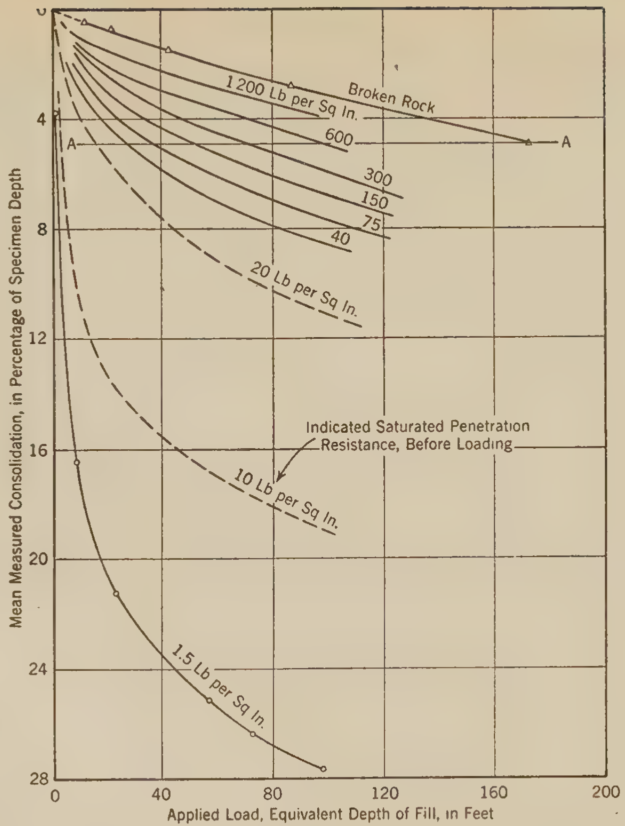

FIG. 40.—MEAN MEASURED CONSOLIDATION OF 859 SOILS WHEN PLACED AT VARIOUS INDICATED SATURATED PENETRATION RESISTANCES AND CONSOLIDATED UNDER VARIOUS LOADINGS

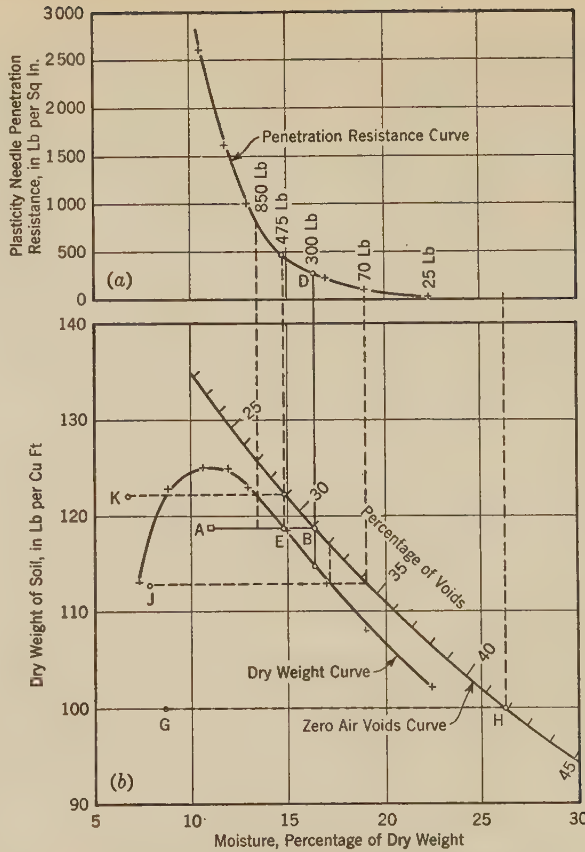

FIG. 41.—TYPICAL COMPACTION-PENETRATION CURVES

for soil consolidation, by proper control of the compacted soil dry weight and moisture content, without the consolidation causing the soil to become saturated. If the soil represented by Fig. 41 is compacted to the dry weight and moisture content represented by point E, subsequent consolidation, without any change in moisture content, will be represented by a vertical line in Fig. 41 from point E. When the dry weight of the soil represented by point E is increased by 3.5 lb per cu ft, complete saturation is reached. Fig. 40 indicates a required depth of fill of about 30 ft to cause this consolidation. However, this consolidation also involves compression of entrapped air in the soil. Therefore, for a 30-ft depth of fill loading, or 30 lb per sq in., it is better to compact this soil, in the case of the dry weight shown at point E, at a moisture content not higher than 13.5%, thus allowing for the aforementioned consolidation to take place with a resulting soil dry weight and moisture content that falls on the dry weight curve. If a soil becomes saturated by consolidation, part of the applied load is carried by water pressure, reducing the effective coefficient of friction of the soil. The writer's opinion is that no appreciable internal pressure will occur in the soil at this and lesser moisture contents when the consolidated dry weight and moisture content are not to the right of the right-hand side of the soil dry weight curve.

Variations in Density of Natural Soils.—Points G, J, and K of Fig. 41 show the variations in soil density of a particular soil encountered during the foundation excavation for a dam. The comparative consolidation to be expected from these soils can be found by noting the indicated saturated penetration resistance of each and comparing the consolidations shown in Fig. 40 at these resistances for some particular soil loading. Point G is a commonly found relative soil density and consequent saturated penetration resistance for soils one to two feet below the original ground surface. This indicates the need for extreme care in using natural soils for subgrade purposes.

Miscellaneous Notes on Soil Testing Methods.—The modified CBR (California bearing ratio) test described by Colonel Stratton has one serious defect—that is, the establishment of an "optimum" soil density as that presumably secured by dropping a 10-lb, tamper eighteen inches. The writer has not found the use of an "optimum" soil density, thus secured, to be reliable as a standard for soil compaction. However, this should be a considerable improvement over the standard CBR method, as a study of the foregoing discussion of Figs. 40 and 41 shows that the consolidation secured from tests after compressing a soil under 2,000 lb per sq in. would have no connection with the consolidation when the soil was compacted to lesser dry weights. A better method for performing this test would be to compact and test the soil at about three different densities, representing the range of variation in moisture content in a well-controlled compacted fill; that is, at penetration resistances of 500, 1,500, and 4,000 lb per sq in. penetration resistance. The lower value is selected in order that the effect of compacting while the soil is too wet may be determined. There is one important point in experimental soil compaction that is overlooked generally. Whenever soil is compacted the soil particles break down; the percentage of fines is increased, evidently by erosion of the larger sized particles. The experimental compaction method should not alter the soil characteristics in this respect to a greater extent than occurs during the actual compaction by the rollers. Repeated compaction of soil samples can change their characteristics enough to make the tests worthless. Another rather common practice in preparing compaction-penetration resistance curves should be avoided; that is, an entire soil sample should never be dried in an oven and then tested by adding various amounts of water to secure predetermined moisture contents. These curves are best prepared by dividing the soil sample in two parts at about 800 lb per sq in. penetration resistance and then progressively drying and compacting to secure the left half of the curves, and progressively wetting and compacting to secure the right half of the curves.

If a plate bearing test is made of this soil at the density and moisture content shown at point G, the resistance to penetration by the plate should increase as the penetrating load is increased, in accordance with the soil consolidation curves of Fig. 40, until the applied pressure becomes great enough to start actual penetration, at which time the deformation curve turns in the opposite direction, following a path similar to that shown in Fig. 4. However, if this soil is tested similarly when in a nearly saturated condition, most of the test load is carried almost immediately by water pressure and a resistance curve similar to Fig. 4 is secured. Fig. 5 indicates that the bearing plate deformation remains constant for a given unit pressure loading for plates larger than 30 in. This indicates that the laws of soil consolidation, rather than of penetration, should apply or that, during the tests that established this ratio, there was not sufficient depth of soil below the plates to determine the true relationship of load to deformation. The writer would expect to secure results similar to those of Fig. 5 by testing a 4-ft thick layer of compacted soil placed on a hard surface.

Fig. 40 shows the soil consolidation that may be expected from a confined soil; it is believed that the results shown in Fig. 40 more nearly portray the action to be expected in a subgrade from either compacted or natural soils than do the results of penetration tests, the plate bearing test is essentially a large penetration needle test. The results secured in Fig. 40 occurred over a period of about two weeks; however, an average of 75% of the consolidation occurred within a period of 5 min. The load repetition test merely determines the time required for a given load to consolidate the soil below the pavement sufficiently to cause failure by excessive slab deflection. For instance, if the duration of an aeroplane wheel loading is 0.1 sec, 75% of the soil consolidation shown in Fig. 40 should occur after 3,000 trips, if it is not necessary to force water from the soil to permit this consolidation.

Both Fig. 5 and Fig. 40 show an increased rate of subgrade resistance with increased deformation; this appears to indicate a serious error in any method of computing slab thickness that is based on the assumption of constant subgrade reaction.

Application of Laboratory Methods to Construction.—It appears that the use of the determined indicated saturated penetration resistances of compacted or natural soils, assembled from compaction-penetration curves made from soil samples taken from frequent field soil density tests as the subgrade is being constructed, should serve as a better guide to the bearing power of a subgrade than plate bearing tests. This is particularly true if the relationship between the indicated saturated penetration resistance of soils and bearing power of soils for slabs is determined by trial loading of test slabs. This testing procedure during actual construction may be illustrated best in connection with Fig. 42, which shows typical soil compaction results secured during one month's work on an earth-fill dam project involving 7,000,000 cu yd of compacted earth fill; 374,000 cu yd were compacted during this month, equivalent to two 7,000-ft runways, 200 ft wide, with 3 ft of compacted fill below the subgrade. A constant check of the addition of water to the soil, both at the dam and borrow pits, was maintained by use of the compaction cylinder and needle. A total of 238 compacted fill density and penetration resistance measurements was made and the results compared with results secured by immediate hand compaction of the removed soils. The mean of these results is shown in Fig. 42 as: Mean cylinder needle, 2,198; mean fill needle, 1,880; mean cylinder, 122.7; and mean fill, 120.7. The minimum compacted penetration resistance was 700 lb per sq in.; the maximum was 3,900 lb per sq in. From the 238 soil density measurements, 69 representative soil samples were selected for preparation of compaction-penetration resistance curves; 25 of the 69 specimens selected for test were taken from the area showing the lowest soil density secured for each day's work. The determination of the indicated saturated penetration resistance of the fill was made from these curves, 28 samples being selected from the 69 samples for which compaction-penetration resistance curves were prepared for consolidation-percolation tests. A corresponding number (28) of plate bearing tests to the consolidation tests would place one every 500 ft along the runways. The soil density and compaction-penetration resistance tests (69) would be spaced apart 200 ft and the compacted density hand-compaction comparison tests (238) would be spaced apart 60 ft. As all of these measurements and tests have been found necessary to control soil compaction in dams, they should be required for similar compaction control in subgrades and should also yield the data for determining pavement thickness as they are obviously much more representative of actual soil conditions than plate bearing tests ever could be. The variations found in actual measured consolidations of apparently similar samples of the same soil show that the mean of a large number of soil tests is more to be relied upon than that of a few tests. A soil density and compaction-penetration resistance test costs six man-hours. A consolidation test costs six additional man-hours. It is obvious that dozens of these tests could be made for the cost of a plate bearing test; furthermore, no heavy equipment need be provided, with consequent high hourly charges for its use. Inspection of the rates of consolidation of soil samples indicates that at least 24 hr should be allowed for each added increment of soil loading for a plate bearing test and, if five increments are added, a total time of six days would be required for each test, involving at least $1,500 of equipment rental and being equivalent in cost to about 100 consolidation tests. The aforementioned 24-hr increment assumption applies to soils that do not become saturated by consolidation; several weeks might be required for an accurate plate bearing test on dense, clayey soils.

Control of Expansion of Compacted Soils When Saturated.—The foregoing condition of compaction (see Fig. 42) has not, in fourteen years of experience of compacting soils by this method, resulted in a dry enough soil to permit subsequent expansion from the absorption of water. Conditions represented by point A of Fig. 41 may possibly permit such expansion; those represented by points G, J, and K of Fig. 41 are almost certain to permit expansion of lightly loaded clay soils.

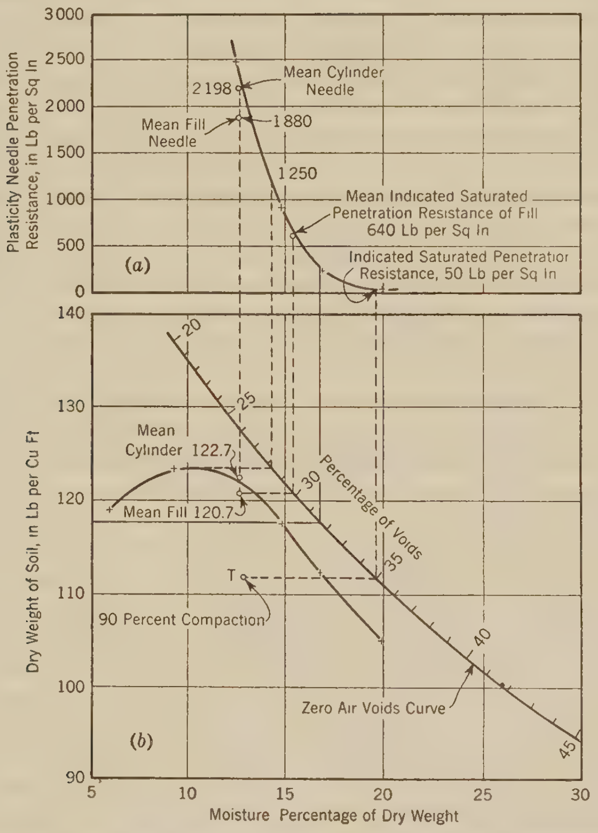

Fig. 42.—A Representative Compaction-Penetration Resistance Curve for 374,000 Cu Yd Compacted Earth Fill, Showing the Mean Values Secured from 238 Compacted Fill Density Tests and Hand-Compaction Tests

Reduced Bearing Power from 90% Compaction.—It is interesting to note the comparison of the results shown with the "90% compaction" standard. The relative consolidation under a given loading to be expected from the mean indicated saturated penetration resistance secured of 640 lb per sq in. may be compared with the 50 lb per sq in. indicated for the 90% compaction point T, Fig. 42. Incidentally, the degree of compaction shown in Fig. 42 is higher than is usually secured by the many variations of hand-compaction methods now in use. It has been the writer's practice for years to require hand compaction that secures a maximum dry weight of soil at about 2,500 lb per sq in. penetration resistance. All of the various "modifications" of the originally published methods for hand compaction (53), such as dropping various weight tampers from different heights, mechanical tampers, etc., were tried and discarded as too cumbersome and not worth while several years ago. No use is made of the actual peak dry weight; the measure of soil compaction used is the indicated saturated penetration resistance. Referring to Fig. 40, the consolidation under a loading of 10 lb per sq in. would be 2.9% for the 90% compaction and 1.3% for the mean compacted fill density shown. Also, referring to line AA of Fig. 40, it will be seen that a loading of 172 lb per sq in. is required to secure a consolidation of 4.9% for the broken rock, 110 lb per sq in. is required for the mean of the compacted fill, and 32 lb per sq in. is required for the 90% compaction. This indicates that, if the loading required to cause a given deflection of a bearing plate is to be used as an index of the bearing power of this soil, the bearing powers of the mean compacted fill (dry weight, 120.7 lb per cu ft) and the 90% compaction (dry weight, 112 lb per cu ft) will be 61% and 19%, respectively, of that indicated for the broken rock. Assuming the broken rock bearing power to correspond to the k of 800 lb per sq in. per in. of Fig. 1, the corresponding values of k for the mean compacted fill and 90% compaction will be represented in Fig. 1 by 490 and 152 lb per sq in. per in., respectively. Applying these values along the 75,000-lb wheel loading curve of Fig. 1(a) the following concrete thicknesses are secured: Broken rock, 5.5 in.; mean compacted fill, 7.2 in.; and 90% compaction, 9.7 in. It is thus seen that, for whatever wheel loading the 75,000-lb curve might represent under these assumptions, the mean compacted fill would require 2.5 in. less concrete than the 90% compaction when used in a landing field subgrade.

Bearing Power of Natural Soils.—The results of plate bearing tests on natural soils cannot be used safely because the process of preparing the subgrade and placing the concrete is almost certain to disturb or remold such soils enough to affect materially their bearing power in their natural state. Concrete, cement, or aggregate trucks in particular are almost certain to have this effect. This remolding of natural soils can also occur after the pavement is placed, particularly in the case of bituminous pavements or where concrete pavements become cracked or broken. It is the writer's opinion that the values for soil consolidation secured from Fig. 40 by use of the indicated rather than the actual saturated penetration resistance are the more reliable for natural soils.

Preparation of Compacted Fill Subgrade for Paving.—There are two practical points of construction that appear to have been overlooked in subgrade construction. One is that the soil should be compacted to at least a foot above the finished subgrade and then trimmed carefully to grade immediately ahead of the placing of the pavement. This is probably the most important point contained in this discussion. It has been found repeatedly in dam construction that soil density tests must be taken from a greater depth than 10 in. from the surface of compacted fills in order to secure a true check of the density of the compacted fill; samples taken closer to the surface show lower soil density in most cases. In pouring the concrete, placing machines have a tendency to leave large areas of rock pockets next to the subgrade. A half inch of mortar brushed on the freshly trimmed subgrade, from which all loose soil has been removed, just ahead of the pavement placing will increase greatly the contact area between concrete or bituminous pavement and subgrade. One landing field came to the writer's attention at which the sheepsfoot fill was of fair order but the loose material remaining after the sheepsfoot rolling was finished was compacted by a smooth-drum roller. The indicated saturated penetration resistance of this part of the fill was 50 lb per sq in. The actual penetration resistance at the time of construction was much higher; the subgrade appeared to be firm and hard. After the first good rain an aeroplane with a tire pressure of 60 lb per sq in. penetrated the 4-in. oiled macadam surfacing and the subgrade until the sheepsfoot compacted fill was reached, just as had been predicted from the soil density test made at the time of construction. It is almost certain that no trouble would have been experienced if the sheepsfoot fill had been trimmed as described.

The use of at least 3 ft of compacted fill subgrade below the trimmed surface, unless the natural soil has an indicated saturated penetration resistance of at least 400 lb per sq in., will eliminate much of the uncertainty of the bearing power of subgrades as the subgrade will at least be uniform in bearing power if the work is done properly. The cost of this work should not be more than for 1.5 in. of extra concrete pavement thickness.

Design and Use of Sheepsfoot Roller.—All of the elements of roller design found necessary to secure soil compaction results comparable to Fig. 42 may be combined in one machine. The materials used successfully for compacted fills in earth-fill dams include decomposed granite and diorite, sandstones and shales soft enough to be dug with a rooter, glacial moraines, alluvial soils, volcanic ash, glacial clay, and heavy California adobes. The roller consists of three drums, universally mounted abreast, 5 ft long outside dimension, by 42 in. inside diameter and fitted with six circumferential rows of thirteen teeth each, arranged so that no more than two teeth may bear on a plane surface at onetime, when directly below the axis of rotation of the drum. The teeth are 8.5 in. long and are fitted with removable shoes having areas of 6 sq in., 7 sq in., 8 sq in., and 10 sq in. The area used is dependent on the material, the choice of area being made to secure a final penetration of 3 in. to 5 in. after sixteen roller trips have been made. The weight, including frame, on each drum should be 10,500 lb, with provision for adding water in the drums to increase the weight to 13,000 lb per roller drum, or 39,000 lb for the entire unit. If required, water and sand can be placed in the roller drums, increasing the weight per drum to 15,500 lb. This roller, at 39,000 lb total weight, can be handled economically by the larger tractors, with a drawbar pull of 13,000 lb at 240 ft per min, up to 6,500 ft above sea level. It may be necessary to use two-drum rollers having a loaded weight of 20,000 lb each to compact some heavy clay soils; this type of roller has also been used successfully to compact decomposed granitic rocks. The aforementioned tractor should haul the three-drum roller, loaded to 20,000 lb per drum, at a speed of 176 ft per min. However, there may be some advantages to the higher speed of travel attained by the use of only two drums of this weight as the compacting load is applied more suddenly. The correct soil moisture content for use with such rollers will be that wherein a penetration resistance in the compaction cylinder from 2,000 lb per sq in. to 4,000 lb per sq in. is secured, the maximum moisture content should be that of an indicated saturated penetration resistance of 400 lb per sq in., with average results of about 600 lb per sq in. indicated saturated penetration resistance.

All of the dam construction experience of the writer indicates that the correct use of the type of roller described will secure substantially similar bearing power from all materials that can be compacted. Actually the only problem in a subgrade is to determine the proper slab thickness for a given loading after the soil is compacted by the roller available for use. All that technical supervision can do is to regulate the soil moisture content so the roller will get the maximum compaction it is capable of producing and to make sure the correct number of roller trips are made over all parts of the fill.

Emergency Construction Procedure.—For hasty or emergency construction the use of the three-drum roller described previously will automatically create high soil densities with no other precaution than controlling the soil moisture so the 7-sq-in. tooth penetration with 13,000-lb drums will be between 3 in. and 5 in. and making certain that sixteen roller trips are made over all parts of the fill. A similar roller, with 10,500-lb drums, was used to secure the results shown by Fig. 42. This method applies only to soils that need addition of water. Where most of the soils are too wet for use some of the previously mentioned decomposed sedimentary or igneous rocks, glacial moraines, and even alluvial soils may be found in place while so dense that, when saturated, the moisture content is low enough to permit compaction of the type described. Where excessive moisture cannot be avoided the use of larger shoes and 10,500-lb roller drums to prevent complete penetration of the roller teeth will secure the maximum soil density possible. The method of testing outlined will determine the indicated saturated penetration resistance of the resulting fill and, in itself, furnish data for determining the pavement thickness or will show which areas of the runways are representative of the fill in order that tests of any other type may be made at locations known to be representative of actual compacted fill conditions.

Concluding Remarks.—The foregoing discussion describes methods of soil compaction that should be especially applicable to hasty or emergency construction; that is, the work of preparing the subgrade could start without delay and the construction forces, by use of the methods described herein, could secure the best compacted subgrade possible with the equipment and materials at hand, after which the type and thickness of paving could be selected to fit the constructed subgrade. The success of emergency or deliberate construction depends on the functioning of the engineering force in charge; poor engineering will result in poor compaction. The engineering procedure for securing this type of compaction control, while exacting, is simple and does not involve complicated test methods; personnel for the control of dam construction have been assembled and trained for several different projects without difficulty. A carefully planned series of tests to determine the required thickness of pavement, landing field or highway, in terms of the indicated saturated penetration resistance of the subgrade would be most useful in that, at least for emergency construction, the data for determining pavement thickness could then be secured from the records of the engineering inspection of the compaction of the subgrade soils.

It appears from this discussion that subgrade soils should be compacted to relative densities represented by "Mean Cylinder 122.7" of Fig. 42 if possible, rather than holding the soil dry weight to a lower value as was done in connection with dam construction in this case to provide for soil consolidation without appreciable internal pressure. It appears that the close approach to saturation of such soils, with consequent internal pressure, will do no harm but, rather, the necessity of forcing water from the soils will slow the consolidation and result in a longer trip-life for the pavement if it is subjected to wheel loads that, if static, would break the pavement. The same reasoning indicates that subgrades compacted to lesser dry weights, because of the presence of too much water in the soil to allow full compaction, should be also compacted to the dry weights and moisture contents represented by the right-hand half of the dry weight curve, as close to saturation as possible. In the case of the slab being designed to withstand full soil consolidation under loading a longer period will elapse, more load trips, before the full slab deflection is reached, allowing the concrete to attain greater strength before being stressed fully.

D. M. Burmister,[26] Assoc. M. Am. Soc. C. E.—A most important and timely contribution to the design and construction of airports is given by this Symposium. The Corps of Engineers, U. S. Army, should be credited with developing the principles and construction practices for the unprecedented program of wartime airport construction. There are a few comments the writer wishes to make on Colonel Stratton's paper.

Subgrade Support.—It is evident from the design curves of Fig. 1 and Fig. 3 that subgrade support is of somewhat less importance for rigid concrete pavements than for flexible bituminous pavements. With the small deflections permissible in concrete slabs to keep the tensile stresses within safe limits, only a minor increase in subgrade support can be developed by deflection of the slab directly under the load. In other words, a rigid concrete pavement has a very considerable load-spreading effect on the pressures transmitted to the subgrade, the load being distributed more uniformly over an area, possibly as large as 10 ft or more in diameter, at correspondingly greatly reduced intensities. On the other hand, the subgrade support is far more important for flexible bituminous pavements, because the deflections are greater and the load-spreading effect is smaller. The greater concentration of stress on the subgrade and the greater curvature of the pavement under the load tend to cause greater deformations in the subgrade, which, under the action of repeated loadings, tend to accumulate to the point of failure of the pavement, unless kept to sufficiently small values. Whether this limitation can be expressed in terms of a maximum allowable settlement under a single load application for different types of soil conditions is an open question. The performance of existing airfields under traffic conditions should clarify this subject considerably.

---

[26] Asst. Prof., Civ. Eng., Columbia Univ., New York, N. Y.

It is hoped that Colonel Stratton will be able to present some factual data on settlement or deflection limitations for design purposes.

Base Courses.—Colonel Stratton has emphasized that extremely thick concrete pavements can be avoided by the use of base courses to improve the subgrade support. Although the improvement of pavement support was not always evidenced by plate bearing tests, traffic tests and service performance have demonstrated the value of base courses. The importance of the restraints exerted by a concrete pavement on the supporting capacity of a base course has been investigated (54). The effect may well increase the effectiveness of the base course by 50% to 100%. The restraint effects are due (*a*) to the surcharge effect of the weight of the concrete slab; (*b*) to its rigidity and marked load-spreading effect, which prevents any tendency for upheaval resulting from the deflection of the slab; and (*c*) to the shearing restraint at the interface between the slab and the base course, which prevents lateral displacements in the base course.

In the case of flexible bituminous pavements, the base course furnishes the primary support, and the bituminous layer serves as a wearing course. In Fig. 3, which gives the design curves of required thickness of base course for flexible pavements, there is no distinction made as to the quality of the base course. It is evident, however, from the minimum values of the California bearing ratio (CBR) equals from 50% for light plane loads to 80% for the heaviest plane loads that there is a very considerable range of quality and strength. The supporting capacity depends on the kind of material and the grading, the construction procedures of placing and rolling, and the degree of compaction achieved. When performance under actual traffic conditions has been observed in sufficient detail, it may be possible to establish minimum standards of good construction practice for design and construction purposes. The type of base-course construction can then be selected with due regard for economic and practical considerations, local use of materials, and the thickness required to provide adequate support and length of service. Minimum

standards of base-course construction are suggested in Table 13 as a basis for discussion (54).

Experience and performance records will indicate what the relative thickness factors should be. Relative density should be a more suitable measurement than percentage of compaction for the degree of compaction achieved in the field. This is illustrated in Fig. 43. Relative density is based on the loose, dry state as 0% and on the maximum compacted state as 100% as convenient references (laboratory), which give a clear picture of conditions with respect to degree of compactness and also supporting capacity. For example, 95% compaction is only 70% relative density for the material shown, and can be considered only fair to good, being on the border line between medium compact and compact. With the development of better rolling equipment and compacting procedures, it may be possible to obtain 95% to 100% relative density, and ultimately even 110% or more, based on laboratory densities.

Fig. 43.—Comparison of Relative Density and Degree of Field Compaction

Good compaction is the most essential factor. The close packing and interlocking of the larger particles, whatever the grading may be, give high strength and resistance to deformations. To achieve this condition practically, especially in the upper layer directly beneath the pavement, where the stress concentrations are greatest, the methods used so successfully in the construction of "water-bound macadam" pavements may be used, omitting, however, the topping of fines with water. The principles are simple: A single-sized coarse layer (1¼ in. to 2½ in. in size) 4 in. thick is rolled to maximum compactness. This achieves the close packing and interlocking of the large particles. Choke or filler stone (½ in. to 1 in. in size) is spread and worked into the interstices of the base and rolled until the base is filled. This choke stone provides the proper bedding, so that the large particles cannot rock or shift. An almost ideal condition is achieved for the top course of the base. Where the heaviest wheel loads are anticipated, the best bases so far constructed should be used to avoid excessive thicknesses.

The service and performance records under traffic conditions of the airports constructed by the Corps of Engineers would be of inestimable value for future construction, when correlated with the design and construction procedures given in the Symposium.

Ralph Hansen,[27] Assoc. M. Am. Soc. C. E.—A valuable contribution to the design of airfield pavements is presented in this excellent paper by Colonel Stratton. As the author states (see heading, "Synopsis"), "* * * the design and construction procedures have been verified by accelerated traffic tests utilizing heavy, rubber-tired earth-moving equipment." The following is a description of one of the traffic tests on flexible pavements, initiated by the Chief of Engineers, the results of which confirm the design curves tentatively established for wheel loadings in excess of 12,000 lb.

Barksdale Field, near Shreveport, La., was selected for this accelerated traffic test as it was believed the subgrade at this site would be representative of plastic clay subgrades which might be encountered in the construction of flexible pavements in the southern part of the United States. The specific purpose of the Barksdale Field test was to determine the following for a 20,000-lb and a 50,000-lb wheel load on flexible pavements with a 3-in. asphaltic concrete wearing course:

Fig. 44.—Plan and Profile of Test Section

---

[27] Head, Soils and Pavement Section, U. S. Engr. Office, Little Rock, Ark.

1. The thickness of pavement and base necessary to prevent detrimental shear deformation in the subgrade;
2. The effect of the quality of base materials on the total specified thickness of pavement and base;
3. The quality of base materials required directly under the pavement;
4. The thickness of a soil cement base needed to prevent detrimental shear deformation in the subgrade; and
5. The adequacy of the compaction requirements as adopted by the Office of the Chief of Engineers to prevent detrimental consolidation of the base materials and subgrade.

Extensive tests on the subgrade and materials locally available for base-course construction were conducted to determine the CBR (California bearing ratio), compaction requirements, and other properties prior to design and construction of the test pavements. The subgrade was stripped level, compacted, and a test section consisting of two test tracks, one for the 20,000-lb wheel load and the other for the 50,000-lb wheel load, was constructed. Each test track comprised the following four different types of bases: (*a*) Layered base construction consisting of several layers of different materials with a high CBR material directly under the pavement; (*b*) layered base construction similar to the first type but with a lower CBR material directly under the pavement; (*c*) a high CBR material for the full thickness of the base; and (*d*) a soil cement base. The test section was oval in shape with two parallel paved straightaways joined at the ends by semicircular unsurfaced turnarounds, with the inner track for the 20,000-lb wheel load and the outer track for the 50,000-lb wheel load (Fig. 44(*a*)). The unsurfaced turnarounds and shoulders offered an opportunity to obtain data on the effect of repetition of heavy wheel loads on unsurfaced bases. Deflection plugs were installed in both tracks to measure the deflection, by means of electrical apparatus, of the pavement, base, and subgrade under the action of moving and static wheel loads and plate bearing loads. In Fig. 45 some typical oscillograms are shown for deflections under moving wheel loads at item 1, section 3, Fig. 44(*a*). The curves are recorded on a 60-cycle time base. The T gage measures the deflection of the surface of the pavement and the B gage measures the compression of the base materials. The difference between the two readings is the deflection in the subgrade. Hydrostatic and earth pressure cells were installed in both the 20,000-lb and 50,000-lb tracks. Loaded earth-

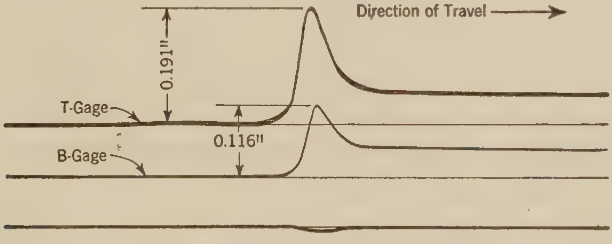

FIG. 45.—TYPICAL OSCILLOGRAMS FOR DEFLECTIONS UNDER MOVING WHEEL LOADS, 50,000-LB TRACK

moving equipment with tire contact areas approximately comparable to those of planes with similar wheel loads were used to produce the specified wheel loads. The loaded equipment was pulled around each test track by traction units, with one rear wheel of the loaded equipment traveling successively in three adjacent tracking paths, each path equal in width to the width of the tire imprint. Traffic was continued until 5,000 trips were made in each tracking path. Traffic was halted at various intervals for test measurements, maintenance and repair to the tracks, and observations. After completion of the traffic test, trenches were excavated in each test track to determine the lateral displacement and consolidation of the base materials and subgrade.

FIG. 46.—TYPICAL CROSS SECTIONS, VERTICAL FACES, AFTER TRACKING

In Fig. 46 are included typical cross sections (item 2, Fig. 44(*a*)) of the lateral displacement of the base materials and subgrade, vertical deformation of the pavement, and curvature of the 3-in. asphaltic concrete pavement resulting from repetitions of wheel loads. Extensive field and laboratory tests were made on the asphaltic concrete pavement, all base materials, and the subgrade. After they have been assembled and analyzed and after correlation with the data from other tests, these data will be used in improving the design technique for airfield pavements.

H. V. PITTMAN,[28] M. AM. SOC. C. E.—Some of the more serious problems encountered in the construction of flexible pavement with clay-gravel base during late fall and winter are included in this discussion of Colonel Stratton's paper which deals particularly with "Construction of Concrete Pavements" and "Drainage of Airfields."

Construction of Concrete Pavements.—As stated by Colonel Stratton (see heading, "Concrete Paving"),

> "A well-prepared rigid pavement design may be vitiated by carelessness or improper construction, and emphasis is placed on the quality of

---

[28] Prin. Engr., War Dept., U. S. Engr. Office, Little Rock, Ark.

> subgrade and base-course construction; protection of the prepared subgrade, base courses, and the concrete during the construction; the selection of proper equipment for construction; construction sequences; and adequate curing of the concrete."

These requirements are considered about the minimum essentials necessary to obtain satisfactory results. Experience has shown that, due to the exigencies of the war necessitating tight construction schedules which at times appeared almost impossible of execution within the time limit specified, the final results are considerably less than these minimum essentials or those which would obtain under more normal conditions. Therefore, the ultimate service behavior of some of the wartime airfields is certain to reflect some faults in construction and it should be evaluated accordingly. However, even under the very adverse conditions encountered, the results obtained, as attested by service use, are remarkably good.

From the writer's experience with airfield pavement construction, the subgrade and base-course construction was generally satisfactory. However, provisions for the proper protection of the subgrade, base course, and concrete during construction were often inadequate, due primarily to rapidity of construction, lack of carefully prepared construction schedules and sequences, etc., with resultant damage by traffic, rain, frost, and by drying out during the hot summer months. The specifications, in addition to providing for the exclusion of traffic from the prepared subgrade, should also provide for adequate protection from the elements. It might be possible to use some type of soil treatment that would waterproof the prepared subgrade. Such treatment would insure retention of the original moisture, exclusion of additional moisture, and permit easy disposal of accumulated rain water and continued operations with a minimum of delay. The spanning of one lane with a covering consisting of some type of substantial but lightweight housing of the low-trussed type is deemed worthy of consideration. Some type of protection similar to the foregoing is very much needed so that a minimum of from 800 to 1,000 lin ft of prepared subgrade can be adequately protected from the elements and kept in a state of readiness for pavement operations at all times.

More adequate protection and curing of concrete during construction should be provided, particularly during the hot summer months. Specifications for airfield pavement usually provide for the use of any one of five methods of curing concrete—namely, impervious membrane, cotton mat, ponding, wetted earth, and waterproof paper. Of these methods which serve the dual purpose of protecting and curing the concrete, contractors invariably select and use the impervious membrane curing method because of the ease in handling and applying the membrane and because of the resultant low cost. This type of curing does not adequately protect the concrete from the high summer temperatures which are known to cause severe warping of the pavement. The other methods specified, particularly the cotton mat method, would, if used, provide adequate protection and curing. However, contractors will continue to use the cheapest and most convenient method permitted by the specifications even though it is less effective.

Alternate and Successive Lane Construction.—Colonel Stratton's statements (see heading, "Construction of Concrete Pavements") that "* * * there is need for improvement in placement methods" and that

> "Alternate lane construction of multi-strip airfield pavements is conducive to serious disturbance to the subgrade by the operation of construction equipment and by ponding of rain water on the intervening subgrade between completed strips"

are in accord with observations of the writer. In order to meet design requirements fully the alternate lane method of construction should be eliminated, particularly where concrete is placed directly on a prepared subgrade. Experience has shown also that superior and satisfactory results can be obtained by using the successive lane method of construction of airfield runways progressively from the center line to shoulders by following a carefully prepared construction schedule, based on a proper order of work and operations sequence. This method results in improved drainage conditions on the shoulders and excludes traffic from the prepared subgrade. In addition, where all work of grading, subgrade preparation, and paving is properly coordinated, a minimum of time is lost in backtracking and in waiting until the concrete pavement has aged sufficiently to accommodate the necessary construction equipment.

Drainage of Airfields.—Referring to the section on "Drainage of Airfields," a serious drainage problem encountered during construction should be mentioned—namely, the design location of the pavement below ground surface at the shoulders, a problem not normally encountered in highway construction. Such location or depression of the pavement, in the writer's experience, has proved particularly troublesome during rainy weather and winter construction, has resulted in serious delays to progress and has necessitated excessive ditching at shoulders, pumping out excess rain water, and, in some cases, removal, replacement, and reworking of the subgrade. Whenever possible the pavement grade should be raised so that the base of pavement will correspond to ground elevation at shoulders after stripping, thus affording free surface drainage of the prepared subgrade from center line to shoulders and thence to the drainage disposal system. This procedure would increase the amount of shoulder fill where subgrade is in fill, and would reduce the amount of shoulder excavation where subgrade is in cut. In cases where the stripped natural ground would coincide with the base of elevated pavement, the excavation would be reduced to a minimum as the material in such cases requires only scarifying and compacting, and the operations of excavating, wasting, or hauling to fill to accommodate a depressed pavement are eliminated.

The elevation of pavement grades would also be advantageous at those fields where the terrain is extremely flat and where the drainage system slopes for disposal of surface and subsurface water to border ditches and beyond to natural drainage systems are at a very minimum. The combination of depressed pavements with successive lane construction should eliminate many of the difficulties, delays, and expenses in the construction of some airfields.

Later designs employed in some districts have provided grades which preclude most drainage difficulties encountered earlier in the program.

The location of the water table in rice-growing areas should be given more serious consideration than usual—particularly in late fall, winter, or early spring. In such areas, the cultivated topsoil is invariably underlain with a so-called clay hardpan—a dense, impervious material the existence of which determines the suitability of such land for rice growing. In many cases this hardpan occurs near the surface with a correspondingly high water table and very wet topsoil. In such cases, it is necessary to waste the otherwise suitable topsoil and to substitute borrow material having suitable moisture content for the compacted subgrade. This procedure often results in delay and additional cost while more soils investigations are made and in the necessity for longer hauls. In some cases it was necessary to use the only borrow available which was less desirable than that originally specified. In selecting a site for an airfield in a rice-growing area, it is very important to determine if the site contains sufficient suitable borrow for completion of the compacted subgrade in case seasonal conditions prohibit the normal use of the designated topsoil. Also, this determination of availability of suitable borrow should be made in advance of final selection of the site and, in any case, well in advance of construction.

Problems and Difficulties of Winter Construction.—The construction of concrete pavements can be successfully prosecuted during winter, even in regions of rather severe climatic conditions, without appreciable increase in cost or letdown in design requirements. The most serious problem is that encountered in the preparation and protection of a satisfactory subgrade—a problem common to all types of pavement. On the other hand, the construction of flexible pavement with a stabilized clay-gravel base under winter conditions in areas of frequent rainfall and freezing temperatures, such as prevail in latitudes of Little Rock, Ark., and Memphis, Tenn., is difficult, involves additional time for completion and an appreciable increase in costs, and, more often than otherwise, results in a pavement considerably below the usefulness contemplated by design requirements.

Among the most serious problems encountered are the following:

(*a*) Exposure to damage of large areas of prepared subgrade by all the vagaries of the weather and by construction equipment in delivering, spreading, and compacting the base course.

(*b*) Exposure of large areas of partly or completely prepared base course to like damage by weather and traffic while being constructed in two layers of equal thickness. Often the initial layer is subjected to damage by rain and frost action and requires reworking and compaction before the succeeding or final layer can be placed. When this condition occurs, excess moisture penetrates the subgrade, necessitating complete reworking and compaction of both the subgrade and the initial base course. This same condition may obtain during or after placement of the second or final base course and, at times, after application of the prime coat. Once moisture, appreciably in excess of the specified optimum, enters the base-course material, its removal is a difficult problem due especially to low temperatures and a very low rate of evaporation. Also, the clay-gravel base course is very susceptible to damage by freezing which destroys its stability, necessitating reworking of all areas so affected.

(*c*) Exposure of large areas of primed surface to the elements necessitated by the required minimum curing period of 48 hr and in order to provide sufficiently large primed surfaces for the economical prosecution of paving operations. Such exposure often results in serious damage to the base course, thereby requiring reworking, compaction, and repriming. Also, exposed primed areas hold excess surface water which must be dissipated before application of the wearing surface, resulting in additional delay.

TABLE 14.—NUMBER OF DAYS SUITABLE FOR WORK (SUNDAYS EXCLUDED) FOR PAVEMENTS WITH FLEXIBLE BASE, AND FOR CONCRETE PAVEMENTS

Month	FLEXIBLE BASE				CONCRETE

December	11	186	6	16	22	265	20	24

Table 14 shows, in summary, a comparison between the days suitable for work (Sundays excluded) on flexible base and concrete pavement, based on climatological data for Little Rock and vicinity for 1935 to 1942. Table 14 indicates that much time is lost in construction of flexible pavements with a clay-gravel base during the winter months and during periods of heavy rainfall, whereas the experience on concrete shows relatively short periods of lost time occurring during cold weather and following heavy rainfall. Table 14 should afford a good comparison of the effects of weather on construction progress for the two types of pavement.

Winter construction of flexible pavement with a clay-gravel base should be limited to areas of more favorable climatic conditions than exist in the vicinity of Little Rock and Memphis, if results comparable to those of concrete are to be obtained.

G. R. SCHNEIDER,[29] ASSOC. M. AM. SOC. C. E.—The rapid advances in airfield pavement and drainage design procedures are emphasized in this Symposium, and the authors are to be commended for the thorough manner in which the information has been presented. However, some of the unusual problems encountered in the field during the recent construction program in the United States are not mentioned, and it may not be out of place to note some of them in order to complete the record.

---

[29] Lt. Col., Corps of Engrs., U. S. Army; Chf., Eng. Div., U. S. Engr. Office, Little Rock, Ark.

Many elements affected the location of the sites selected, and it was sometimes necessary to construct the fields in areas where the conditions were unsuitable from an engineering standpoint. When military airfields are to be constructed for training many thousands of fliers in a short time, they must be located far enough apart to permit construction of auxiliary or satellite fields from which fliers can train without interference with each other and with fliers from other fields. Obviously, a training field should not be located on an important airway. It should be placed where there is a reasonable amount of safe flying weather during the year, where air currents will not cause an undue hazard, and where it will not be subject to overflow by flood waters. Railroad and power line connections must be reasonably close because of critical labor and materials, and an adequate water supply must be readily obtainable. Nearness and accessibility of population centers must be considered because of the labor supply for construction and maintenance of the field and because of the social and recreational benefits. A location where the field would be useful after the war was preferred to one which would have little or no utility in peacetime. It was desirable to avoid hilly land because of the large amount of grading necessary, but flat land where little grading was involved made drainage difficult. Cultivated land was undesirable because the time and energy expended in working the soil to make it suitable for farming rendered it unsuitable as a pavement foundation. On the other hand, if the land was not cleared, the operations of clearing and grubbing, in addition to being time consuming and expensive, disturbed the original soil structure and often resulted in a poor foundation. It was usually desirable to have an all-over landing field in which case the soil had to be suitable for the growth of sod. The aforementioned limitations on site location meant that sites were selected which, in many cases, involved difficult foundation, drainage, and construction problems.

A further difficulty was the urgent need for speed in selection, planning, and construction. It was not possible to spend the desired amount of time on preparation of plans; and the time of construction could not be chosen so as to conform with favorable weather conditions. Because of the magnitude of the construction program, all sources of concrete aggregate and base materials that could be considered at all suitable were used, and, in some cases, materials that were not as good as might be desired had to be utilized. The railroads did an excellent job in hauling enormous quantities of concrete aggregates and base materials, and the Office of Defense Transportation distributed the available railroad cars and expedited their movement very efficiently. However, the pavement design was influenced in some instances by consideration of the difference in railroad haul requirements of the construction materials.

Airfields in the northern part of Louisiana and the eastern part of Arkansas were usually located in the flat alluvial areas where relief is slight and drainage problems are serious. In fact, some of the sites were selected by studying maps of areas that had been overflowed by major floods and then examining the narrow strips of relatively high land between the streams that had not been overflowed for the most suitable site. The soils generally are relatively impervious sandy clay silts, in some instances underlain by sand and in other instances by clay pan. Some of the latter areas were planted in rice or had been used for rice cultivation. Generally, these subgrade soils fall in the Public Roads Administration classification A-4-6. In their natural state they are loose and in the summer they dry out until they are quite hard, but they rapidly become saturated in the presence of water. When wet, the original structure of the subgrade soils is quickly broken down by the passage of construction equipment and their shear strength is largely lost.

Three important considerations in designing a pavement to be constructed on a subgrade of this type under any except the most favorable weather conditions are the depth of the clay pan below the finished subgrade, the limitation imposed by the subgrade on the wheel load of the construction equipment, and the selection of a type of pavement that can be constructed with a minimum of working of the subgrade. If the impervious clay pan is near the surface of the ground, water will collect readily and will saturate the subgrade making construction impossible unless the subgrade soil is removed to the clay pan and replaced with more stable material. Even though favorable weather conditions permit construction, there is the possibility of pavement failure during a wet season with field operations at or near capacity load. Consideration should also be given to the use of runway gutters and inlets, as shown by Fig. 8(*c*), to remove water from the pavement. Otherwise, the turf along the edge of the pavement will act as a dam in accumulating water which saturates and seriously weakens the subgrade at the edge of the pavement. This type of runway gutter is particularly desirable along taxiways if the field is to be used by planes in which the pilot's field of view is restricted so that he cannot see the edge of the pavement.

Subsurface drainage is generally ineffective with subsoils of this type, but if a subsurface drainage system is used special care must be taken in the design and construction of the filter surrounding the pipe to prevent the soil from being washed into the drains. It is essential, too, that the pipe used in the storm drainage system have absolutely tight joints or soil will be washed into the pipes, undermining the fill over the pipe and resulting in sinkholes.

This Symposium provides a sound rational basis for the design of airfields. However, so many factors are involved in the selection, design, and construction of an airfield that the engineer should study carefully all the local conditions that will affect the cost or utility of the field, in addition to familiarizing himself with the features described in the Symposium.

H. M. WILLIAMS,[30] ESQ.—A most acceptable method of airfield drainage design, which has proved useful during the present war emergency construction program, is presented in the paper by Mr. Hathaway. The suggested methodology, however, does not provide for the determination of runoff from lengths of flow greater than 600 ft. The selection of such a limiting value is basically correct since the phenomenon of sheet flow as expressed in the basic equations is normally not experienced on typical airfield covers for lengths greater than 600 ft. In fact, it may be limited to much shorter distances before channelization occurs. However, in many types of airfield layouts, other than that indicated in Fig. 26, the engineer is frequently confronted with conditions under which it is entirely feasible and desirable to permit considerably longer lengths of flow than are covered by Mr. Hathaway.

---

[30] Office, Chf. of Engrs., War Dept., Washington, D. C.

In an effort to provide such an extension to the design criteria, consideration has been given to the development of a synthetic hydrograph procedure following, in general, the methodology suggested by Franklin F. Snyder, Assoc. M. Am. Soc. C. E. (29). For the necessary data on which to base the required hydrograph constants, recourse has been made to the data of the U. S. Soil Conservation Service for small, turfed watersheds having characteristics which, in so far as possible, were similar to those of typical airfield areas. The data for the various watersheds which have been studied are assembled in Table 15.

To provide a common basis of comparison for these various watersheds, use was made of the relationships expressed in Fig. 17 by means of which an effective length for $n = 0.40$ and $S = 1\%$ was determined for each area. In these determinations the effective length is subdivided into effective channel length and effective overland flow length. The length of flow in the channel was measured along the proposed collecting channel or swale for that section in which appreciable depth of flow may reasonably be expected to occur during the design storm. Length of overland flow is the average distance from the end of the effective channel to the edge of the drainage area measured in the direction of flow as indicated on the proposed grading plans.

From Mr. Snyder's concept of the unit hydrograph, the following equations may be obtained:

$$t_p = T_p - K_q (t_r - t_d) - \frac{t_r}{2} \qquad (14a)$$

and

$$q_u = \frac{37.5}{t_p} = \frac{Q_{pR}}{R\,A}\left[1 + \frac{K_q (t_r - t_d)}{t_p}\right] \qquad (14b)$$

Also,

$$Q_{pR} = \frac{37.5\,R\,A}{t_p + K_q (t_r - t_d)} \qquad (15)$$

In Eqs. 14 and 15, in addition to the notation of the Symposium:

K_t and K_q = factors which vary as functions of $\frac{t_r}{t_d}$;

Q_{pR} = peak rate of discharge for given area for given rainfall excess;

q_u = peak rate of discharge of unit graph, in cubic feet per second per acre;

R = rainfall excess, in inches;

T_p = time, in minutes, from beginning of rainfall excess to peak discharge;

t_p = lag, in minutes;
t_r = length of rainfall excess, in minutes; and
t_d = unit of duration of rainfall excess, in minutes $\left(\text{assumed equal to } \frac{t_p}{5.5}\right)$.

(This notation has, of necessity, been varied from that presented in Mr. Snyder's paper (29).)

Because of the possible wide range in duration of design rainfall, when using the procedure of constant rainfall intensity for critical durations, it was found necessary to change the assumption by Mr. Snyder that $K_q = K_t = \frac{1}{4}$. The addition of the dimensionless unit hydrograph, discussed subsequently, to

determine hydrographs for durations of rainfall in multiples of t_d indicated that K_q and K_t varied as functions of $\frac{t_r}{t_d}$. This relation is shown in Fig. 47.

Values of t_p and q_u shown in Table 15 were obtained for the various runoff occurrences by means of Eqs. 14, and, in turn, were plotted against the effective length of the corresponding drainage areas. From these data, the following relations were determined:

$$t_p = 0.466\ (L\ L_{CA})^{0.3} \qquad (16)$$

or, if L_{CA} is assumed to be $\frac{1}{2}$ L, then:

$$t_p = 0.378\ L^{0.6} \qquad (17a)$$

and

$$q_u = \frac{37.5}{t_p} \qquad (17b)$$

A dimensionless unit hydrograph was adopted (Fig. 47), the peak of which could be determined for any drainage area by Eqs. 17. The length of the recession was assumed to be four times the rising side of the hydrograph or a total hydrograph base length of $5\left(t_p + \frac{t_d}{2}\right)$. With these instruments, several of the hydrographs were reproduced with a resulting degree of agreement which was considered good.

Runoff data obtained by the foregoing method have been incorporated in a reproduction of Fig. 23 for a comparison of results of the two methods, as shown in Fig. 48. For lower values of supply, the synthetic unit hydrograph produces a higher rate of peak discharge, and, also, for peak discharges reduced by any appreciable amount of ponding and with the more common supply values of between 1.0 and 2.0, the required drain-inlet capacity does not vary greatly for either method. However, because of the inherent differences in the basic principles of the unit hydrograph and the theory of overland sheet flow, it would be impossible to achieve complete agreement in the results obtained by both methods for a given area subject to a given rainfall intensity.

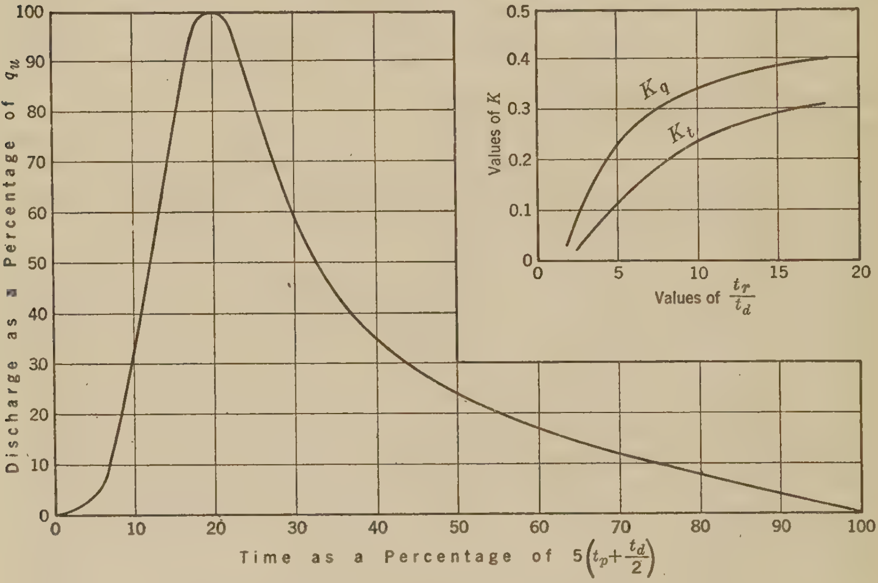

FIG. 47.—DIMENSIONLESS UNIT HYDROGRAPH AND RELATION OF K_q AND K_t TO $\frac{t_r}{t_d}$

For a further comparison of the two methods, the runoff from an assumed turfed airfield area 400 ft wide and 2,000 ft long was computed for a supply of 1-in. volume occurring in 20 min. Runoff from the area was assumed to be collected in a shallow swale with 1.5% transverse slope and 0.5% longitudinal slope along the long axis of the area. To conform with the limits of overland flow suggested by Mr. Hathaway, the area was subdivided into twenty subareas, 200 ft square. The hydrographs for the subareas, determined by Mr. Hathaway's method, were routed through the storage in the swale. It was observed that the resulting hydrograph for the total area was very similar to the synthetic hydrograph, both having a peak of 23 cu ft per sec, but the synthetic hydrograph lagged 6 min. Needless to say, the effort required to route the hydrographs for the subareas through storage greatly exceeds that required to develop the synthetic hydrograph.

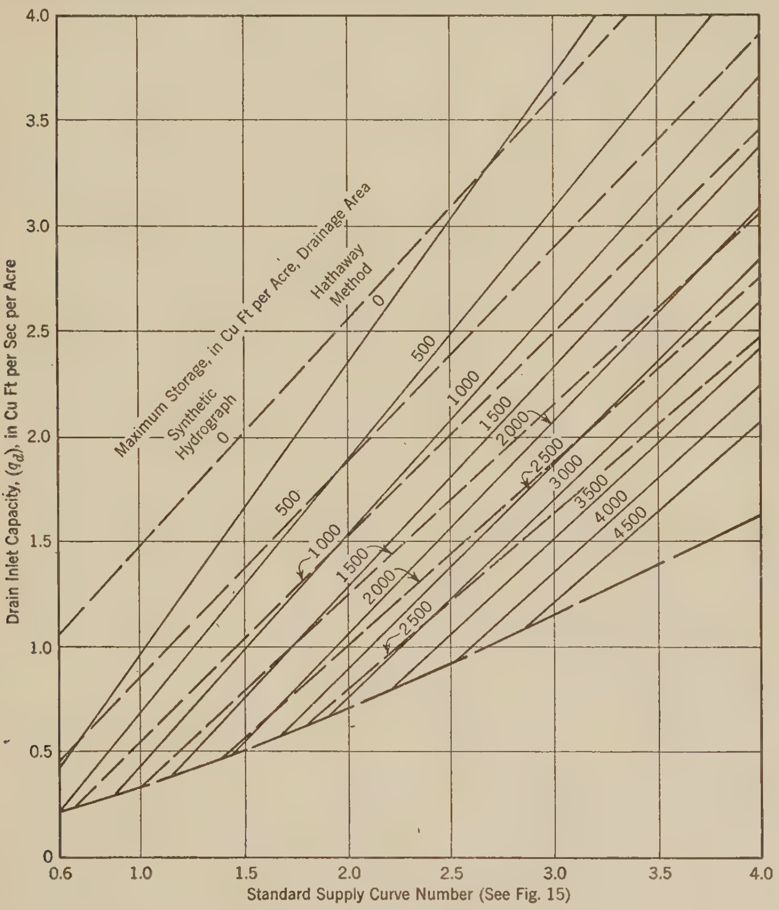

Fig. 48.—Comparison of Required Drain-Inlet Capacity by Mr. Hathaway's Method and by Synthetic Unit Hydrograph ($L = 400$ Ft, $S = 1\%$, and $n = 0.40$)

The records on which to base a unit hydrograph study of this nature are somewhat limited, but additional records are becoming available rapidly to amend these preliminary investigations. However, the study presented herein indicates a feasible method of extending the design criteria presented by Mr. Hathaway to the determination of runoff from larger airfield drainage areas.

Acknowledgment is made to Mr. Snyder for his helpful comments in connection with these studies and to the U. S. Soil Conservation Service for field data on small watersheds.

Ira B. Mullis,[31] Esq.—This Symposium is one that deserves to be widely read and discussed. Apparently Brigadier-General Stratton has found that the AASHO Method (55) is an inadequate one; otherwise, he would not have modified the method by utilizing a 10-lb rammer dropped from a height of 18 in. in five sets of twenty-five drops each (see heading, "Compaction Tests and Control"). In terms of compactive work applied, this is more than four times that of AASHO Method.

The writer has also found that the AASHO Method (55) is entirely inadequate, except in cases of well-graded sandy clay or other materials of a similar nature. Many failures over a widespread area have been observed where this standard of compaction was followed. Flexible pavements have failed in many cases under rolling operations during construction or later. Of course, the roadbed at the time of failure was wet enough to be plastic. To complete the work over wet spots that had failed, the pavement was removed and later patched when dry. Since patching does not alter the porous condition of the roadbed, other failures follow during wet periods. One project is recalled in which a concrete pavement, built under the general supervision of an ardent advocate of the AASHO Method (55), had settled and broken so that much of it has been raised by means of the mud pump to overcome the depressions.

Although General Stratton states that the service performance of airport pavements under severe operating conditions has been extremely gratifying, he makes no prediction as to final results to be expected except to state that the optimum moisture condition at which the subgrade and base courses are placed does not represent the moisture condition after the passage of time. Data collected by Bert Myers (56) tend to support this statement.

Apparently the water content at the time of compaction has no effect on controlling the future water content, though pore space does have a marked effect as shown by Mr. Myers' data (56*a*). The writer has many data (a considerable part of which has not been published) in support of the statement that limiting the pore space is a means for controlling the water content (57). One reason for the strong resistance of hard pan and consolidated sandy clay to loads and to the penetration of water is its very limited pore space.

Although many hold that certain static or impact forces can be used as standards for forecasting the ability of roadbed materials to resist traffic and weather, the writer knows no data that will support this belief. Indeed, if one should supplement pressure with high-frequency vibration, the method would not constitute an adequate standard of stability, although it might represent the maximum compaction obtainable by any method. Furthermore, work is not a measure of results to be expected; but skill in applying work, and the ease with which certain types of materials are formed, are items that must be considered. In view of this fact, the result obtained in making a roadbed resistant to traffic and water must be the sole standard of quality.

---

[31] Research Engr., Southern Aggregates Corp., Raleigh, N. C.

Fig. 41 is a well-suited illustration of the relations of density, water content, voids, and resistance to force. It shows that resistance to force or penetration decreases uniformly with increase in water content from 2,500 lb to about 1,000 lb at which point resistance to force decreases rapidly. Above the 1,000-lb point the curve shows that the body of soil is rigid, but below this point the soil is plastic. The proportional limit having been passed, near the 1,000-lb point, none of the loads corresponding to the densities and moisture contents of about 121.5 lb per cu ft and 13%, respectively, can be considered safe for the load imposed unless confined.

If the moisture-density curve and the moisture-penetration curve were extended to the left as far as they are to the right, the moisture-penetration curve would begin to drop at a point in excess of 2,500 lb. The cause of the drop of the curve at this point would be due to an increase of air content. As the density of the mass and its water content are lowered, the air content increases and thereby changes from a state of rigidity at 2,500 lb to a state of plasticity due to excessive volumes of air.

If the dry weight curve were extended downward to the left to a weight of 100 lb, the voids would be 39.6% on the basis of an assumed specific gravity of 2.65; at 90 lb the voids would be 45.7%; and at 80 lb, 51.7% with little resistance to loads or the penetration of water. Consequently, the penetration resistance curve on the dry side (left) would decrease in a manner similar to the wet side of the curve.

Although engineers are aware of the softening effect of water on roadbeds, few seem to realize that rutting or plastic flow does not start until a certain amount of water is absorbed. Of course a small amount of water in pore spaces is desirable at all times, but when a critical amount is absorbed the material is plastic, as shown by Fig. 41 where a less than 2% increase of water changes the resistance from 850 lb to 475 lb. Fig. 42 shows a similar critical change near the 750-lb point.

Elsewhere, the writer (58) has presented many data concerning this critical change, which he had previously indicated in 1938 (57). Inasmuch as the presence of a critical amount of water in a clay body produces a sharp and definite change in its structural properties it conforms to Hooke's law and must be so regarded. On the one hand, a consolidated body of dry or moist clay that is overstressed fails by rupturing, but one that is critically wet fails through plastic distortion. That which marks the boundary between the rigid and plastic states is rupture, a property universally recognized by physicists. It would seem, therefore, that bodies of earthy sediment containing critical amounts of air or water, or both, should be expected to fail even under light loads.

The method of guarding against this form of weakness is discussed elsewhere (57)(58).

C. F. Izzard,[32] Assoc. M. Am. Soc. C. E.—A comparison of actual runoff hydrographs resulting from simulated rainfall with theoretical hydrographs computed by Eq. 5 for two types of surface—smooth pavement and dense turf—is contained in this discussion. The supporting data are taken from a cooperative project for which the Soil Conservation Service of the U. S. Department of Agriculture performed the experiments and the Public Roads Administration of the Federal Works Agency directed the project and analyzed the results. The equipment used and the method of performing tests are described in detail elsewhere (59). Fig. 49 shows the equipment in operation.

---

[32] Senior Highway Engr., Public Roads Administration, Washington, D. C.

The "paved surface" was actually an asphaltic roofing paper with crushed slate particles on the surface, laid on a wooden platform covered with an asphaltic mastic. The surface conformed closely to a true plane, probably more accurately than the average surfaced runway. The turf surface was obtained by placing a dense bluegrass sod upon the paved surface. The soil was about 1.5 in. thick. Movement of water beneath the soil was checked by transverse wooden strips. Tests were made with the soil in a saturated condition so that infiltration was almost negligible.

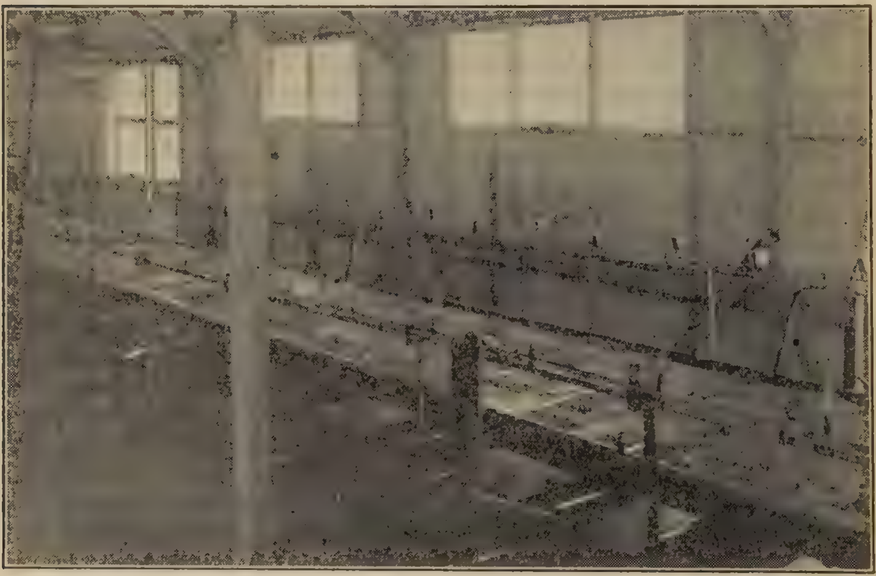

Fig. 49.—Rainfall Simulator in Operation on Bluegrass Turf Plot, 72 Ft Long; Rainfall Intensity, 3.81 In. per Hr; Slope of Plot, 1%; Runoff Rate Approaching Equilibrium

A typical hydrograph with paved surface on a 1% grade is shown as a solid line in Fig. 50. The rain began at zero minutes and continued beyond the time at which equilibrium was reached. The dashed line shows the theoretical hydrograph computed by Eq. 5 for the indicated rainfall intensity, length of overland flow, and slope, with $n = 0.02$ as recommended by Mr. Hathaway for smooth pavement. The dotted line shows the best fit obtainable with Eq. 5 by shifting the time axis and adjusting the value of n so as to fit the slope of the hydrograph at one third the maximum runoff intensity, which is the point of inflection on the theoretical curve. The time shift in this case was 0.52 min as shown in Fig. 50, and the adjusted value of n was 0.00603.

The average percentage deviation of the unadjusted computed hydrograph from the actual hydrograph was 18%, based on ordinates at 1-min intervals excluding the first minute. The average percentage deviation of the adjusted computed hydrograph from the actual hydrograph was only 1%.

Similar comparisons were made for typical runs at 3.6 in. per hr and 1.8 in. per hr on lengths of 12 ft, 24 ft, and 48 ft, and for 72-ft plots on slopes of 2% and 4%. Results were similar to those in Fig. 50, although the adjusted computed curve shown in this figure fitted better than any of the others. In all cases it was necessary to shift the computed hydrograph on the time axis and to change the value of n from the recommended value of 0.02 in order to obtain a reasonably good fit. For unadjusted computed hydrographs on 1% slope ($n = 0.02$) the average deviation was about 15%, generally decreasing with decrease in the length of plot. The deviation tended to increase as the slope of the plot increased. The computed hydrographs, adjusted and unadjusted, were always at or below the actual hydrograph, except during the first minute.

The adjusted computed hydrographs on the 1% slope averaged about 5% deviation from the actual hydrograph. The deviation appeared greatest for the 24-ft and 48-ft plots, and increased as the slope of the plot increased. The adjusted values of n varied from 0.005 to 0.010. The shift in the time axis to bring the adjusted hydrograph into position with the actual hydrograph at the one-third point ranged from 0.3 min to 0.8 min.

The average percentage deviation for both adjusted and unadjusted computed hydrographs as compared to the actual hydrograph was generally greater for the 1.8 in. per hr rainfall intensity than for the 3.6 in. per hr rainfall intensity.

For the turf plot the computed hydrograph shown in Fig. 51, based on the recommended value of $n = 0.80$ for dense turf at a rainfall rate of 3.81 in. per hr, deviated from the actual hydrograph by about 16%. The adjusted computed hydrograph deviated about 6%. The latter deviation was about the same for the other lengths of plot at the same rainfall intensity and occurred principally in the upper half of the hydrograph. The tendency for the actual hydrograph to differ from the theoretical curve was common to all turf runs and was observed in runs made under actual field conditions.

The unadjusted computed hydrograph for the 1.83 in. per hr rate of rainfall, on a 72-ft plot sloping 1%, deviated 39% from the actual hydrograph. The adjusted computed hydrograph for this case, with $n = 0.429$ and a time shift to the right of 1.33 min, deviated less than 2% on the average from the actual hydrograph.

The data so far available do not justify changes in the values of n recommended by Mr. Hathaway or the introduction of an arbitrary time displacement.

The tests here reported did not extend beyond a 3.8 in. per hr rainfall intensity on a 72-ft plot. Within this range the evidence is fairly conclusive (60) that discharge on both paved and turf surfaces is proportional to the third power of the depth instead of the second power, as indicated by the exponent

$M = 2$ in Eq. 5. When one attempts to use $M = 3$ in Eq. 4, the turbulence factor I becomes zero, and the factor K in Eq. 3 becomes infinite. Furthermore, the general formula, Eq. 2, was derived by Mr. Horton using an assumed value of $M = 2$ for which the integration of his differential equation resulted in the hyperbolic tangent function. For $M = 3$, integration results in a more complex function; and for other than whole-number values of M, integration becomes almost impossible. Mr. Horton states (18) that the equation here referred to as Eq. 2 is only quasi-rational for values of M other than 2.

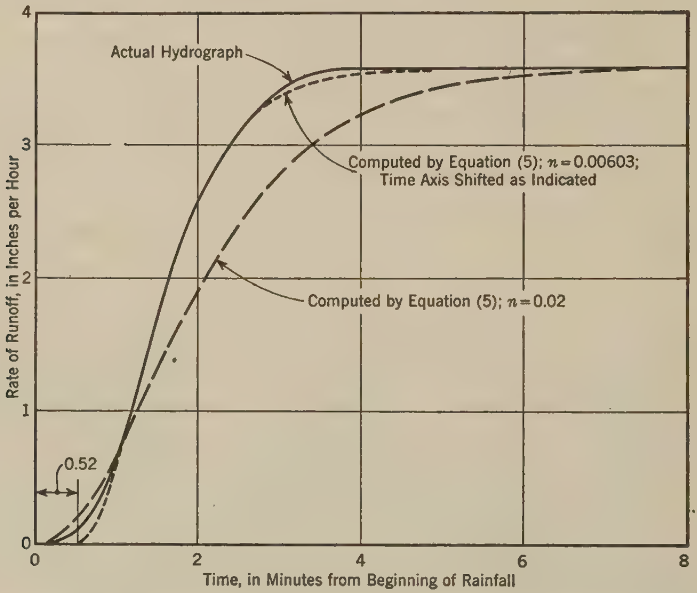

FIG. 50.—ACTUAL AND COMPUTED HYDROGRAPHS FOR PAVED SURFACE (LENGTH OF PLOT, 72 FT; SLOPE, 1%; AND RATE OF RAINFALL, 3.57 IN. PER HR)

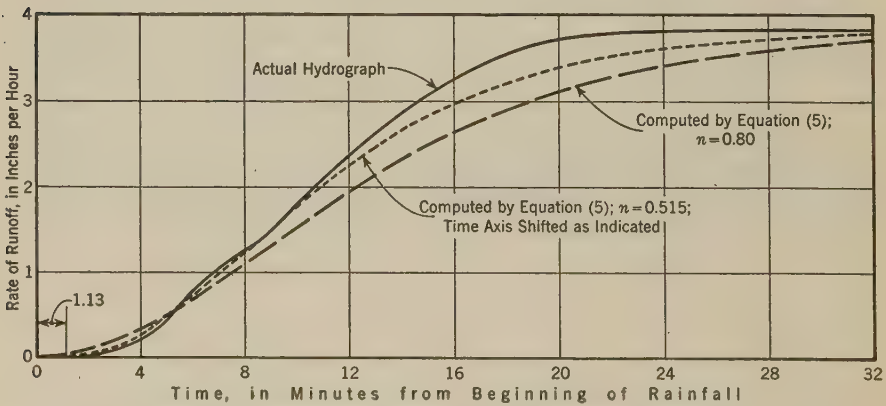

FIG. 51.—ACTUAL AND COMPUTED HYDROGRAPHS FOR TURF SURFACE (LENGTH OF PLOT, 72 FT; SLOPE, 1%; AND RATE OF RAINFALL, 3.81 IN. PER HR)

It is doubtful that the viscous flow condition, which apparently exists within the range covered by the tests reported herein, continues to exist for greater rates of discharge. A limited series of tests performed on the paved surface by admitting water at the upper end only (60) indicates that, for overland flow undisturbed by rainfall, the viscous type of flow terminates at about R = 2,000 (Reynolds' number) corresponding roughly to runoff at 4 in. per hr from a 72-ft plot. Beyond that range the data are inconclusive and incomplete; but, since flow in pipes becomes fully turbulent beyond R = 2,500 ±, it appears reasonable to assume that overland flow would also become fully turbulent in the same range.

Consequently, from a scientific viewpoint, it appears likely that, with rainfall at 4 in. per hr, discharge is proportional to the cube of the depth up to length of overland flow approaching about 80 ft, and becomes turbulent, with discharge proportional to depth to the five-thirds power for greater lengths. Further experiments are needed to establish what actually happens.

The concept of the factor of turbulence I, as used in Eq. 4, appears open to question although it is probable that Eq. 5 gives a rough approximation of actual hydrographs on lengths of overland flow exceeding 100 ft. There is some doubt in the writer's mind as to whether elaborate developments based on this equation are warranted, although it must be admitted that nothing better exists at the present time.

L. J. Mensch,[33] M. Am. Soc. C. E.—The student of highway and airfield pavements will gain much information from this excellent Symposium, especially if he compares the data presented by Brigadier-General Stratton with the specifications for concrete pavements available in the 1930's. This discussion will be confined mainly to the joint spacing and design of joints, as illustrated in Fig. 2.

In most cases longitudinal expansion joints may be dispensed with even in airfields 300 ft wide. Concrete pavements expand lengthwise from two causes—moisture variation and increase in temperature. The Arlington (Va.) tests of the Bureau of Public Roads (5*a*) show that, due to moisture variation alone, concrete pavements lengthen 0.0003 in. per in. in 4.5 years after construction. It is probable that the expansion may be as much as 0.0005 in. per in. after 10 years. The expansion due to an increase in the temperature of the slab depends on the difference between the temperature at which the concrete has set and the average temperature of the slab (between top and bottom surface) when the sun is shining on the pavement in June or July.

If this interval is 50° F, for example, the expansion from this interval will be approximately 0.00025 in. per in., or a total expansion of 0.0005 + 0.00025 = 0.00075 in. per in.; that is, 1.35 in. at each side shoulder in a pavement 300 ft wide. The shoulders will yield, and the only considerable resistance comes from the friction of the ground and the weight of the slab. Assume the slab to be 12 in. thick, weighing 150 lb per sq ft, and the coefficient of friction to be 2 (5). The total resistance in a slab 12 in. wide, 150 ft long, and 12 in. thick will then be 150 × 2 × 150 = 45,000 lb. This force divided by the section of the slab, 12 in. × 12 in., gives about 300 lb per sq in. as the maximum stress in the center line of the 300-ft-wide airfield. Such a compression helps the concrete as it diminishes any tensile stresses that may occur. Because of the time loading, it would shorten a pavement 150 ft long about 0.2 in. when the modulus of elasticity is assumed as 1.33×10^6, leaving a net increase in width at each shoulder of about 1.13 in. A drop in temperature of 100° F will shorten the 150-ft length about 0.0004 in. per in., or 0.72 in. This is expected to be distributed among the ten to fifteen longitudinal joints, so that there is a gap at each joint of from 0.048 in. to 0.072 in. Of course, if the dowels are not properly held in place, absolutely parallel to the direction of the movement (for example, if they should depart from the parallel as much as 1 in. in 16 in.), the dowels may freeze this movement in the joints and concentrate it in one joint. On the other hand, they may cause a longitudinal crack or at least a high tensile stress of the order of 300 lb per sq in. near the center of the pavement. When the designer has no confidence in the kind of load-transfer device he specifies or in the kind of workmanship he may obtain and when he fears that the dowels will not be parallel, then he is quite justified in providing a longitudinal expansion joint such as that shown in Fig. 2.

---

[33] Civ. Engr. and Contr., Chicago, Ill.

The size of the pavement slabs between the various longitudinal and transverse joints is shown in Fig. 2 to vary between 10 ft by 12.5 ft and 15 ft by 25 ft. It is generally believed that this size should be limited by the stresses generated by moisture and temperature variation. Another important point has been overlooked by General Stratton, however. The individual slabs are subject to rocking and vibration due to the heavy concentrated wheel loads at the edges and ends. These wheel loads must be resisted by the weight of the slab acting with a moment arm from its center of gravity to the part of the subgrade so located as to relieve the weight of the wheel load and its shock. Well-doweled joints will reduce this rocking greatly, and, therefore, dummy joints without dowels have no place in airfields. It is well known (5) that the greatest stresses occur at the ends and edges of a slab, and this is another important reason that joints in airfield pavements should always have load-transfer devices. No reliance can be placed on the interlocking power of concrete aggregate a few years after the pavement is built (5). Hence, the greater the wheel load, the greater will be the size of the individual slab. Possibly a size of 12.5 ft by 18 ft should be a minimum.

The fear that pavements may be injured by irregular cracking, due to warping from moisture and temperature variation, when the individual slabs are 10 ft by 25 ft or larger is based on the absence of an accepted theory concerning such actions and, of course, on everyday experience. In desperation some engineers have advocated slabs 10 ft by 10 ft which are entirely unsuitable for airfields. Slabs 25 ft long crack mostly because of faulty load-transfer devices, unequal frost heaving of poor subgrades, or excessive wheel loads.

Approximate Theory of Stresses Produced by Warping.—Temperature warping has been investigated thoroughly by engineers of the Bureau of Public Roads (5*b*), who found that the highest temperature differential, Δ, between top and bottom surfaces occurs in the spring and early summer when the sun is shining on the slab. This value, in degrees Fahrenheit, is given approximately by

$$\Delta = 3.75\, d \quad \text{(18)}$$

in which d is the depth of the slab in inches, corresponding to a unit differential in the length of these surfaces of

$$\delta = 3.75 \times d \times 0.0000048 \doteq 0.000018\, d \quad \text{(19)}$$

For example, a temperature differential of 33° F was found for a 9-in. slab. A weightless slab would deform into the shape of a sphere of radius $r = \frac{d}{\delta} = \frac{d}{0.000018\, d} = 55{,}555$ in. The Bureau of Public Roads measured the warping of a 9-in. slab, 20 ft long, at a temperature interval of 23° F. The radius in this case would be $r = 55{,}555 \times \frac{33}{23} = 79{,}700$ in. To simplify the calculation and at the same time to arrive at safe and acceptable results, assume that the warped surface is a cylinder with its axis along the transverse center line of the slab, thus forming the arch ACB (Fig. 52(a)). The rise of this arch may be found by the well-known formula,

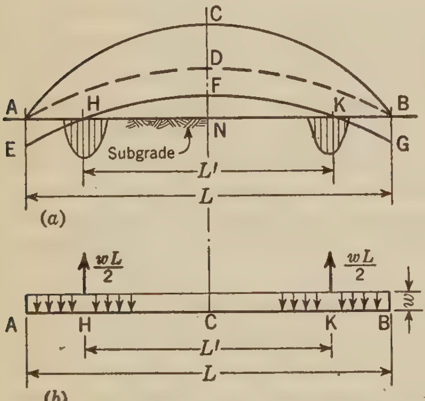

FIG. 52

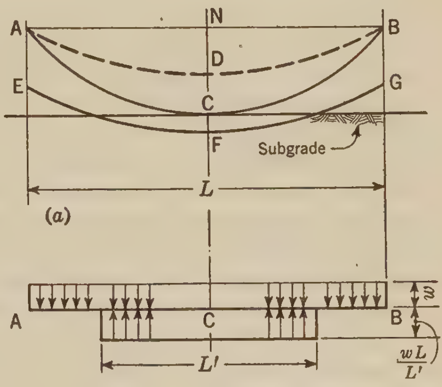

FIG. 53

$$f = \frac{L^2}{8\, r} = \frac{240^2}{8} \times 79{,}700 = 0.09 \text{ in.} \quad \text{(20)}$$

Under its own weight, however, the arch will become embedded in the subgrade near ends A and B, somewhat as shown by line EFG, depending on the soil modulus, the condition of the subgrade near the ends, and the moisture warping. The line ADB (Fig. 52(a)) has been drawn equidistant from line EFG to compare the deflection of the slab with the ideal condition shown by line ABC. The deflection CD is caused by the loading shown in Fig. 52(b); that is, by a uniform dead load of 113 lb per sq ft acting over the entire span of the arch and by two subgrade reactions (shaded areas) assumed concentrated at points H and K, symmetrical with the center line.

The deflection caused by the uniform dead load is easily found to be: $\frac{w\,L^4}{8 \times 16\,E\,I}$. The deflection of the end in relation to the center point C caused by the load $\frac{w\,L}{2}$ at point H is most easily found by the moment area method: $\frac{w\,L}{2} \times \frac{L'}{2} \times \frac{1}{2} \times \frac{L'}{2}\left(\frac{2}{3} \times \frac{L'}{2} + \frac{\qquad\prime}{2}\right) = \frac{1.688\,w\,L^4}{8 \times 16\,E\,I}$. The difference—$0.688\,\frac{w\,L^4}{8 \times 16\,E\,I}$—gives the deflection CD. Let $L = 240$ in.; $w = \frac{113}{12}$; $L' = 0.75\,L$; $E = 4 \times 10^6$; and $I = 729$. Then the deflection CD = 0.0578 in. The vertical distance between points E and F was measured as 0.035 in. (5*c*). This is equal to DN; and the total rise of the arch, CN = 0.0578 + 0.035 = 0.0928 in., as compared with the 0.09 in. found theoretically from the temperature interval. In other words, agreement between theory and practice is very good. The bending moment at the center of this arch, 1 ft wide, is found to be: $M = \frac{w\,L}{2} \times \left(\frac{L'}{2} - \frac{L}{4}\right) = 33{,}800$ in-lb, leading to a flexural stress of 209 lb per sq in. with tension at the bottom, as compared with a flexural ultimate strength in paving concrete of rarely less than 600 lb per sq in. Furthermore, this stress should be relieved considerably by the action in a transverse direction, which the writer has neglected, and by the continuity of good joints equipped with proper load-transfer devices. The Bureau of Public Roads estimated the largest temperature stress in this slab based on extensometer readings at 350 lb per sq in., but admitted that there might be some reservations concerning the assumed modulus of elasticity. For a differential of 33° F, a similar calculation and an assumption of $L' = 0.8\,L$ would result in a flexural stress of 250 lb per sq in.

Warping due to moisture variation was investigated for the Bureau of Public Roads by W. K. Hatt, M. Am. Soc. C. E. (61). He found the maximum differential change of length between the top and bottom surfaces of a wet subgrade on a dry summer day to be 0.000176 in. per in. in a slab 7 in. thick, in a beam 8 in. thick, and (it may be assumed) also for a 9-in. slab. A weightless slab would deform into a sphere, convex downward (see line ACB, Fig. 53(*a*)), with a radius $r = \frac{9}{0.000176} = 51{,}200$ in. and a rise (line NC) of $\frac{L^2}{8\,r} = 0.14$ in. for $L = 240$ in. Assuming again a cylindrical warping except that the dead load of the cylinder is supported by the subgrade in the middle part of the arch, these upward reactions may be considered to be nearly uniformly distributed on a length $L' = 0.6\,L$ without significant error. The deflection CD of the slab due to its uniform weight of w per square foot and the reactions $\frac{w\,L}{L'}$ per linear foot on the length L' may be found in a manner similar to that described for temperature warping: The deflection due to dead load $= \frac{w L^4}{8 \times 16 E I}$, when $w = \frac{113}{12}$; and the deflection due to the reactions $= \frac{w L}{L'} \times \frac{(L')^2}{8} \times \frac{1}{3} \times \frac{L'}{2} \times \left(\frac{3}{4} \times \frac{L'}{2} + \frac{L - L'}{2} \right) = \frac{0.408\, w L^4}{8 \times 16 E I}$. The deflection CD resulting from time loading $= (1 - 0.408) \frac{w L^4}{8 \times 16 E I} = 0.0982$ in., in which $E = 2 \times 10^6$. The measured vertical rise from the transverse joint edge to the center of the slab can be estimated (5*d*) at less than 0.04 in., giving the rise NC $= 0.0982 + 0.04 = 0.1382$ in. which is practically the same as 0.14 in. computed theoretically from length changes. The maximum bending moment per linear foot of width, $M = \frac{w L}{2} \left(\frac{L - L'}{4} \right) = 26{,}000$ in-lb, leading to a flexural stress of 168 lb per sq in. with tension on top, whereas the maximum stress from temperature variation was found to be 209 lb per sq in. at the bottom. Fortunately these stresses are not additive, except for the small effect of temperature warping at night.

The foregoing speculations seem to indicate that warping stresses increase somewhat less than the square of the length of the individual slabs, and, as the deflections increase with the fourth power of the slab length, soon a stage will be reached where the points D in Figs. 52(*a*) and 53(*a*) will reach the subgrade, which will probably occur in 10-ft-wide slabs when the length is about 25 ft; any increase of length will probably not increase the warping stresses to any extent. Much lower stresses occur in transverse directions at the center, and this fact should be taken into account when it is decided to use reinforcement steel to strengthen the slabs at the bottom. Reinforcing bars are advantageous if placed at the bottom in a longitudinal direction along the edges of the slab and in a transverse direction at the ends. Where top reinforcing is selected, the bars should be of high carbon steel and preferably ⅜ in. in diameter to avoid surface cracking. Such bars have been used by the writer with great success for pavements designed to support heavy trucks. General Stratton has treated the design of load-transfer devices rather meagerly. One gains the impression that he leaves to the discretion of the individual engineer the choice of positive holding devices or resilient fillers for expansion joints. The Bureau of Public Roads has shown (5) that ¾-in. dowel bars are not of much value for heavy loads, even if spaced 12 in. on centers. This has also been found true by the writer (62). It is quite correct to use a greater spacing of dowels for construction joints than for expansion joints, provided that such joints do not become expansion joints (as they have often been observed to become by the writer) while the expansion joints which have been provided become close. The writer has shown that dowels heavier than ¾ in. are needed for heavy wheel loads, especially such as occur on airfield pavements (62) and that it is of the utmost importance that the dowels be held positively, by other means than wire and stake supports, in the correct position parallel to the movement of the pavement. For airfield pavements with 150,000-lb wheel loads, dowels of large pipes or of similar sections will be needed, and the concrete around the dowels will have to be specially reinforced to prevent the edges of the slabs from cracking due to the concentrated bearing pressures exerted by the dowels.

Hibbert Hill,[34] Assoc. M. Am. Soc. C. E.—At the request of Brigadier-General Stratton, who has been assigned to overseas duty, the writer presents the following reply to the discussers of the first paper in the Symposium.

It would appear that the design of airfields constitutes simply the synthesis of known elements into a structure of new form. The problem is a tantalizing one in that respect, for close study shows that many of the elements are also new, although seemingly familiar. It was General Stratton's purpose to reveal this point. The discussions have amply assisted him.

Loads.—Brigadier-General Newman presents a graphic illustration of the magnitude of present large airplane wheel loads, and Mr. Stanton comments in similar vein. Mr. Rudolph asks when and where the limit will be. The answer to this question is not now discernible. It does appear that, if airplane design proceeds on the basis of two main wheels carrying substantially the total load, an economic balance of some kind between cost and value of runways will soon be reached. In one instance, an estimate of cost for a single runway and taxiways, proposed for a future heavy plane, was $7,000,000. Airplane designers can extend the limit of total load, so far as it is governed by paving costs, by spreading the weight on more wheels, as Professor Casagrande suggests. In doing so, it is necessary that soils engineers and pavement engineers be consulted so that there can be a thorough understanding of the effects of tire pressure, footprint area, and wheel spacing. The airplane designer's problem, however, is to minimize the dead weight of landing gear in the interest of pay load. Landing gear for the present heavy planes represents from 10% to 15% of the gross weight which, in terms of tonnage, is a very real consideration—increasingly so as gross weight increases. The solution of this problem is concentration of loads on few wheels, with resultant high pavement costs. It has been suggested by Col. Bartley M. Harloe that the great planes of the future might be compared to ocean liners, not expected to be landed under their own power, but rather to be warped carefully into position by tugs or by aerial equivalents. Under this conception, paved tracks would be substituted for wide runways. Some new thought on the subject is certainly in order. Mr. Rudolph has suggested the possibilities of catapults, and rockets may be used for the same purpose. Both catapults and rockets would project the planes into the air. Similar means for landing them may be found in reversible propellers.

In the same vein, the runway designer should be able to take all possible advantage of the peculiarities of airplane traffic distribution in designing pavements. Mr. Pringle has defined "capacity" and "limited" operation, as used by the Corps of Engineers, to rate pavement strength and life. Mr. Stanton has referred to the reduction in pavement strength permitted by the limited number of repetitions of load on runways.

---

[34] Lt. Col., Corps of Engrs., U. S. Army, Office, Chf. of Engrs., Washington, D.C.

In his general discussion of the Symposium, the writer also points to possible variations in pavement thickness to meet the peculiar distribution of traffic on runways. There appear to be economies in this direction which have not been fully realized.

The reality of high impact loads, as discussed by Mr. Cotton, is not in doubt. The effect of these loads on the pavement, however, is another question. Numerous measurements of pavement deflections, and a number of base and subgrade pressure determinations, have been made under static and moving loads. These measurements, made in the course of accelerated traffic tests, all show a marked reduction in deflection under the moving load, and a marked reduction of subgrade pressure—that is, an apparent spreading of the load—under the moving wheel as compared with the static wheel. These results, coupled with the fact that no airfield pavement failures attributable to impact have been observed, have led the Corps of Engineers to conclude that allowance for landing impact stresses in the pavement design is not warranted.

Site and Layout.—It is unfortunately true, as Professor Haswell has noted, that soil and drainage seem often to be the last considerations in site selection. The swamp and power line criterion mentioned by General Newman may not actually be contained in site selection instructions, but the combination has occurred too often to be comfortable. Exigencies such as those discussed by Lieutenant-Colonel Schneider, or the need for a location within given boundaries, often force selections which are not the best. However, the economies to be realized, in initial construction as well as in maintenance, from good site selections are startling. The cost of the aforementioned runway—an estimated $7,000,000—became less than $1,000,000 when the location was changed to one having a suitable soil. In the case of military airfields, and particularly in the case of airfields for very heavy planes, sites can be sought over a wide area. An additional 100-mile flight is a bagatelle for such planes, whereas the savings of time in construction and in construction and maintenance costs, resulting from a choice location, are decisive. There is also the possibility of improved atmospheric conditions and, hence, of improved flying conditions, which may be gained from the selection of sites within a wide area.

General Newman has given a number of layout criteria for military airfields. The criteria he gives are for training fields. Under operational conditions, with trained pilots, these standards may be reduced. These criteria are not fixed. They are being studied in the light of past experience and in the light of the requirements of the newest planes. They will no doubt be continually revised as airplanes change and experience accumulates. The entire question of requirements for airfield sites and layouts appears to offer a fruitful field for continuous study.

Drainage.—The numerous comments on the critical importance of adequate drainage serve to emphasize a subject which General Stratton in no way meant to minimize. Captain Parmer cites a number of considerations of perhaps controlling interest, which indicate some of the difficulties of the subject. Mr. Feld states that pavements are not impervious at joints and cracks and that, as a consequence, positive subsurface drainage is necessary. Such drainage is automatic if base and subgrade are permeable. If base and subgrade are not permeable (the usual case), the damage is done before any feasible method of subsurface drainage becomes effective. Either the pavement must be designed to carry the load under the worst conditions, or it must be kept properly sealed. The latter is a feasible course. Mr. Greulich fears that moisture accumulation makes guesswork of plate bearing data and California bearing ratio (CBR) test information. The designs of the Corps of Engineers are based on the important assumption that base and subgrade will become saturated by capillary action and condensation which cannot be controlled by drainage. The validity of this assumption is proved in general by available data, although a serious doubt remains as to whether saturation occurs in arid and semiarid regions. In this respect, Mr. Murray makes a very interesting comment on the entire absence of any moisture accumulation under conditions in Australia.

In general terms, the function of drainage is to prevent the entrance of moisture into load bearing areas of soil. The removal of rainfall by proper surface drainage thus would be better practice, than, as suggested by Mr. McGuire, the removal of rainfall, as filtered water, by subsurface drains.

Mr. Cotton advocates a combined surface and subsurface drain. Experience with such drains has been unfortunate. If the drains are properly constructed to avoid infiltration of the surrounding soil, they quickly clog at the surface and thus become ineffective for removal of surface runoff. When drains are constructed of coarse material, their use has, in numerous cases, resulted in failure of the pavement edge because of infiltration of soil from the subgrade or base course. The drains, under these conditions, also are very likely to clog, with consequent saturation of the subgrade by backwater.

Mr. Cotton's discussion of backfill filters for subdrains is valuable. It should be emphasized that the material in Table 10 represents a maximum size. Finer gradations, containing materials passing the 150-mesh sieve, will be required for silt and clay soils. Filters should be designed to fit the foundation soils at the site. The design of satisfactory filters is discussed in detail in the *Engineering Manual* (23), and Karl Terzaghi, M. Am. Soc. C. E., has also presented a method (63) of design.

Messrs. Cotton, Greulich, Haswell, and Feld have criticized the design of drain shown in Fig. 8(*b*). Professor Haswell's question as to the need for the natural earth backfill beneath the drain is very pertinent. It is no doubt best practice to trench exactly to grade and to lay the pipe on undisturbed soil, thus avoiding tamping beneath the pipe and the excavation required for the fill. The placing of the perforations upward, criticized by Mr. Cotton, is the result of mature consideration. With upward perforations, the hydraulic characteristics of the pipe are believed to be improved; there is not the same opportunity for outward flow in areas where ground water is below the pipe that there is when the holes are downward; and placement of the backfill and filter is facilitated. Specifications require that the filter be designed to fit the local soil conditions, so that the filter material cannot drop through the perforations. If the filter material could drop through the perforations, it could also be pushed through the perforations by hydraulic pressure in Mr. Cotton's design. Mr. Feld raises a very practical point of construction. He is entirely correct for the drain design that he discusses, but he does not consider filled shoulders, which would introduce a somewhat different problem. His remarks also recall the problem of drainage during construction. This problem is intimately related to construction procedures and is of such critical importance that, in the writer's opinion, the necessary procedures should be incorporated in the plans and specifications by the designer, and should not be left to decision in the field under the stress of construction exigencies.

Mr. McGuire expresses a hope that a clear and usable analysis of subsurface drainage requirements, comparable to Mr. Hathaway's analysis of surface drainage, will be prepared, and Mr. Greulich comments in similar vein. The writer, unfortunately, can only echo the hope. Such an analysis is greatly needed. A beginning has been made in the *Engineering Manual* (23), on the basis of available information, and revisions of the *Engineering Manual* will be made as knowledge accumulates.

Base and Subgrade Requirements.—Specifications for base and subgrade materials are intimately concerned with moisture and drainage, as Mr. Cotton notes. Mr. Cotton's remarks on the value of pervious materials from this standpoint are reinforced by the information given by Messrs. Casagrande and Parmer on the strength and compaction of such materials. Field experience is rapidly accumulating to show that a wide variety of granular materials can be compacted satisfactorily and that when so compacted these materials form very strong bases, relatively or entirely free from moisture troubles. These properties are especially important in the foundations of runways to carry the very heavy planes. Such loads create important soil stresses to depths as great as 5 ft below the surface of flexible pavements and will cause consolidation to such depths, as well as high shearing stresses at somewhat lesser depths. Recent field experience indicates that sands not fully compacted will compact under traffic without shear failure and that moisture content is not critical. On the other hand, tests (unpublished) by staff members of the Flexible Pavement Laboratory, U. S. Waterways Experiment Station, Vicksburg, Miss., show that the shearing strengths of plastic soils, including those of soils of medium and low plasticity, are very likely to decrease severely upon further compaction under traffic and that, in such a case, water content is extremely critical. Ideally, of course, any base and subgrade should be initially compacted to at least the ultimate density it will acquire under traffic. Allowing for a margin of error, however, and in view of the great wheel loads involved, the use of granular base and subgrade materials provides a comforting factor of safety.

Mr. Mullis' remarks on the inadequacy of the standard AASHO test are certainly correct, for these conditions. The modified test used by the Corps of Engineers results in a much greater density than does the standard test. It was found in tests at Barksdale Field, La., with a 50,000-lb wheel load, that compaction of from 103% to 105% of modified AASHO density was required in the 17 in. of base material (to 20 in. below the pavement surface); the compaction requirements then decreased with depth to 90% of modified AASHO density in the subgrade at a depth of 53 in. below pavement surface.

It appears beyond question that the high densities and deep compaction required by airports will necessitate the development of new equipment for this purpose, including the vibratory equipment foreseen by Professor Casagrande.

The subject of frost effects, briefly discussed by Messrs. Casagrande, Feld, and Parmer, is most important. The reasonably satisfactory treatments that have been developed in highway practice require reexamination and refinement in the light of the deep and expensive base construction required for airfield loads. In this respect, again, the value of clean granular base courses, not subject to frost effects, is reiterated. The possibilities of such insulating materials as Professor Casagrande mentions, and the possible advantage that can be taken of relative heat transmission coefficients, as noted by Mr. Feld, are appreciated. In the past, reliance has been placed on natural granular materials—in large part because these materials have been available and furthermore because of a lack of information on the behavior of other materials. Curiously enough, in areas of permanently frozen ground mentioned by Professor Casagrande, the principal problem is most often one of avoiding interference with the natural ground-water regimen rather than one of maintaining a permanently frozen subsoil. For this purpose very coarse granular materials are best.

Construction Practices.—The discussion by Mr. Pittman emphasizes the fact that design and construction practices must be coordinated to obtain a satisfactory job. He and Mr. Feld agree that successive lane construction of concrete pavements is the best practice. In the writer's opinion, this method of construction is essential for good results, unless someone could guarantee that there would be no rain! The writer also agrees that the usual loss of bearing power under thickened edges, resulting from excavation of the compacted base material, is likely to offset the value of the thickened edge, as noted by Messrs. Feld and Parmer. The same excavation traps rain water during construction, thus also contributing to the loss of bearing. For these reasons, the Corps of Engineers has eliminated the thickened edge as standard practice, except at exterior edges and at the longitudinal expansion joint at the center of the runway. Emphasis has been placed on obtaining compaction and base support under these edges equal to the design assumptions.

Mr. Pittman calls attention to a very troublesome design feature found in those cases where the pavement is below ground level at the shoulders. Thus, subgrade and pavement have to be constructed in a broad shallow trench. If the soil is not pervious, this situation results in drainage difficulties during construction and quite possibly after construction. In this case, design and construction sequences must each be directed toward providing means of drainage during and after construction. Mr. Pittman gives one solution.

Mr. Pittman's remarks on winter construction arise from extensive experience. It is no doubt correct that concrete pavements can be constructed under conditions that would make construction of flexible pavements impossible. The writer believes, however, that, unless the need is pressing, as it has been during World War II, airfield construction should not be undertaken in seasons of unfavorable weather. In the case of such construction, extremely conscientious attention must be given to the quality of work, and delays must be accepted, to obtain desired results. Thus, an almost impossible burden is placed on contractors and inspectors. It may be remarked, also, that one disadvantage of concrete is that it can be placed on an unsatisfactory base, to look well on the surface but in fact to have nowhere near the load supporting value contemplated in the design. The base for flexible pavement must have strength enough, at least, to permit rolling of the pavement surface!

Mr. Proctor advocates compacting the soil to about a foot above grade, then trimming this foot off to reveal a fully compacted surface. In the last analysis, the question of how to obtain the desired compaction at the surface is an economic one. Subgrade planers are used to advantage to remove the top inch or so, in both highway and runway construction. However, it is the writer's opinion that the removal of 12 in., as proposed by Mr. Proctor, is not essential and is not economical. Mr. Proctor's remarks on the use of the sheepsfoot roller, and on emergency construction procedure, are very interesting, and grow out of long experience. These remarks center around the use of an "available" roller. To obtain the high compaction necessary in airfields for heavy planes, it will be necessary to specify the use of particular rollers, although admittedly the characteristics of those rollers are not yet fully determined.

The use of membrane curing for concrete pavements is permitted by specifications of the Corps of Engineers. These specifications require moisture retaining ability as determined by an established test procedure. This method of curing has great advantages in ease and speed of application, economy, and negligible maintenance cost. The material has no insulating or cooling properties, and it may be, as Mr. Pittman states, that its use in hot weather will permit dangerous thermal stresses in the concrete to occur, especially if the material is of dark color. Mr. Pittman's statement, however, is the first to that effect which has come to the writer's attention, and the writer has been unable to find any case in which damage to the concrete can be ascribed to such thermal stresses.

Design.—Messrs. Turnbull and Jervis, and Hansen have presented interesting background material on the development of the CBR method and on the method of accelerated traffic testing. Their statements with respect to the findings of these investigations are just sufficient to whet the reader's interest, but by no means to satisfy it. In continuation of their remarks, it may be stated that, since Mr. Hansen's discussion was written (September, 1944), the Barksdale tests have been made available to a limited distribution (64).

The application of the formulas introduced by H. M. Westergaard, M. Am. Soc. C. E., to design of pavements on marshy ground is questioned by Mr. Horonjeff. His doubt, it appears to the writer, is not in fact directed at the formulas but rather at the method of determining K which is used by the Corps of Engineers. In the writer's opinion, Mr. Horonjeff's question is justified. The plate bearing test for the determination of K has little to recommend it except that no other method is available and except that, within the usual range of subgrade soils, it gives results which are reasonably consistent with experience. There is no present method for extending this experience to soils such as Mr. Horonjeff describes. On such soils, the plate bearing test will give indeterminate results; yet such soils do have supporting values under rigid slabs.

Professor Casagrande's remarks on the difficulties of a theoretical approach to the design of flexible pavements are illuminating. In spite of these difficulties, engineers will not rest until such an approach has been accomplished. Present studies by the Corps of Engineers are aimed at computing the soil stresses, and specifying the necessary treatment of soils and bases to resist these stresses. The accomplishment of this goal is an indefinite distance in the future. Until that time, refinement of the CBR and similar empirical methods will not be neglected.

Messrs. Casagrande and Horonjeff both discuss the problem of load transfer between rigid slabs under heavy wheel loads. This problem becomes more pressing as loads and slab thicknesses increase. One absolute requirement for a successful joint is that the joint surely function. In this respect, the writer fears the doweled joints, suggested by Professor Casagrande, in which the dangers of improper installation would be increased by the large number of joints.

In the writer's opinion, there is no such value as an "allowable pavement deflection," on which Professor Burmister hopes to obtain factual information. Considering the pavement alone, the allowable deflection is a function of the curvature, and will be greater the longer the radius of curvature; hence, the allowable deflection will be greater the larger the tire imprint—other factors being equal. Allowable deflection will also vary with the soil and base constants. In the Barksdale tests, initial subgrade deflections, exceeding about 0.1 in. under moving wheel loads of 50,000 lb, increased under succeeding wheel passages to more than 0.2 in., and shear failure occurred. In similar tests with 40,000-lb wheel loads, but on a pavement laid over a fine sand subsoil, no failure occurred although the initial deflections were somewhat greater than at Barksdale. Considerable settlement did occur, however, as the subsoil compacted. In such cases, the differential, rather than the maximum, settlement is important. To the writer's knowledge, no flexible airfield pavement has been overstressed as the result of compaction, unaccompanied by shear failure, under traffic. T. A. Middlebrooks and R. M. Haines, Assoc. Members, Am. Soc. C. E., have presented the results (65) of numerous deflection measurements, and Mr. Stanton also contributes some information.

In Table 13, Professor Burmister introduces a thickness factor which, when applied, permits a good base material to be less thick than a poor one. The CBR method of design is predicated upon the hypothesis that a given total thickness of base and pavement is required over a given subsoil or base and that the total thickness is independent of the quality of the material as long as the material has sufficient strength. This hypothesis is based upon experience, and is definitely proved by the Barksdale and other similar tests. Professor Burmister thus argues erroneously that, because material with a CBR value of 50 is allowed immediately under pavements for light wheel loads, a lesser thickness of material with a CBR value of 80 would be suitable. These minimum CBR values are needed to resist stresses (shear principally) in the base material itself, and do not influence materially the stresses in the underlying soil, so far as available evidence shows. This statement must be limited to the usual base materials. Evidently, in the extreme, it would not apply to concrete.

The general adoption of relative density in place of percentage compaction, as suggested by Professor Burmister, is an end to be desired. It has special virtue in the case of sandy soils, since these soils undergo marked changes of strength in passing from loose to dense states. However, in order to use relative density as a measure, it is necessary to have some standard definition of the end points—that is, of the loose and dense states. Such a definition or test is not available.

Mr. Proctor, raises a number of interesting questions concerning soil compaction in earth dam construction. In reply to one of his first statements, it should be mentioned that methods of compaction and compaction control developed in earth dam practice are the bases for similar operations in pavement construction. It does not follow, however, that criteria which have been successfully applied in earth dam construction will suffice for successful pavement construction. The maximum unit loads found in earth dam construction greatly exceed the unit loads encountered in pavement construction, but this comparison does not consider the size of the loaded areas, the load distribution, or the repeated stresses found in pavement practice. Because of these factors, all present information leads to the conclusion that the permissible soil strain in pavement practice is only a fraction of that required to develop the ultimate strength of the soil under a single loading, and permitted in earth dam practice. It appears, therefore, that, for airfield pavements, relatively higher densities must be obtained than are commonly accepted in earth dam practice. It appears also that, possibly excepting sands, the bases and subgrade must be initially compacted to substantially such a density that no further compaction will occur under traffic. On the basis of the same information, the writer very much doubts Mr. Proctor's interpretation of Fig. 41, although all the information necessary to resolve this doubt is not given in Fig. 41.

To clarify several apparent misapprehensions which appear in Mr. Proctor's discussion, it may be stated, first, that the CBR method is not dependent upon an optimum density. This test evaluates the soil at any density and moisture content. The most desirable values of density have been discussed in previous paragraphs. On the basis of available tests, it appears that the most desirable water content is somewhat on the dry side of optimum for the compactive effort applied.

Secondly, Mr. Proctor very correctly points out the great reduction in strength of soil at 90% compaction, as compared to its strength at 100% compaction. It should be noted that 90% of modified AASHO density is still a rather high density by usual standards, but, more especially, that 90% compaction is allowed by the specifications of the Corps of Engineers only in fill, the top 6 in. of which are required to be compacted to 95% density. The 90%

criterion is not applied to base courses. The present hope is to determine the actual density and compacting moisture content necessary at a given depth, and to specify the values. In the aforementioned Barksdale tests, it was determined that 90% compaction was sufficient at certain depths, 95% was required at an intermediate depth, and from 103% to 105% was needed in the upper base materials.

In the same connection, Mr. Proctor stresses the need for control of moisture content at such a value that subsequent consolidation, from whatever cause, will not build up excess hydrostatic pressures in the soil. This is a very grave possibility in airport practice where the heavy wheel loads may cause consolidation under traffic, and, if such pressures occur, they are fatal to the pavement. This phenomenon was observed in one failure of a test pavement on a silty clay soil.

Messrs. Rudolph and Horonjeff each briefly raise the problem of reinforcing existing pavements to withstand heavier loads than those for which they were originally designed. The problem has already arisen at a considerable number of Army fields. The procedure has been first to evaluate subgrades, bases, and pavements as they actually exist, by field and laboratory tests—and, where applicable, by accelerated traffic tests—then to design the reinforcement. The thickness of flexible pavements is increased in accordance with the CBR requirements. This increase may involve base courses on top of the existing pavement. In such a design, careful consideration must be given to the effects of moisture in the new base; hence, closed crushed stone is preferred for this base. In the case of concrete pavements, the thickness of a slab required for the new and greater load is calculated, and the equivalent two-beam (one beam being the existing slab) thickness is determined. The general practice thus far has been to place a leveling course of sand asphalt, where necessary, or a thin bituminous bond breaking course, between the old and new slabs. This is done to relieve temperature stresses in the upper slab, but principally to avoid irregular bearing of the upper slab following movements resulting from temperature effects.

Present limited experience with such designs is satisfactory. When pavements are thus thickened, original grades and drainage may be so disturbed that the required changes in these elements result in an uneconomical over-all design. It may then be necessary to remove and reconstruct a part of the existing pavements to meet grades at buildings and drainage structures.

In conclusion, it is evident from the discussions, and from General Stratton's paper, that, although much progress has been made toward the rational and exact design of airfield pavements, many questions are at present unanswered, and much remains to be done. Mr. Pringle has outlined a program of periodic condition surveys, and other discussers have mentioned the need for correlation of test and laboratory results with field experience. A number of organizations are working on these problems. The Corps of Engineers has established three laboratories to work continuously on the correlation of field and laboratory experience and on the extension of knowledge through field testing. These laboratories are the Flexible Pavement Laboratory at Vicksburg, Miss., the Rigid Pavement Laboratory at Cincinnati, Ohio, and the Frost Effects Laboratory at Boston, Mass.

Gail A. Hathaway,[35] M. Am. Soc. C. E.—The comments and suggestions on drainage facilities contained in the discussions of the Symposium are appreciated. Several valuable modifications in procedure have been suggested, and recognized deficiencies in the method have been indicated.

Professor Howland presents a mathematical method for the determination of a runoff hydrograph for a rain of limited duration and compares the hydrograph so obtained with hydrograph No. 2, Fig. 18. The rising limb of hydrograph No. 2, Fig. 18, was computed by the general equation (Eq. 2) developed by Mr. Horton and utilized by Professor Howland, whereas the crest shape and recession limb of the hydrograph were derived from the curve of overland flow rates by utilizing the unit hydrograph procedure. The unit hydrograph method is recognized as an empirical procedure based on the analysis of actual runoff data. However, the writer has found that the method gives excellent results for small areas when reliable and accurate basic information is available. The limitations of the equation developed by Mr. Horton for lengths of flow greater than 600 ft are recognized, and alternate procedures are contained in Mr. Williams' discussion. In that connection, a few test runs by Mr. Izzard on the bluegrass turf strip, in which instance rainfall was stopped before equilibrium was reached, would have furnished valuable information on the shape of the crest and recession limb of the hydrograph. Professor Howland's contribution outlines problems as yet unsolved and emphasizes the need for actual runoff data from airfields.

The writer agrees with Mr. Jenkins' statement stressing the need for, and the practical value of, a table showing the range of infiltration capacities for different soils and soil covers. The data on infiltration capacities as shown in Tables 6 and 7, and in Mr. Jenkins' accompanying discussion, are very informative and valuable for design purposes. More information of a similar nature in the files of the Department of Agriculture should be made available to the engineering profession. Mr. Jenkins states that airfield turf is generally not well established until about the end of the first year, and in many cases not for two years, following completion of grading. It has been the writer's observation that many fields do not have a grass cover at the end of the third growing season although every effort has been made to secure a good turf. The points raised by Mr. Jenkins on the applicability of the unit hydrograph theory to the determination of runoff from graded airfield slopes 500 ft or 600 ft long have been covered to some extent by Mr. Williams.

With reference to Mr. Jenkins' comments on the relation of airfield grading requirements to drainage, it is gratifying to note that the importance and necessity of good drainage have resulted in modifications and improvements of grading criteria for Army airfields. The transverse slopes of runway shoulders and graded areas have been increased to 2%. Along the drain line, normally 250 ft from the runway center line, a 2% longitudinal grade is permitted with a maximum change in grade of 3%. In addition, where the foregoing criteria will not permit development of ponding areas, it is permissible to provide a small transverse ridge at least 100 ft downstream from the inlet, with the crest not more than 0.5 ft above the inlet.

---

[35] Head Engr., Corps of Engrs., Office, Chf. of Engrs., Washington, D. C.

Mr. Jenkins suggests that the method of maintaining the hydraulic grade line near the top of the drain pipe be clarified. The design assumptions are based on a controlled outflow from each ponding basin. He also discusses the formula used by the Civil Aeronautics Administration (see Eq. 9). The utilization of this formula in the determination of runoff from airfield areas is questionable. For example, T (the duration of rainfall) is assumed to be 1 hour. The use of a value of 1 hour for T with no consideration for varying times of concentration, particularly for apron and runway design, is obviously incorrect as the computed runoff will be inadequate for numerous high intensity storms of short duration but with a frequency less than that of the design storm. The quantity t in Eq. 9 (time allowed for removal of rainfall after the end of the storm) assumed to be 2 hours is actually a storage correction; and, in many cases, the storage is not available. It has been observed that the apparent simplicity and ease of using Eq. 9, with T equal to 1 hour and t equal to 2 hours, have led to numerous cases in which storage reductions are assumed without the required storage being available or even being considered. Mr. Jenkins' thorough discussion covers several points not touched by the writer and clarifies and expands others in the paper.

The comments of Mr. Irwin on the need for infiltration data and the results of his experience with clogging are timely and informative. Much work remains to be done in obtaining accurate field data on roughness coefficients for varying types and degrees of grass cover. In that connection, the tests conducted by Mr. Izzard are of inestimable value.

It is of interest to note that Mr. Jenkins' computations for a typical layout using the modified rational method (Eq. 9) give runoff values considerably lower than those obtained by the procedures described by the writer, whereas the example presented by Mr. Irwin gives somewhat higher runoff values. The writer concurs in Mr. Irwin's statement that a careful study of critical rainfall distribution deserves investigation to determine critical conditions for the area under consideration.

Mr. Greulich and Mr. McGuire stress the great need for a type of analysis that can be utilized in the design and efficient adaptation of subdrainage pipe. More data are needed on this phase of airfield drainage, and every effort should be made to conduct field tests supplemented by the necessary laboratory research to provide a satisfactory method for rational design of subsurface drainage systems. It is desirable to maintain a low ground-water table in the airfield area, and lowering the ground-water table can be facilitated by providing proper surface drainage.

The theoretical purpose of the "surface intercepting drain" or modified "French drain" (namely, to intercept the surface water without changing the uniform sheet flow to a piled-up flow) is a good one; but unfortunately the intercepting drains fail to function, in many instances, under practical operating conditions. Not only do the surface intercepting drains become silted by fines but, in most instances, the assumed collecting capacity is in excess of the quantity of water that is intercepted by the drain. Instances have been recorded in which the pavement base-course material has moved into this type of drain, resulting in the subsidence and failure of the outer lanes of the runway. The suggested combined catch basin and intercepting drain for turfed valleys in Fig. 39 may have considerable merit for ponding areas, provided the intercepting drain does not permit water to have access to the foundation of the runway or apron pavement.

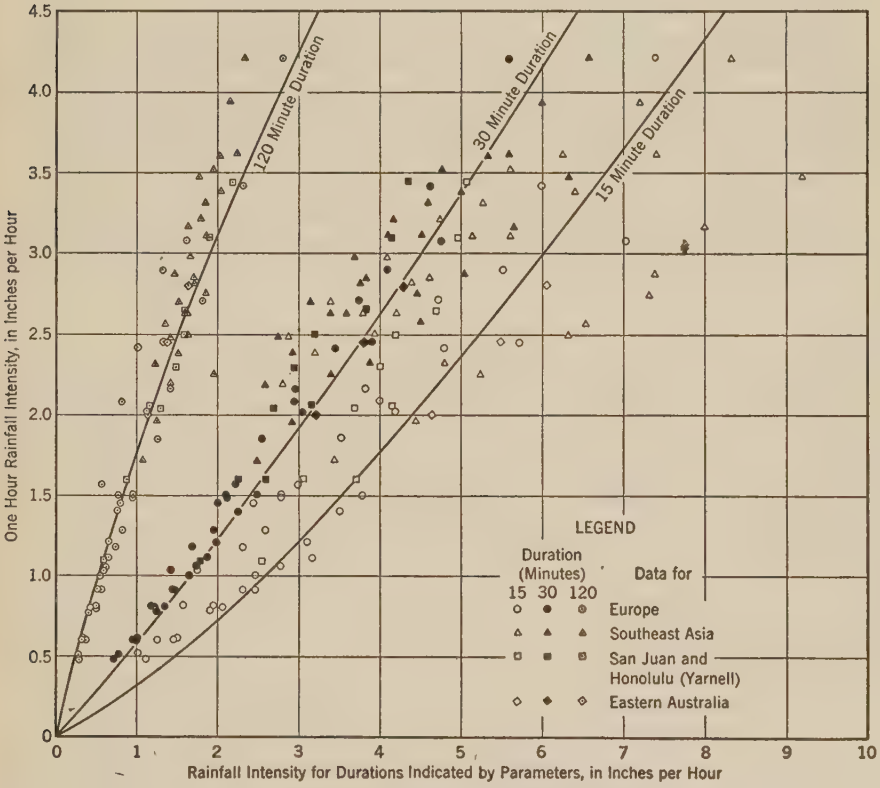

FIG. 54.—RELATION OF 1-HR RAINFALL INTENSITIES TO INTENSITIES FOR DURATIONS OF 15, 30, AND 120 MIN IN CERTAIN FOREIGN COUNTRIES

The statement by Mr. Murray that intensity curves for rainfall on the eastern coast of Australia conform closely to those in Fig. 15 is especially significant. Subsequent to the preparation of the curves in Fig. 15, rainfall intensity data were obtained for Europe and southeast Asia which conform closely to those for the United States. (Data for eastern Australia were taken from Table 12. In foreign countries, data for durations of 5 min and 240 min are not available.) These data have been plotted in Fig. 54 for comparison with the curves previously developed in Fig. 14 for the United States. In general, the foreign data for short-duration rainfall indicate a lower intensity—a condition which may possibly be attributed to a lack of recording gage records. However, the general agreement of the foregoing data does suggest a possible universal application of the design methods discussed herein.

The discussion by Mr. Williams is a valuable contribution to the paper, and the procedure he suggests will be found useful in extending the design criteria to the determination of runoff from larger airfield areas.

Mr. Izzard's comparison of actual hydrographs resulting from simulated rainfall with the theoretical hydrographs included in the paper provides a valuable check on the accuracy of the runoff computations. Although a shift in the time axis is necessary to bring the adjusted hydrograph into position with the actual hydrograph, the change would not seriously affect the ultimate drain-inlet capacity. Laboratory and field checks along the lines pursued by Mr. Izzard are of inestimable value in arriving at correct design procedures and in establishing confidence in new and better approaches to the solution of rainfall-runoff problems.

FLOOD FORMULAS BASED ON DRAINAGE BASIN CHARACTERISTICS

By H. B. Kinnison,[1] M. Am. Soc. C. E., and B. R. Colby,[2] Esq.

With Discussion by Messrs. Clarence S. Jarvis, L. R. Beard, M. J. Ord, Howard M. Turner, Byron O. McCoy, C. O. Clark, and H. B. Kinnison and B. R. Colby.

Synopsis

The determination of the magnitude and frequency of expected floods has been the subject of constant study by the engineering profession. The systematic collection of stream-flow records in every section of the United States has contributed immeasurably to a knowledge of the subject. The long-time records of precipitation assist in extending the frequency studies beyond the range of stream-flow records. Contributing to this knowledge also have been the disastrous floods since 1927, which in many instances exceeded the maximum expected, based on previous records.

In this paper, flood formulas are developed from stream-flow records of Massachusetts streams, for which fairly complete data are available. The formulas define the magnitude of flood peaks having probable recurrence intervals of 15, 100, and 1,000 years, and the maximum possible flood.

Volumes of runoff per unit area for the different classes of floods except the maximum were computed for streams having the longest stream-flow records, from frequency curves of observed floods and of observed precipitation. The peak discharge of each type of flood was computed for these streams by means of the unit hydrograph. These discharges were then correlated with known physical characteristics of these streams, and general equations were prepared which are applicable to both gaged and ungaged areas.

These formulas are based upon data for drainage basins in and adjacent to Massachusetts and therefore are conceived as applicable only to basins of that state or basins having similar physical and meteorological characteristics. The formulas might assume a different form in the case of drainage basins in other sections of the United States. The primary purpose of the paper is to present

an extensive analysis of flood experience which engineers may embody in their knowledge of floods and utilize with some benefit in problems involving flood magnitudes and frequencies.

INTRODUCTION

Numerous methods of predicting future flood flows have been developed and described in engineering publications. Prior to 1900 these methods were necessarily rather crude, because authentic records of stream flow were scanty and less accurate than later records. Practically all such studies were based on observations of flow in small areas or on single streams, and were usually summarized as formulas giving the expected rate of flow as a function of the drainage area, although some investigators added other variables. These early formulas were usually developed for maximum floods, the meager base data precluding any except the roughest qualitative consideration of frequency.

In 1913, the late Weston E. Fuller,[3] M. Am. Soc. C. E., published the first comprehensive study of statistical methods applied to floods in the United States. He developed a formula introducing the concept of a magnitude-frequency relationship, in this respect following a line of reasoning that was introduced into studies of river flow about the same time by the late Allen Hazen, M. Am. Soc. C. E. Mr. Hazen's application of statistical methods to engineering studies and Mr. Fuller's adaptation of these methods to flood prediction have had an important influence on engineering developments since that time.

Shortly after the Civil War, the late Maj. E. T. D. Myers, M. Am. Soc. C. E., developed a formula for computing the cross-sectional area of the waterway required to pass a limiting flood. The Modified Myers formula[4]—

$$Q = C_m \sqrt{M} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

—was developed from the original. In this formula, Q is the discharge in cubic feet per second, and M is the area in square miles. The base factor C_m is taken as 10,000, but for any particular area it is multiplied by a percentage which is referred to as the Myers rating. Eq. 1 has had wide application, and is discussed in recent engineering publications.[5,6] The reliability of the results obtained by it depends upon the choice of the coefficient C_m. The magnitude of the coefficient selected will be governed principally by the magnitude of the observed floods in the locality, and by the judgment and experience of the engineer.

Further studies have developed a different approach to the problem of flood prediction, by the so-called "rational" methods. These involve the relation of rainfall to the resulting runoff by an analysis of rainfall records and corresponding hydrographs, with due consideration being given to the influence of ground water, evaporation, transpiration, shape of drainage area, and other factors. This method includes studies of the frequency of intense rainfall and its distribution over large areas. Reports on the frequency and distribution of rainfall having relation to New England have been made by the Miami Conservancy District[7] and by the U. S. Weather Bureau.[8]

[6] "Physics of the Earth," Pt. 9, Hydrology, National Research Council, McGraw-Hill Book Co., Inc., 1942, p. 536.

As stream-flow records have become more extensive and reliable, the tabulations of extreme floods have increased in value and have made obsolete some of the earlier formulas based on very limited or deficient experience. It is inevitable, however, that the much more extensive experience now available should be analyzed with a view to expression by formulas of relationships between magnitude and frequency of floods as well as of the influence of physical characteristics of basins on the magnitude of floods. Thereby, the maximum utility may be given to the available data which, although much more plentiful than formerly, often have only a rather remote relation to the needs of a specific problem.

The "rational" method of approach has been extended in this paper. Investigations by the writers have shown that the magnitude of a flood of a particular frequency can be correlated with various physical characteristics of the drainage basins. By means of these characteristics, formulas have been developed which are applicable to drainage areas for which stream-flow records are not available or are inadequate.

The common practice in the past has been to use enveloping curves of maximum known discharge per square mile in the design of hydraulic structures. This practice ignores the element of frequency, which may have an important bearing on the risks involved. This paper undertakes to develop a basis for a more discriminative method of considering flood magnitudes in which consideration may be given both to probable frequency and to the influence of the various physical characteristics in the production of floods.

These formulas should not be expected to give exact or unquestionable results on ungaged areas. However, they do provide a convenient means of evaluating the risks involved in the design of hydraulic structures on streams in or near Massachusetts even though the drainage areas may have widely different drainage basin characteristics.

The writers are under no illusion as to the reliability of deductions that may be drawn as to frequencies of major or rare floods from a record which covers little more than 25 years. Nevertheless, it is desirable to make an attempt at such a deduction, and in this paper the results of a systematic, scientific attempt are presented. The writers conceive that the specific form of the formulas developed may not comprise a substantial or lasting contribution to engineering knowledge. However, they hope that the account of the studies and the results may be in such a form that other engineers may assimilate some worth-while ideas in their body of experience with consequent benefit to their handling of flood-frequency problems.

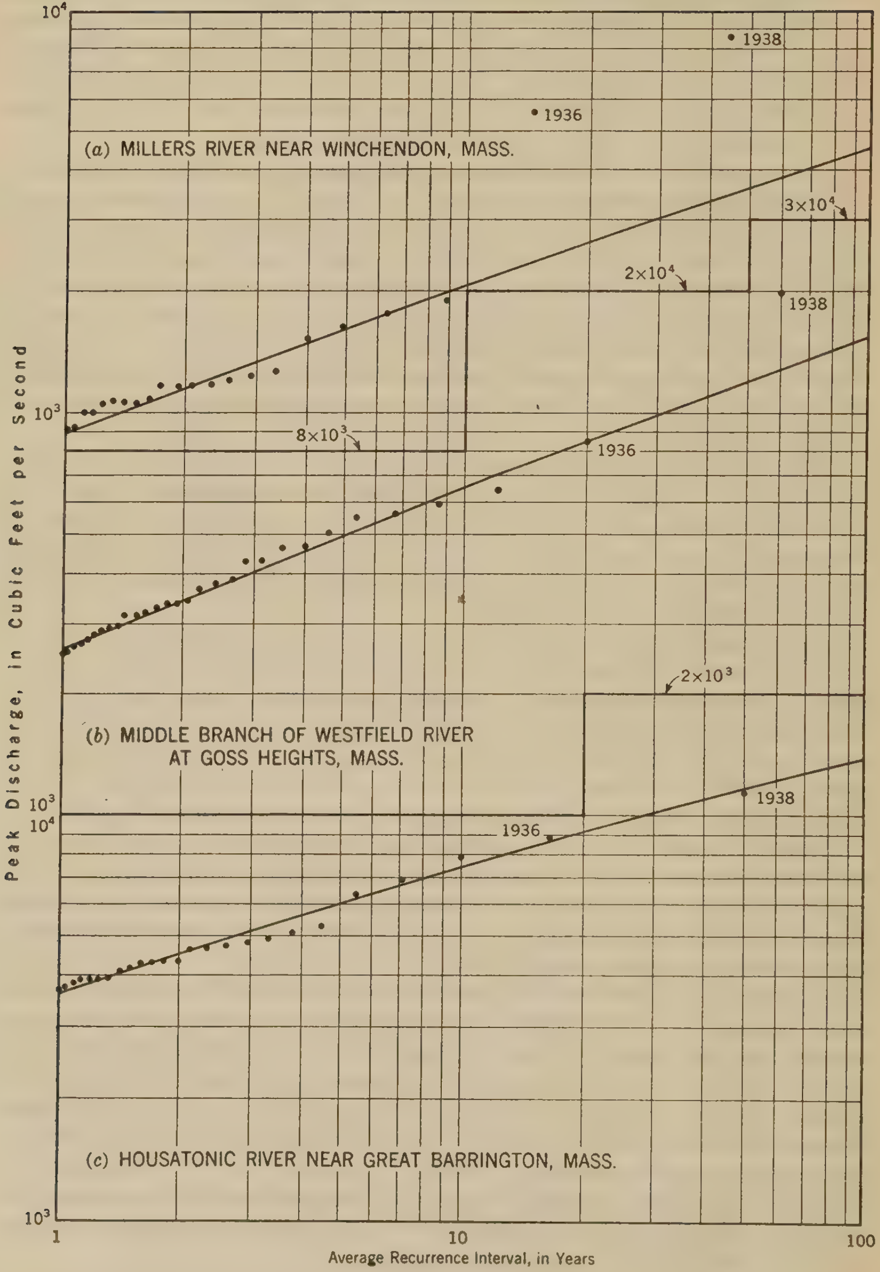

FIG. 1.—FREQUENCY OF FLOOD PEAKS

Frequency Curves of Peak Discharge from Observed Floods

The most logical method of determining the magnitude of expected floods is by a study of the frequency and magnitude of past floods. A frequency curve of instantaneous peak discharges was plotted for each gaging station having a sufficient length of record to justify its use. Fig. 1 shows frequency curves for Millers River near Winchendon, Mass., with 23 years of record, Middle Branch of Westfield River at Goss Heights, Mass., with 26 years of record; and Housatonic River near Great Barrington, Mass., with 25 years of record. In this diagram, the average recurrence interval in years is plotted against discharge. The average recurrence interval I is computed from the equation

$$I = \frac{N_y}{N_p - 0.5} \quad \text{(2)}$$

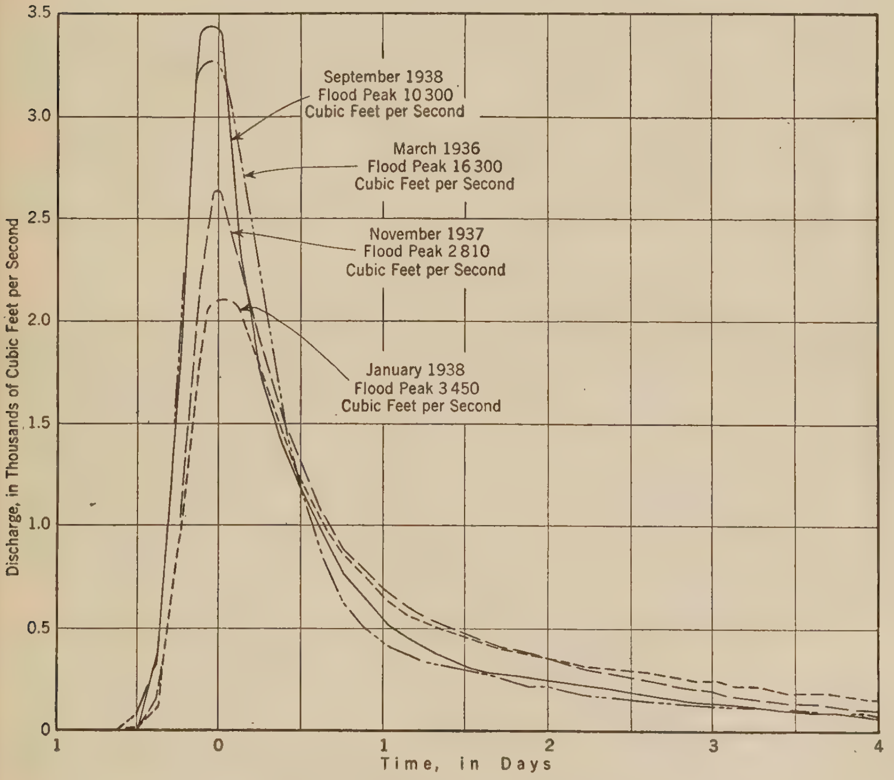

Fig. 2.—Six-Hour Unit Hydrographs Computed from Indicated Floods; North Nashua River, Near Leominster, Mass.

in which N_p is the number of the flood peak in order of size without regard to the time of its occurrence, and N_y is the number of years of record.

Widely different frequency curves can be drawn from the base data for any particular station, and extensions of the curves to recurrence intervals of 100 and 1,000 years are not defined because of insufficient length of record. If the floods of 1936 and 1938 had not occurred during the period of record, much different curves might have been drawn. However, by allowing for extreme severity of these floods in certain areas, the magnitude of a flood having an average recurrence interval of 15 years (called a 15-yr flood) can be determined with reasonable accuracy for many streams.

Because stream-flow records are not long enough to define the frequency curves of peak discharge beyond short recurrence intervals, peak discharges at recurrence intervals of 100 and 1,000 years were computed from a study of unit hydrographs, and depths and distribution of runoff.

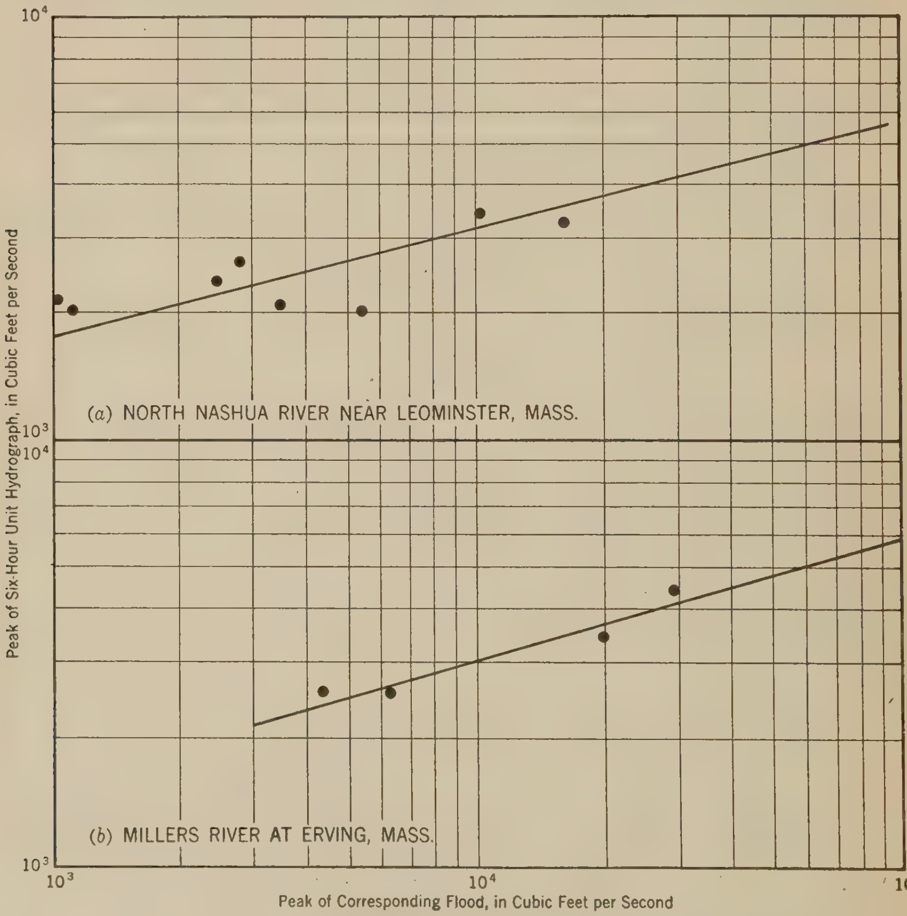

FIG. 3.—RELATION BETWEEN UN

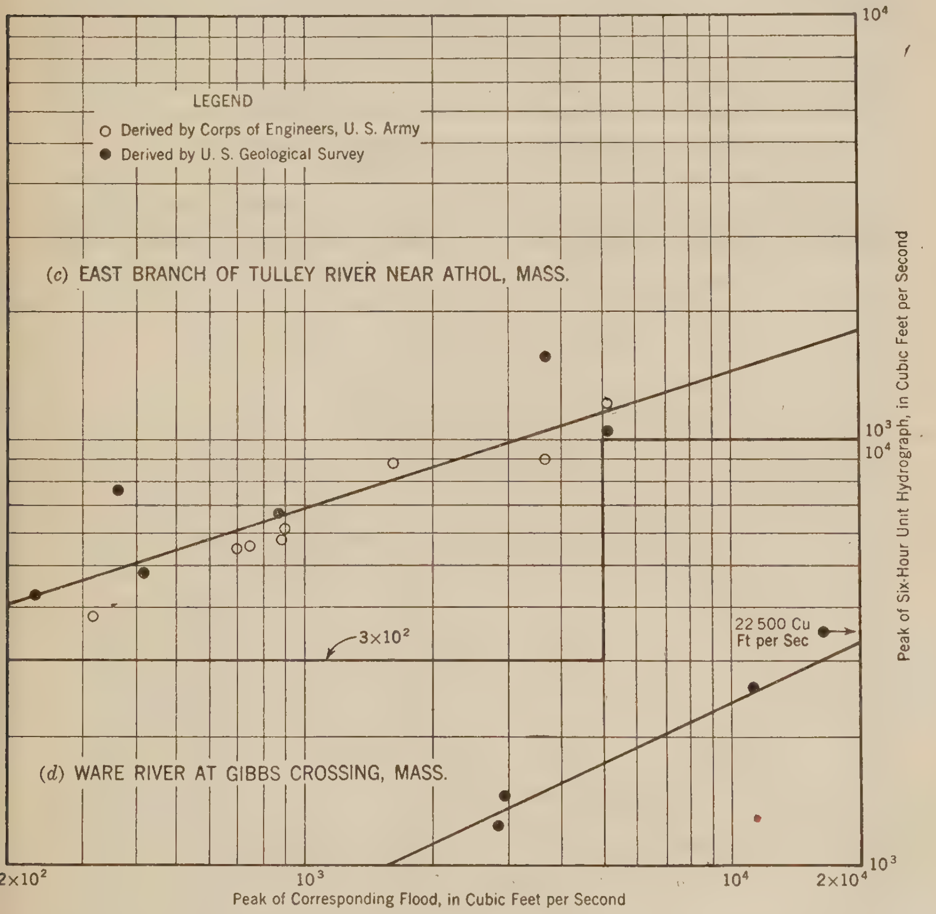
UNIT HYDROGRAPHS

The unit hydrograph method was used to compute the discharge hydrographs of floods from runoff data. The peak discharges were then determined by these hydrographs.

As used in this paper, the unit hydrograph is the discharge hydrograph of 1 in. of direct runoff uniformly generated over the drainage area at a uniform rate. This definition is in common use, although it differs from that given by W. G. Hoyt, M. Am. Soc. C. E., in 1936,[9] by restricting the term to uniformly generated runoff of unit depth. The term, unit hydrograph, usually is qualified by stating the duration of the runoff that generated it. For example, a 4-hr unit hydrograph is the discharge hydrograph resulting from runoff generated uniformly during the period of 4 hours at a rate of 0.25 in. per hr.

The unit hydrograph theory usually presumes that the base and shape of the unit hydrograph for a particular point on a stream will be the same for all floods where the runoff generation is uniform over the area. Differences in the unit hydrographs derived from observed floods have been attributed



Hydrograph Peaks and Flood Peaks

---

[9] "Studies of Relations of Rainfall to Run-Off in the United States," by W. G. Hoyt, *Water-Supply Paper No. 772*, U. S. Geological Survey, 1936, p. 124.

usually to the uneven distribution of runoff generation over the area. This is undoubtedly true of many unit hydrographs derived from observed floods, and such distortion must be expected. However, studies by the writers and others[10] have indicated a definite tendency for the peak of the unit hydrograph to increase with an increase in the magnitude of the flood from which it was derived. Several typical unit hydrographs for North Nashua River near Leominster, Mass., are shown in Fig. 2. These curves illustrate the difference between the peaks of the unit hydrographs derived from the higher floods and

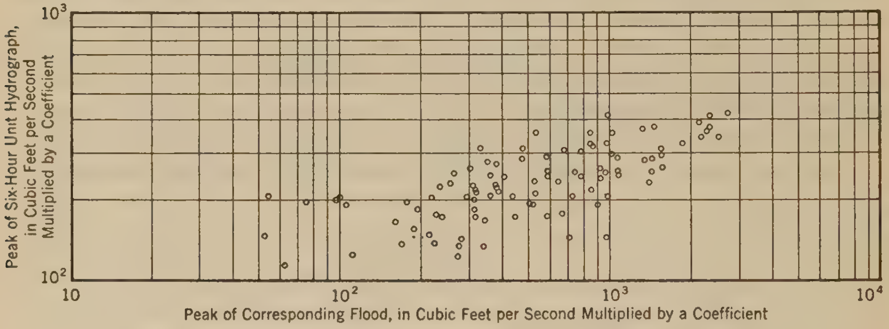


FIG. 4.—RELATION BETWEEN UNIT HYDROGRAPHS AND PEAK FLOWS, BOTH MULTIPLIED BY A COEFFICIENT

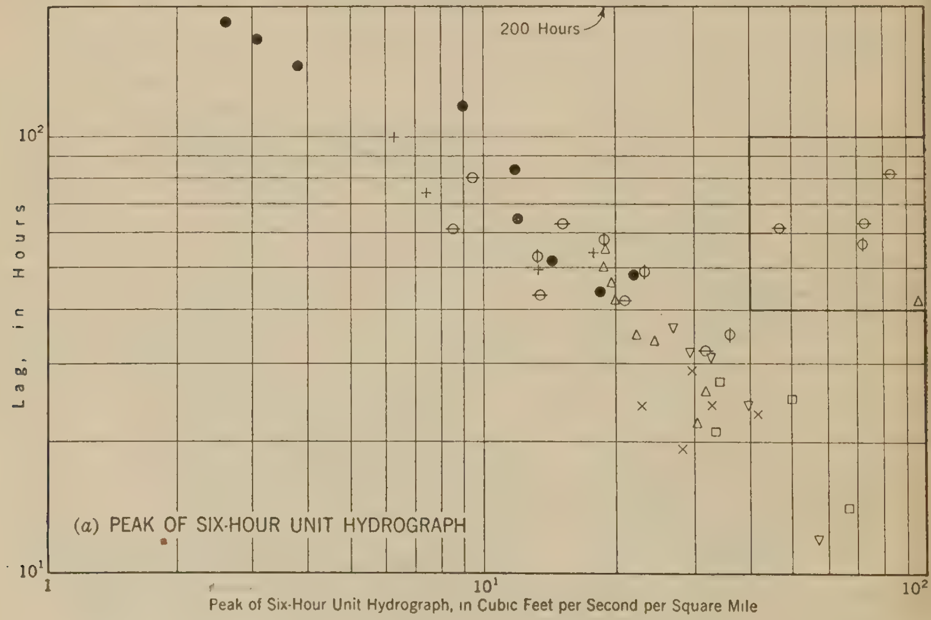

FIG. 5.—RELATION BETWEEN

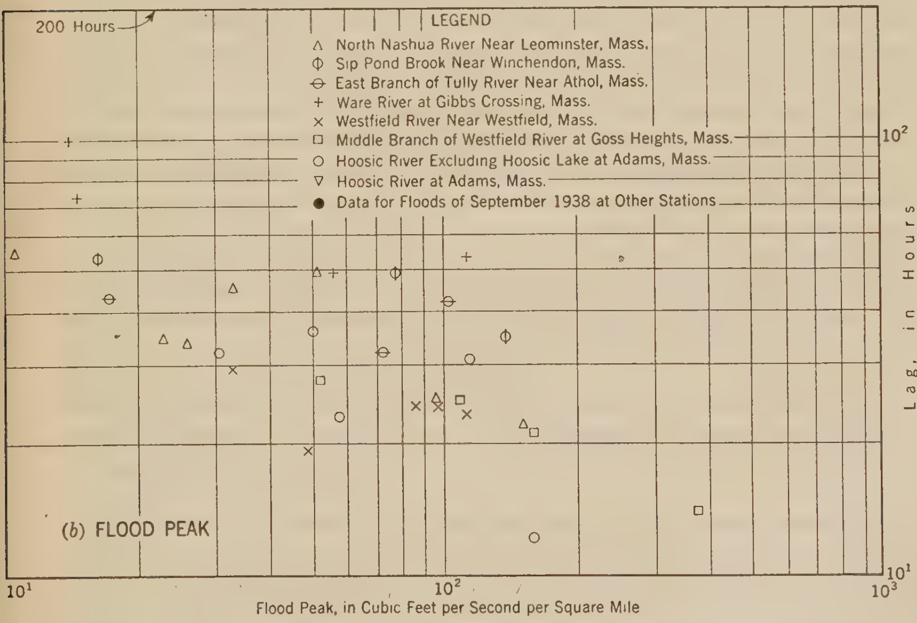
---

[10] "Application of Hydrology in Flood Control," by G. A. Hathaway, *Proceedings*, Hydrology Conference, State College, Pa., 1942.

those derived from smaller floods. This tendency is shown graphically in Fig. 3, in which the peaks of several floods are plotted against the peaks of the corresponding 6-hr unit hydrographs. The general increase of unit hydrograph peaks with increase in the corresponding floods is demonstrated also in Fig. 4, in which similar data from several stations are plotted on a composite diagram. Each coordinate has been multiplied by a coefficient which would make the trend line of each station pass through a point whose coordinates are 3,000 and 400. In spite of the scattering of the points on this figure, the general upward trend is indicated clearly.

The peaks of unit hydrographs for many gaging stations in and adjacent to Massachusetts were plotted in the manner similar to Fig. 3. The trend for some stations is uncertain and it was not defined at all if the observed floods did not cover a fairly wide range of discharge. The relation, if it could be completely defined, probably would not be a straight line on logarithmic paper either for a composite graph or for an individual station. The data are insufficient to define any trend other than a straight line. However, the data were sufficient to justify the adjustment of the peaks of the unit hydrographs for the types of floods considered in this study. Extensions of the relation curves for extremely large floods are inexact, but certainly are more accurate than results obtained by assuming no increase in unit hydrograph peaks with increase in the size of the flood.



Lag and Peak Flows

W. B. Langbein,[11] Assoc. M. Am. Soc. C. E., has shown that the peak of unit hydrographs, as expressed by the S-curve, increased with a decrease in the time by which the center of mass of discharge lagged behind the center of mass of runoff generation. "Runoff generation" as used in this paper is defined as the origination of direct runoff, and "direct runoff" is that part of the precipitation which flows more or less over the land surface. The lag time was computed from the recession curve by the method suggested by Mr. Langbein for different floods at each of several gaging stations, and for the flood of September, 1938, at several other stations. Fig. 5(*a*) shows the relation between the lag time and the peak of the unit hydrograph. In Fig. 5(*b*) the lag time, in hours, for different floods at seven gaging stations is plotted against the peak discharge of these floods. The tendency for this lag time to decrease with an increase in size of flood peak, in cubic feet per second per square mile, is shown both for the different floods at a single station and for floods at different stations. Thus, Fig. 5 confirms the increase in the peak discharge of the unit hydrograph with an increase in the peak discharge of the corresponding flood.

[11] "Channel-Storage and Unit-Hydrograph Studies," by W. B. Langbein, *Transactions*, Am. Geophysical Union, Pt. II, 1940, pp. 620–627.

Frequency Curves of Depth of Runoff

In order to use the frequency curves of precipitation in a study of the frequency of peak discharges, the use of frequency curves of depth of runoff is desirable. Although a relationship exists between precipitation and peak discharge, a much closer relationship exists between precipitation and the volume of runoff which is usually expressed as a depth in inches over the basin. Once this correlation between precipitation and depth of consequent runoff is established, the frequency of a given depth of runoff can be computed from the frequency curve of precipitation. When the depth of runoff for a flood of certain frequency is known, the discharge hydrograph can be computed by means of the unit hydrograph.

To establish the relationship between precipitation and runoff, the amount of direct runoff resulting from each storm of 1.5 in. or more precipitation over each of three areas was plotted against the corresponding precipitation. The depth of runoff was determined from stream-flow records, and precipitation records published by the U. S. Weather Bureau were used. From these plotted points and a general consideration of the probable limits and distribution of runoff factors, a probability table was prepared. It showed the probability of a given depth of runoff being generated by any given depth of precipitation.

Frequency curves of precipitation used in this study are shown in Fig. 6. The frequency curve of 24-hr precipitation was included only as an aid in defining the curve of 72-hr precipitation, for which the data are less complete. These curves are based on data for precipitation at a point, from "Rainfall Intensity-Frequency Data"[12] and "Storm Rainfall of Eastern United States."[7] The upper ends of the frequency curves are based on the maximum precipitation as shown in the Miami Conservancy Report of 1936;[13] the maximum possible precipitation on an area of 100 sq miles as given in the Ompompanoosuc Report of the Weather Bureau in 1940;[14] and the maximum point rainfall of the northeastern United States from unofficial records as indicated by an extension of a curve in the Ompompanoosuc Report.[15] These maximum amounts of precipitation are plotted at arbitrary recurrence intervals of 10,000 or 100,000 years to provide some basis for an extension of the frequency curves.

---

[12] "Rainfall Intensity-Frequency Data," by David L. Yarnell, *Miscellaneous Publication No. 204*, U. S. D. A., 1935.

[13] "Storm Rainfall of Eastern United States," *Technical Reports*, Miami Conservancy Dist., Pt. 5 (revised), 1936, Figs. 38 and 40.

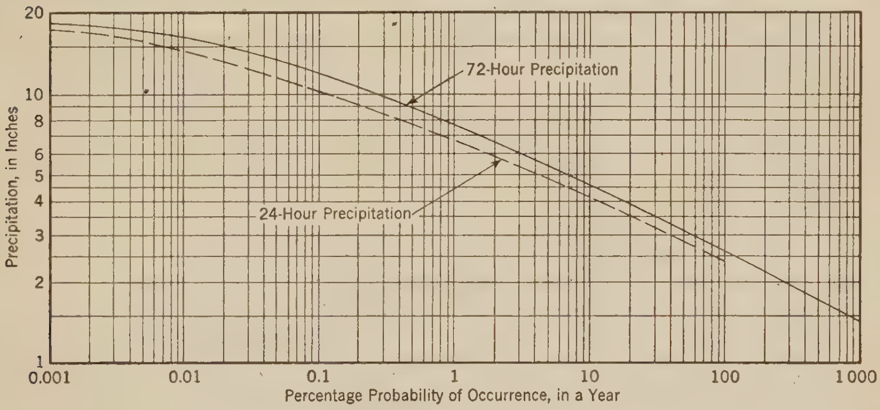

FIG. 6.—FREQUENCY OF SEVENTY-TWO HOUR PRECIPITATION FOR DRAINAGE BASINS IN MASSACHUSETTS

The frequency curve of precipitation in 72 hours was assumed to be applicable to drainage basins in Massachusetts, although certain assumptions had to be made in drawing it. The upper end of the curve was drawn to represent frequency of precipitation on drainage areas of 100 or 200 sq miles. At average recurrence intervals of 100 years or less, the curve is based more or less directly on observations of precipitation at a point, so that it does not apply exactly to precipitation over the actual drainage area. The difference

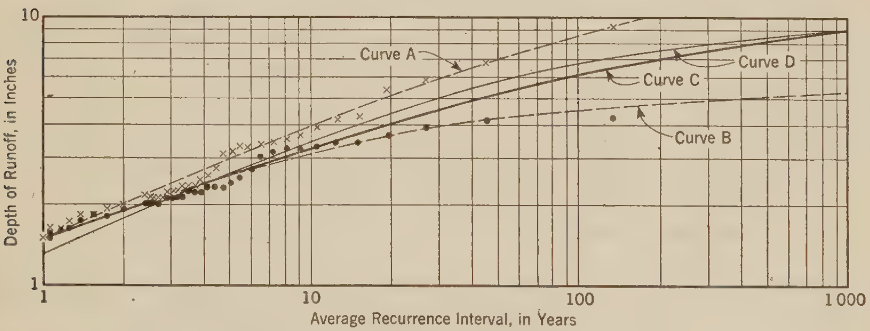

FIG. 7.—FREQUENCY CURVES OF DEPTH OF RUNOFF; COMBINED RECORDS FOR TAUNTON RIVER, PRIEST BROOK, AND THE MIDDLE BRANCH OF WESTFIELD RIVER

between point and areal precipitation probably is not great on drainage areas of less than a few hundred square miles and for average recurrence intervals not longer than 100 years. Probably the error from using the same curve of 72-hr precipitation for drainage basins of all sizes is partly compensated by the error in using the duration of 72 hours for precipitation on all basins.

---

[14] "A Report on the Maximum Possible Precipitation over the Ompompanoosuc Basin Above Union Village, Vt.," U. S. Weather Bureau, 1940, Table VI (unpublished).

[15] *Ibid.*, Fig. 24.

The frequency curve of 72-hr precipitation was combined with the probability table which showed the probability of a given depth of runoff being

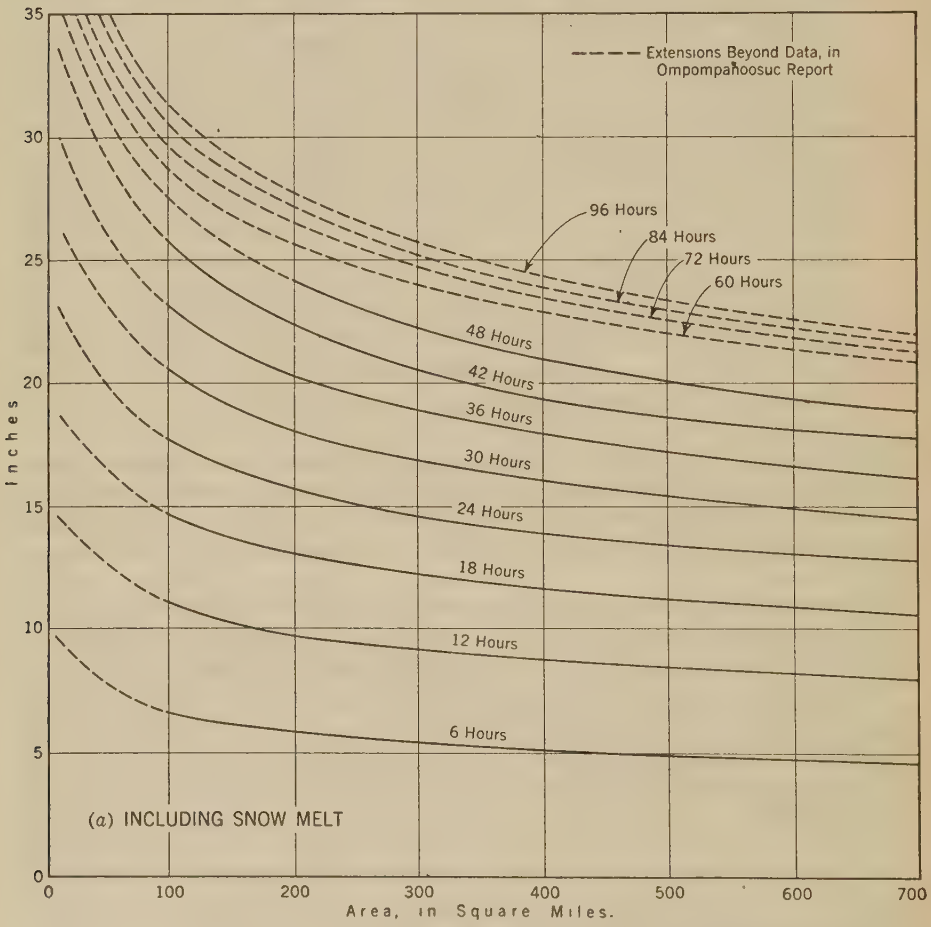

FIG. 8.—MAXIMUM RAINFALL BASED

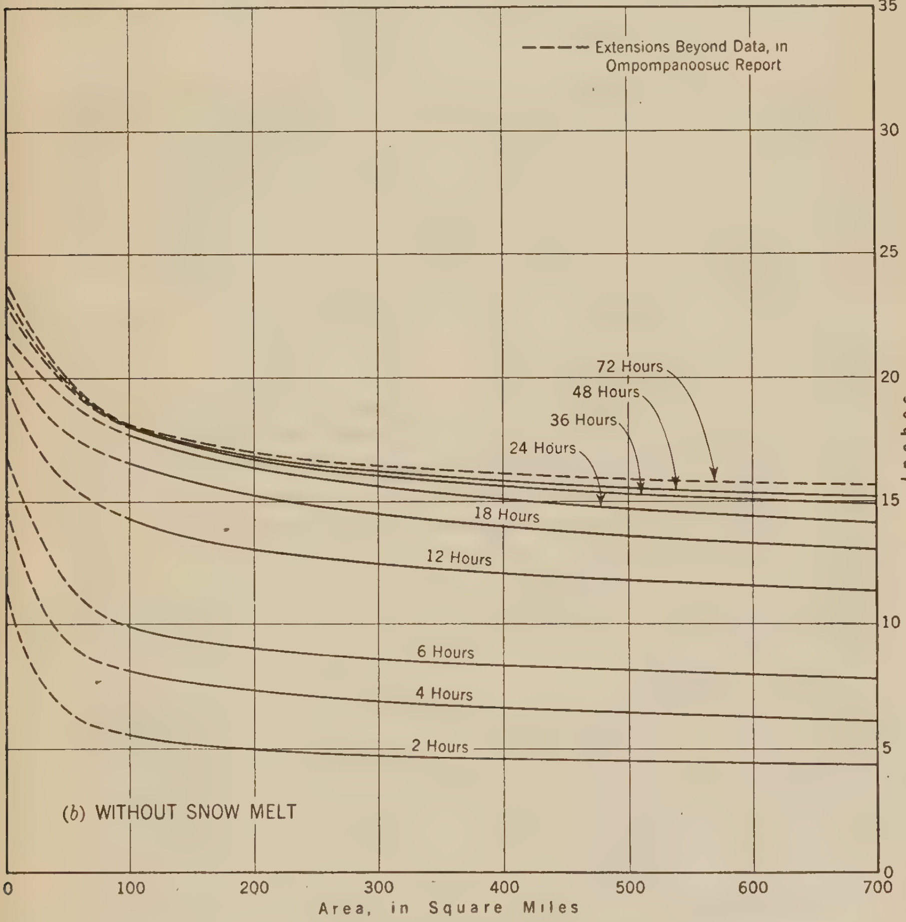
generated by any given depth of precipitation, and a frequency curve of depth of runoff obtained. This curve is shown as curve D in Fig. 7.

Frequency curves of depth of runoff were prepared for ten streams in Massachusetts. They have the same limitations as frequency curves of discharge, owing to shortness of record. Three of these drainage areas are widely separated, and for this study the records may be combined and used as one continuous record of a length equal to the sum of the three individual records. These areas are Taunton River at State Farm, Mass., Priest Brook near Winchendon, Mass., and Middle Branch of Westfield River at Goss Heights, Mass., whose combined length of record is 69 years. Curve A in Fig. 7 is the frequency curve for this combined record. On the assumption that floods of the magnitude of those of March, 1936, and September, 1938, on the Middle Branch of Westfield River and Priest Brook might not have occurred during the period



ON THE OMPOMPANOOSUC REPORT

of record, these have been omitted in determining frequency curve B. The floods of 1936 and 1938 on Taunton River at State Farm were not exceptionally high.

Curves A and B differ widely for the larger recurrence intervals, and illustrate the possible influence of one or two extremely large floods in a comparatively short period of record. These curves represent the probable extremes of a true frequency curve. Curve D shows lower depths of runoff at short recurrence intervals because some winter storms having less than 1.5 in. of precipitation were followed by as much as 2 in. of runoff.

The depths of runoff at recurrence intervals of 15, 100, and 1,000 years were estimated from curves A, B, and D. These depths were used later, with assumed time distributions of the runoff, to compute flood peaks. After a study of these peaks, the depths of runoff were revised slightly, and curve C, Fig. 7, represents these revised depths.

Maximum Flood Runoff

In the report of the Ompompanoosuc Basin in Vermont,[8] maximum possible rates of precipitation during both summer and winter storms and the maximum possible rates of snow melt were computed. Fig. 8(*b*) was prepared from that report.[16] Extensions from data shown in that report are indicated by dashed lines. One extension is from rainfall on a drainage area of 100 sq miles to rainfall at a point. The estimate of maximum rainfall at a point was also taken from that report.[17] The extension from a duration of 48 hours to a duration of 72 hours was determined by logarithmic plotting.

Fig. 8(*a*) shows the maximum possible winter rainfall[18] plus the maximum possible snow melt.[19] Extensions beyond the data available are indicated by dashed lines. The maximum possible quantity of water accumulated as ice and snow was estimated to be 10 in. on a drainage area of 1,000 sq miles and 16 in. on a drainage area of 10 sq miles. The detailed basis of the estimates is not given herein; but, during the time that stream-flow records have been collected, as much as 6 to 9 in. of precipitation have accumulated as ice and snow on some drainage basins in Massachusetts during winters when the total snowfall was much less than the greatest observed seasonal snowfalls. However, if the maximum possible amount of accumulated precipitation were overestimated by as much as 6 in., the computed peak discharges for the maximum winter floods would be less than 10% too large for most of the drainage basins which were investigated.

To any one who has not studied snow melt and amount of precipitation accumulated as ice and snow on the basis of the maximum possible limits of occurrence, the limits used in preparing Fig. 8(*a*) may seem too large. By "maximum possible" is meant not the maximum that should be expected, but the maximum that could not be exceeded under any possible, even though very unlikely, combination of circumstances.

Determination of Flood Peaks for Minor, Major, Rare, and Maximum Floods

The peak discharges of certain defined types of floods have been determined for several streams for which adequate discharge records are available. This was accomplished by determining for each basin the depth of runoff in inches for each type of flood, assuming a distribution of this runoff, and computing the flood hydrograph by means of the unit hydrograph.

[18] *Ibid.*, Table VII.

[19] *Ibid.*, Fig. 9.

Minor Flood Peaks.—For the purpose of this paper, a minor flood is defined as an approximation of a flood which would be equaled or exceeded on an average of once in 15 years. The depth of runoff for a minor flood has been found to be fairly uniform for drainage basins in Massachusetts. However, the depths of runoff do vary with physical characteristics. The best correlation of depth of runoff is with mean altitude above sea level. This relationship is shown in Fig. 9 where depth of runoff for minor floods is plotted against mean altitude above sea level. The points were obtained from frequency curves of depth of runoff for drainage areas having about twenty-five years of record, except No. 10, which has eight years of record. To make this relatively short record comparable to the longer records at other stations, it has been adjusted by the proportion which the frequency curve based on the last eight-years of a longer record bears to a curve based on the complete record. Although the points scatter, and the relation below an altitude of 800 ft is not defined, the runoff definitely increases with an increase in altitude. The runoff for Swift River at West Ware, Mass., appears low in comparison with the other records, and was given very little weight in determining the correlation. The increase in runoff with an increase in the altitude of the basins may be attributed to factors other than the altitude, such as soil types, land slopes, and temperature, but these factors probably correlate fairly well with altitude.

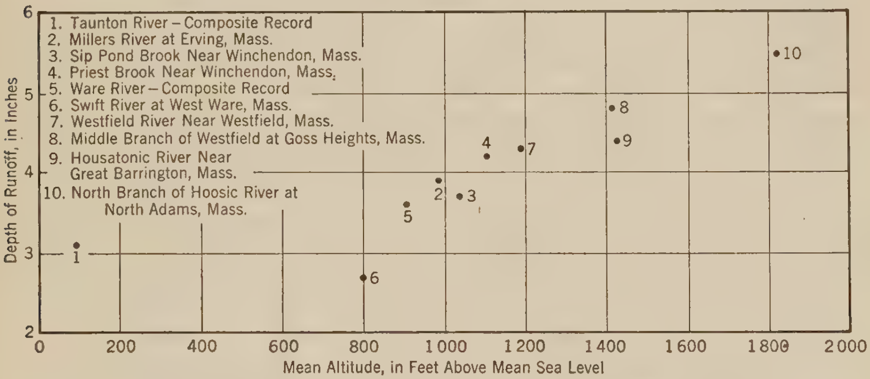

FIG. 9.—RUNOFF EQUALED OR EXCEEDED ON AN AVERAGE OF ONCE IN FIFTEEN YEARS

The surface area of lakes, ponds, and reservoirs within a basin correlated to some extent with depth of runoff. No other correlation between depth of runoff and physical characteristics was found.

From the foregoing data, and Fig. 7, the final equation for depth of runoff for a minor flood was determined to be:

$$D = 3.6 - 0.3\,a + 0.001\,E \qquad (3)$$

in which D is depth of runoff in inches; a is the water surface of lakes, ponds, and reservoirs expressed as a percentage of the drainage area; and E is the difference, disregarding negative quantities, between the average altitude of the basin in feet above mean sea level and 800 ft.

The depth of runoff for a 72-hr storm was distributed by successive 6-hr increments of 3%, 5%, 5%, 10%, 10%, 20%, 34%, 10%, and 3%. For some areas, the 12-hr period covered by the two largest 6-hr increments was subdivided into 2-hr increments, 2%, 6%, 12%, 24%, 8%, and 2% of the total depth. The assumed runoff pattern has been determined from a study of precipitation and discharge records of Massachusetts and near-by areas, and a study of the distribution used by the Corps of Engineers for design floods.

Peak discharges computed from the depth-of-runoff formula and the distribution for 72-hr runoff were in agreement with the peak discharges of 15-yr floods obtained from frequency curves of peak discharges for those streams where these curves were well defined. The runoff, however, should not be presumed to follow the assumed distribution for any particular storm; nor should the depth of runoff be considered a representative value for 15-yr floods. On drainage basins having sharp flood peaks, the depth of runoff occurring in 72 hours may have little significance, for the highest flood peaks may follow short, intense periods of rainfall. Depths and distribution of runoff, as used in this study, are interdependent. The depths of runoff which have an average recurrence interval of 15 years may not be the same as the average depths of runoff associated with peaks of 15-yr floods. The distribution used here is only a means, uniform for all basins, of converting depth of runoff to discharge hydrographs having peaks which may be expected to occur with the same frequency as the depth of runoff.

Fig. 10.—Key to Gaging Stations in Table 1

The discharge hydrograph for a minor flood on each stream was computed by applying unit hydrographs to the 6-hr increments of depth of runoff assumed for the storm, and a base flow of 1 cu ft per sec per sq mile was included. The peaks are listed in Table 1 (and Fig. 10) together with the peaks of other classes of floods and the physical characteristics of the basins.

Major Flood Peaks.—A major flood is defined as an approximation of a flood that would be equaled or exceeded on an average of once in 100 years. The final equation for the depth of runoff was determined to be:

$$D = 6.1 - 0.35\,a + 0.001\,E \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

The effect of lake and reservoir surface on the major floods as compared with minor floods was assumed to be slightly greater as measured in inches but to be considerably less as measured in percentage of the depth of runoff, and the effect of mean altitude was assumed to be the same as for minor floods.

A slightly more concentrated runoff distribution was assumed for the major flood than for the minor flood. Successive 6-hr increments of 2%, 3%, 5%, 10%, 10%, 20%, 38%, 10%, and 2% of the depth of runoff were used. For some areas, the 12-hr period covered by the two largest 6-hr increments was subdivided into successive 2-hr increments of 2%, 6%, 12%, 25%, 10%, and 3%. The discharge hydrographs for major floods on all streams were computed by the unit hydrograph method, and the peaks are listed in Table 1, Cols. 13 to 16. A base flow of 1 cu ft per sec per sq mile is included.

Rare Flood Peaks.—A rare flood is defined as an approximation of a flood that would be equaled or exceeded on an average of once in 1,000 years. The depth of runoff for rare floods was computed from the equation:

$$D = 8.9 - 0.4\,a + 0.001\,E \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

The first term on the right-hand side of Eqs. 4 and 5 was based on curve C of Fig. 7. The effect of lakes and ponds on rare floods was assumed to be slightly greater than their effect on minor or major floods; and the effect of altitude on rare floods was assumed to be the same as its effect on other classes of floods.

Successive 6-hr increments of runoff of 2%, 3%, 5%, 8%, 10%, 20%, 40% 10%, and 2% of the total depth of runoff were used, and for some areas the two largest increments were subdivided into successive 2-hr increments of 2%, 6%, 12%, 27%, 10%, and 3%. For rare floods the discharge hydrographs were computed by the unit hydrograph method in the same manner as for minor and major floods. The computed peaks are listed in Table 1 and are plotted in cubic feet per second per square mile in Fig. 11. A base flow of 1 cu ft per sec per sq mile is included.

The depths of runoff used in computing rare floods and the computed peaks of the rare floods were compared with the greatest depths of runoff and the highest flood peaks that have been observed on streams in Massachusetts since stream-flow records have been collected. The computed figures seem consistent with the observed depths of runoff and the observed peak discharges. During the flood of September, 1938,[20] the depths of runoff and the peak discharges at gaging stations in the Millers River Basin except Moss Brook, and the Ware River Basin except Swift River at West Ware, were approximately the same as the depths and peaks which were computed for rare floods.

minimum, and the discharge occurring in accordance with a unit hydrograph having an extremely high peak. The maximum flood (if it occurs during the winter) is a similarly computed flood which is based on the additional assumptions of the largest possible water content in accumulated snow and ice, the fastest rate of melting, and the worst combination of snow melt and precipitation.

Increments of maximum possible precipitation during summer storms were taken from Fig. 8(*b*) by 6-hr periods for each drainage basin. The maximum 6-hr increment was subdivided into 2-hr increments for the four streams whose flood hydrographs have the sharpest peaks. The 6-hr increments were arranged in the order which would produce approximately the highest flood peaks. The largest increment was preceded in order by the second, fourth, sixth, eighth, tenth, and twelfth largest increments. The largest increment was followed in order by the third, fifth, seventh, ninth, and eleventh largest increments.

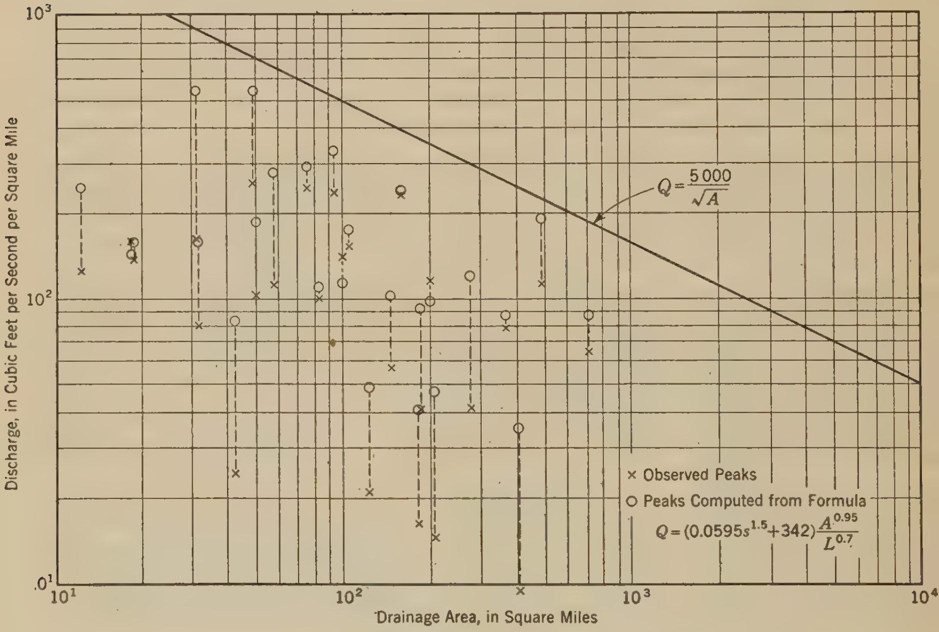

FIG. 11.—RARE FLOOD PEAKS

When precipitation of high intensity falls on saturated soil, the losses by infiltration probably are small. Also, the precipitation which is called the maximum possible may not contain sufficient factors of safety, or the assumed distribution of the precipitation may not be that distribution which would cause the highest possible peak discharge. For these reasons a runoff factor of 100% was used.

Increments of winter precipitation plus snow melt were taken from Fig. 8(*a*) by 6-hr periods for each drainage basin. These increments were arranged to precede and to follow the maximum increment in an order similar to that used for the maximum possible summer storms. A runoff factor of 100% was used for the drainage basins in the Providence, Thames, and Connecticut river valleys. Some appreciable loss by infiltration and evaporation must occur on the coastal basins, from which the discharge is slow. For these basins a runoff factor of 90% was assumed to be the maximum possible for winter floods.

Unit hydrographs were determined and the peaks of the maximum floods were computed in the same general way as those for the other classes of floods. Base flow of 2 cu ft per sec per sq mile was added to the computed net peaks of both the maximum winter and the maximum summer flood peaks. The lower one of the two computed peaks for each basin was discarded from further consideration, and the higher one was listed in Col. 16, Table 1. The maximum summer flood was higher or almost as high as the maximum winter flood for all drainage basins except the Concord River below River Meadow Brook, at Lowell, Mass., the Ipswich River near Ipswich, Mass., the Charles River at Charles River Village, Mass., the Taunton River excluding Assawompsett Pond, at State Farm, and the Millers River at Erving, Mass.

The maximum flood, as the term is used in this paper, is entirely different from a design flood or a maximum probable flood. It is that computed flood which is expected to equal or exceed the flood resulting from the worst combination of flood-producing conditions. It contains factors of safety for the inadequacy of past records and for ignorance both of relationships between cause and effect and the physical limits of natural hydraulic phenomena. Any design based on less than the maximum flood peak should be assumed to involve some risk. The remoteness of the probability that a flood peak even close to the size of the peak of the maximum flood will occur during the existence of any structure is indicated by the great difference between the computed peaks of the rare floods and those of the maximum floods.

The reason for the large size of the maximum flood peak can be shown best by contrasting that peak with a flood having the order of magnitude of a maximum probable flood. This flood might follow precipitation that was 80% of the maximum, the distribution might have an effect on the peak which was 85% of the maximum, the runoff factor might be 85%, and the unit hydrograph might have a shape which would have 75% of the maximum effect on the computed flood peak. This flood would then have a peak discharge which would be about 45% of the peak discharge of the maximum flood. A similar rough analysis applied to winter floods would show the peak of the maximum probable flood to be an even smaller percentage of the peak of the maximum winter flood.

PHYSICAL CHARACTERISTICS

The physical characteristics of more than one hundred drainage basins in New England were computed by the personnel of the Work Projects Administration under the supervision of the Boston district of the U. S. Geological Survey. Of these basins, forty eight were in Massachusetts, although not all of them were entirely separate basins because some overlapped. Except for the type of vegetal cover, which was computed from information supplied by the National Resources Committee, the following physical characteristics were computed from topographic maps published by the U. S. Geologic Survey:

Areas.—(1) Drainage area; (2) area of lake, reservoir, and pond surfaces; and (3) area of swamps.

Altitude.—(1) Maximum altitude; (2) minimum altitude (altitude at the outlet); (3) median altitude (altitude at which 50% of the drainage area is higher and 50% is lower); and (4) mean altitude.

Slopes.—(1) East-west land slope; (2) north-south land slope; (3) average land slope; (4) slope of principal streams (a principal stream being defined as a watercourse that drains more than 10% of the total area of the basin); and, (5) slope of tributary streams (tributary streams being defined as all watercourses contributing to a principal stream).

Configuration of Basin and Streams.—(1) Length of principal streams; (2) stream density (total length of all streams divided by the drainage area); (3) average distance uniformly distributed runoff must travel to the outlet; (4) length of basin (twice average distance water must travel); (5) width of basin (drainage area divided by length of basin); (6) form factor (length of basin divided by width of basin); and (7) branch index (length of stream channels, selected according to an arbitrary criterion, divided by length of basin).

General Type of Vegetal Cover.—(1) Percentage of cropped land; (2) percentage of wooded land; and (3) percentage of grass land not cropped.

Correlations with Flood Peaks

The peak discharge of a flood probably would be affected by any large change in any one of these basin characteristics even though all the other characteristics remained constant; but the change might be very slight. Also a change in one characteristic is usually associated with changes in other characteristics. Therefore, as the computed flood peaks are not exact and the relationships among the characteristics are complex, the effect of any particular characteristic usually cannot be determined accurately. Thus, the results of correlations may not really represent laws of cause and effect, so the formulas may not be applicable to regions other than Massachusetts or to ranges in any of the characteristics which are much beyond the limits included in this study. The correlations show, however, that changes in certain characteristics were associated in a definite way with changes in the size of the flood peaks.

Each computed physical characteristic was considered as a possible basis for correlation equations except the maximum altitude, the minimum altitude, and the east-west and north-south land slopes. Correlations between peak discharge and the physical characteristics for each type of flood were determined first by plotting on logarithmic paper the peaks of that type of flood against the drainage area. A straight line was used to represent the relation between peak discharge and drainage area. The ratio r_1 between each peak discharge and the peak discharge which would plot on the straight line was computed. Correlations of ratios r_1 with stream slopes, land slopes, and mean elevations above the outlet were investigated. Before any one of these characteristics was plotted against the ratios r_1, any correlation between the characteristic and drainage area was eliminated. To do this, the characteristic was plotted against the drainage area, and a curve showing the relationship was drawn. Ratios r_2 of the departure of the characteristic from this curve were computed. Then ratios r_1 were plotted against ratios r_2 and a curve was drawn to fit the plotted points. Ratios r_3 of the departure of the plotted points from this curve were computed. Next these ratios r_3 were correlated with another characteristic from which any correlation with a characteristic previously included in the correlation had been eliminated. When the remaining ratios no longer showed a correlation with a basin characteristic, the correlations already found were adjusted slightly to make them fit the base data as closely as possible.

The formulas representing the best correlations which were found are as follows: For minor floods—

$$Q = (0.000036\, s^{2.4} + 124)\, \frac{M^{0.95}}{a^{0.04}\, L^{0.7}} \quad \text{(6}a\text{)}$$

and for major floods—

$$Q = (0.0344\, s^{1.5} + 200)\, \frac{M^{0.85}}{L^{0.5}} \quad \text{(6}b\text{)}$$

for rare floods—

$$Q = (0.0595\, s^{1.5} + 342)\, \frac{M^{0.95}}{L^{0.7}} \quad \text{(6}c\text{)}$$

and for maximum floods—

$$Q = (0.128\, s^{1.6} + 1{,}800)\, \frac{M^{0.9}}{L^{0.7}} \quad \text{(6}d\text{)}$$

In these equations Q is the peak discharge in cubic feet per second; a is the percentage that lake, pond, and reservoir surface is to the total drainage area; s is the median altitude of the drainage basin in feet above the outlet; M is the drainage area in square miles; and L is the average distance, in miles, which water from runoff uniformly distributed over the basin must travel to the outlet. Thus M is a measure of the volume of water to be discharged; s is a measure of the fall of the water; and L is a measure of the distance that the water travels to the point of discharge. In addition, a in Eq. 6*a* is a rough measure of the effect of storage in lakes and reservoirs on the quantity of water discharged or on the shape of the hydrograph. The form of the equation indicates that a must not be zero. It should always be assumed to equal or exceed 0.05% even though the topographic map shows little or no water surface of lakes, ponds, or reservoirs. As a is not an entirely satisfactory measure of the storage, flood flows should be routed through the large lakes or reservoirs or those which have a large portion of the flow passing through them. The absence of a in the formulas for large floods (Eqs. 6*b*, 6*c*, and 6*d*) should not be interpreted to mean that lakes and reservoirs have no effect on the peak discharge of these floods. These floods should also be routed through the larger lakes or reservoirs. Perhaps no correlation was found because a correlates to some extent with either L or s, or the correlation is obscured by the effect of other basin characteristics or by inaccuracies in computed flood peaks.

The measures of basin characteristics, although the most practicable, are not entirely satisfactory. Average stream and land slopes, altitudes, and lake and swamp areas were used without determining the distribution of them in the basins. Steep slopes on a few tributaries may increase the average slope considerably, yet these slopes may have little effect on peak discharges. Steep slopes or abnormally high altitudes in that part of a basin upstream from a lake may affect the average land slope and mean elevation of the basin materially; but the lake may decrease the peak discharge so much that the peak outflows from the lake would be little different if the slopes and elevations upstream from the lake were greatly reduced. A lake on the headwaters of a flashy stream may have no noticeable effect on flood peaks, but a similar lake on the main channel near the outlet may greatly decrease the peak discharges. Consideration should be given to these facts in the study of any particular basin.

General type of vegetal cover did not correlate with peak discharge. Probably no correlation should be expected in Massachusetts where little of the land is either bare or in cultivated crops and where nearly all of the basins have a large proportion of woodland. Area of swamps seemed to correlate somewhat with stream slopes, with s, and with peak discharges. However, topographic maps based on surveys made at different times usually show different swamp areas. Median altitude usually is about the same as the mean altitude, and the differences between the two did not seem to be associated with a consistent variation in peak discharges. Average land slope is a fairly satisfactory measure of topography for use in correlation equations, but it did not correlate with peak discharges as well as mean altitude above the outlet. Slopes of principal streams and tributary streams are important basin characteristics, but the division between principal and tributary streams is arbitrary, and the average slope of either is not a very satisfactory measure of channel storage or of time of travel to the outlet. Stream density does not change much from place to place in Massachusetts, and the changes which do occur tend to correlate with land slopes. Neither the branch index nor the length of principal streams seemed to be as good a measure of the concentration characteristics of drainage basins as either the form factor or the average distance that water has to travel to the outlet. Length of basin, width of basin, form factor, and average distance water has to travel to the outlet are all interdependent, and as good correlations can be obtained with one as with any of the others. However, the average distance water must travel to the outlet has a simple and direct meaning; so it was used.

Mean altitude above sea level does not appear in the formulas, although it was included in the equations for depth of runoff. However, it correlates fairly well with s, the mean altitude above the outlet of the basin, so that by including s in the formulas, the effect of mean altitude above sea level is not neglected.

Minor, major, rare, and maximum flood peaks were computed with slide-rule accuracy for 48 basins from the formulas and are listed in Table 1 (Cols. 9 to 12). Table 1 also shows the physical characteristics that were used in the final formulas, the flood peaks computed from unit hydrographs, and the maximum observed or known flood peaks published by the U. S. Geological Survey.[21] No maximum known peak discharge is given if the period of record is short and no large flood discharge from the basin has been determined.

The points for which peak discharges were computed, usually sites of gaging stations operated by the U. S. Geological Survey, are shown in Fig. 10. Numbers on the map correspond to the numbers given in Table 1.

Frequency curves of peak discharge for three streams are given in Fig. 12. Curves such as these form the best available check on the computed peak discharge determined from the formulas. However, in determining the curve for Fig. 12(*b*), due consideration must be given to the extreme size of the flood of September, 1938. The frequency curves shown in Fig. 12 are not identical with those shown in Fig. 1 for the same stations, since the values obtained from the formulas are used in making the extensions beyond the observed data.

---

[21] *Water-Supply Paper No. 871*, U. S. Geological Survey, 1939.

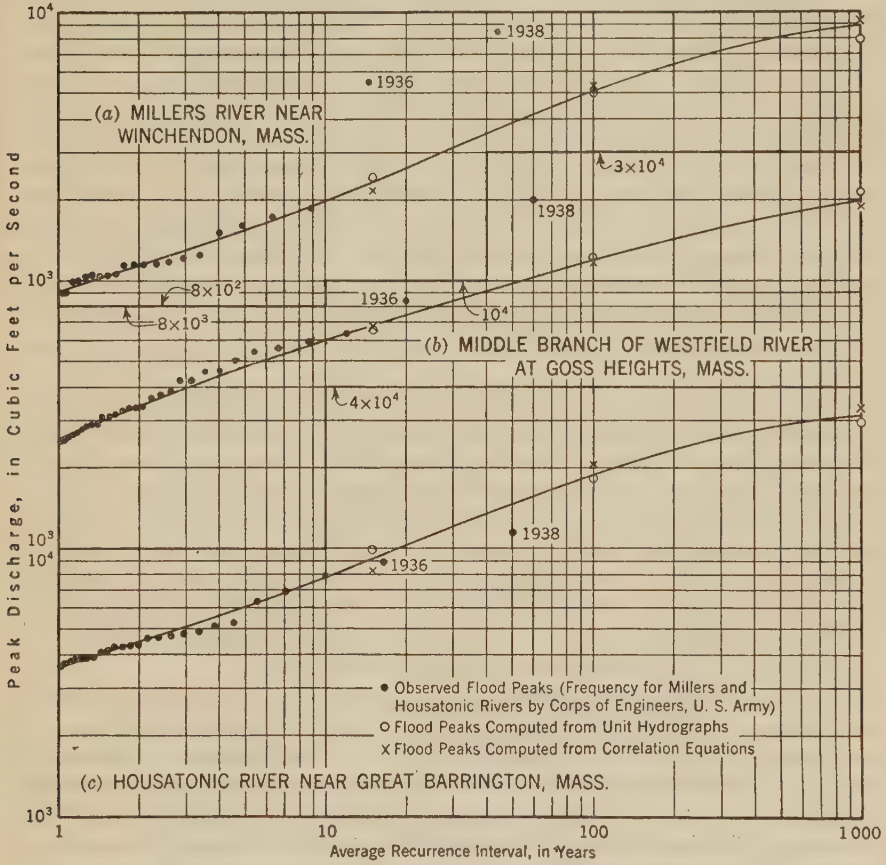

Fig. 12.—Frequency of Flood Peaks

Flood peaks computed from the formulas are too high for Quaboag River at West Brimfield, Mass., because of unusual valley storage in the basin. The slope of the river surface from West Brimfield upstream to Warren is steep, but for about 10 miles above Warren the stream is very flat. Large areas in this part of the valley are flooded at high stages, and the lake thus formed reduces the peak discharges at West Brimfield materially. Short periods of intense precipitation sometimes cause two distinct peak discharges at West Brimfield. The first one is a sharp peak caused principally by the runoff from the area downstream from Warren which is about 10% of the total. The second is a smooth, flat peak caused principally by runoff from the area above Warren.

The formulas should be used with care on streams like the Ashuelot River in New Hampshire and its tributaries. The South Branch of Ashuelot River near Marlboro, N. H., has no large amount of natural or artificial storage in the basin, and the computed peaks are consistent with the observed peaks. Otter Brook, another tributary of the Ashuelot River, near Keene, N. H., the Ashuelot River at Gilsum, N. H., and the Ashuelot River at Hinsdale, N. H., have observed peak discharges which are low in comparison with the computed peak discharges. Discharge from a small part of the Otter Brook tributary area is almost completely controlled by Granite Lake. Nearly half of the remaining drainage area above the gaging station near Keene is upstream from Ellis Reservoir. Storage in this reservoir materially decreases peak discharges at the gaging station. Hence, computed peak discharges based on the drainage area exclusive of the area tributary to Granite Lake are too high, and computed peak discharges based on the drainage area, exclusive of the areas tributary to Granite Lake and Ellis Reservoir, are too low. A lake or reservoir like Ellis Reservoir probably would not greatly reduce peak discharges if it were similarly located in a drainage basin having flat slopes, but Ellis Reservoir reduces the peaks greatly, and delays the discharge from the steep slopes of the area tributary to it.

Similarly, Ashuelot and other ponds, Millen Lake, and unusual quantities of storage at some places along the valley reduce the peak discharges of Ashuelot River at Gilsum. Peak discharges of the Ashuelot River near its mouth at Hinsdale are much below those which might be expected by comparison with the computed peak discharges of minor, major, and rare floods. Storage on the tributaries causes some of this difference, but much more of it is probably caused by the unusual amount of valley storage along the river in the vicinity of Keene where the profile of the water surface is very flat and flooding of marshes and low river banks forms a lake at high stages through which about 80% of the total flow of the river must pass.

The computed peak discharges are too large if the formulas are applied to basins like these which have unusually large amounts of storage, particularly if the basins have steep slopes and hence large average amounts of fall to the outlets. Flood discharges downstream from lakes, reservoirs, and abnormally large quantities of valley storage ordinarily should be considered as individual problems. The inflow should be computed and routed through the storage to the point downstream where discharges are required, allowance being made for inflow to the reaches through which the outflow is routed.

Peak Discharges for Ungaged Areas

To use the formulas in computing the different classes of flood peaks for a particular point on a stream, the basin characteristics, M, a, L, and s, must be computed with whatever degree of accuracy is required. The drainage area M can be readily determined by planimeter. Water-surface areas necessary for computing a can be obtained by measuring with a planimeter large surfaces and estimating small surfaces by comparison with a set of squares or rectangles of known area. Length L can be estimated directly from a map for small areas. Large areas, however, must be divided into small basins, for which the distance of water travel to the point of discharge from the main area can be measured, and L computed by weighting according to the area of each subdivision. The median altitude can be computed by preparing a grid, on transparent paper, of squares representing areas of one quarter of a square mile or other convenient unit, laying this grid over the topographic map on which the basin is outlined, and estimating the average altitude of the area within each unit or fractional unit of area. The weighted average of these units will be the median altitude of the total area. The altitude of the outlet of the basin is subtracted from the median altitude to determine s.

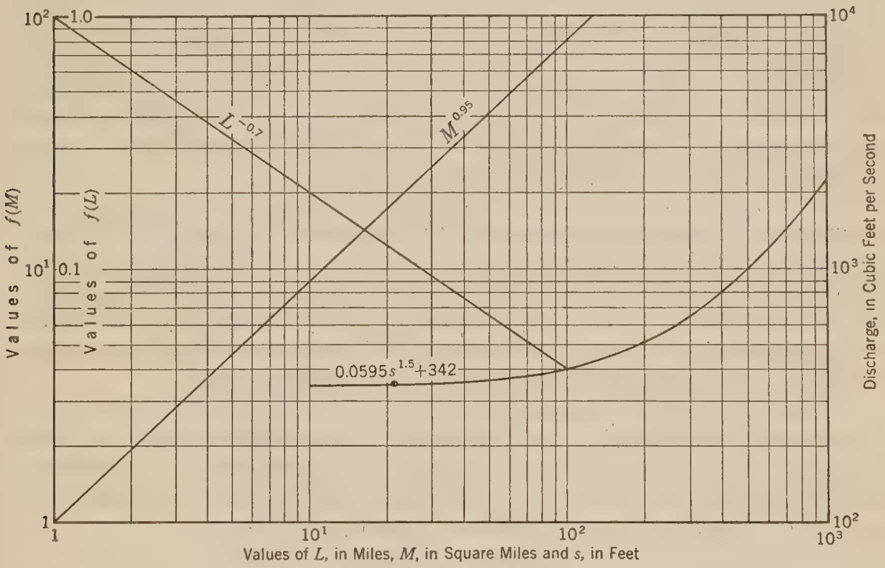

FIG. 13.—DIAGRAM FOR SOLVING EQ. 6c, THE FORMULA FOR RARE FLOODS

Fig. 13 is a diagram that can be used to determine peak discharges for rare floods. Similar diagrams can be prepared for other classes of floods, for convenience in computation.

CONCLUSIONS

The peak discharges of unit hydrographs increase as the peaks of the floods from which they were derived increase, and unit hydrographs developed from small floods should not be used without adjustment to compute the hydrographs of much larger floods.

Depths of runoff and the typical distribution of runoff can be combined with unit hydrographs to construct flood peaks that seem reasonably consistent with the frequency and magnitude of observed peaks. Depth of flood runoff does not vary appreciably with the size of drainage basin except for maximum floods, but it does increase with an increase in altitude, at least above 800 ft, and it decreases with an increase in the surface area of lakes and ponds.

Frequency curves of instantaneous peak discharges or of depths of runoff, even though they are based on 20 to 30 years of record, can be misleading, especially if the records contain one or two very large floods. The frequency curve of the Connecticut River based on 100 years of record was changed radically by the inclusion of the flood of 1936.[22] Studies of frequencies made from records prior to some of the disastrous floods of recent years would have indicated that such floods should never have occurred.

Flood peaks can be correlated sufficiently well with physical characteristics of drainage basins to determine the peaks for ungaged areas more accurately than they can be computed from general flood formulas which involve only the drainage area, or the two factors of drainage area and shape of basin. However, the formulas given in this paper are not applicable to all ranges of characteristics and they should not be used for drainage areas which differ widely in any important physical characteristic from the basins which were included in this study. The formulas should not be applied to a basin that contains a large amount of storage unless a careful study is made of the effects of such storage; nor should they be used for an area outside of Massachusetts without careful analysis of stream-flow data in that area.

Formulas of this type which contain the probable frequency as well as the magnitude of a flood provide a means of evaluating the chances that a hydraulic structure will fail. Any assumed or computed capacity of a hydraulic structure that will handle less than a maximum flood should be expected to involve some risk, however remote. No measure of probable frequency can forecast the particular time when an extreme flood will occur even though the average recurrence interval for this extreme flood were known accurately.

Stream-flow records are inadequate for computing major, rare, and maximum flood peaks directly, and extensions of these records cannot be made precisely. However, a reasonable basis has been developed for determining these peaks, and the computed peaks should be sufficiently accurate to be useful in the design of some hydraulic structures.

ACKNOWLEDGMENTS

The drainage basin characteristics, upon which much of the work in this study was based, were determined by the Work Projects Administration in the Boston office of the Geological Survey, by methods developed by the Division of Water Utilization of the Geological Survey, under the direction of R. W. Davenport, M. Am. Soc. C. E., chief.

The assistance of the Corps of Engineers, U. S. Army, in this study is gratefully acknowledged. This agency furnished many studies used in the investigation, including more than one hundred unit hydrographs, several frequency curves, and rainfall distribution and frequency data.

The material in this paper is drawn to a large extent from an unpublished report by the co-author, B. R. Colby, entitled "Flood Peaks on Massachusetts Streams." The study upon which this paper was based was conducted by Mr. Colby and others in the Boston office of the U. S. Geological Survey, under the direction of the co-author, H. B. Kinnison, district engineer. The writers are indebted to C. C. McDonald, Assoc. M. Am. Soc. C. E., for assistance in the preparation of this paper.

DISCUSSION

Clarence S. Jarvis,[23] M. Am. Soc. C. E.—If the many hours required for the writer to grope through the maze of interrelationships disclosed in this paper may be taken as an index of the authors' labor in exploring, analyzing, and then formulating the wealth of material in the paper, the profession has received the harvest of months if not years of earnest effort. Recognizing the practical value of the authors' masterly approach and the comparatively unique if not new relationships presented, the writer somewhat reluctantly undertakes to examine background or foundational features, to trace the derivations, and to analyze the adopted factors throughout the practicable range, thus introducing both alternate and divergent views regarding major as well as minor issues—all intended as constructive suggestions throughout.

Translation of the quantities listed in Cols. 3 and 9 to 12 in Table 1 into terms of percentage ratings according to the Modified Myers formula[4] (Eq. 1) readily discloses the following relationships:

1. Quantities listed in Table 2, proposed as a supplement to Table 1, form geometric series with the following characteristics—

(*a*) Percentage ratings for major peaks (Col. 10) are usually from 1.5 to 2.5 times those for minor peaks (Col. 9), averaging nearly 2.0.

(*b*) Corresponding ratios between percentages listed for rare peaks (Col. 11) and for major peaks (Col. 10) are usually from 1.5 to 2.0, averaging nearly 1.7.

(*c*) Between maximum peaks (Col. 12) and rare peaks (Col. 11), the ratios are usually from 3.2 to 4.2, averaging nearly 3.6.

(*d*) A notable degree of consistency pervades most of the series, manifested in a tendency to adhere either to average values or to above-average or below-average values throughout.

(*e*) Random selection of items for checking computations, mainly by log-log slide rule, resulted in satisfactory checks, within 3% or less, differences being partly attributable to the mechanics of the procedures and to cumulative errors.

(*f*) Considering all the factors concerned with flood frequencies and magnitudes, it seems advisable to re-examine all items in Table 1 with ratings according to the Modified Myers formula for "maximum" peaks (Col. 12) greater than 90%. Very few, if any, of these stations seem to deserve such high ratings according to the writer's interpretation of all available data pertinent to the locality involved.

2. Factors involved in Eqs. 6 have been platted in Fig. 14 on semilogarithmic paper throughout the practicable range for most rivers. To depict all the trends on a single drawing, it was necessary to convert the three fac-

[c] Maximum known peak discharges correspond to values in Col. 3, Table 1.

[d] Peak values computed from flood formulas (see Cols. 9 to 12, Table 1); percentage $= \frac{Q}{100\sqrt{M}}$, in which Q = peak discharge in cubic feet per second; M = drainage area in square miles (solved from a single setting of a slide rule per item).

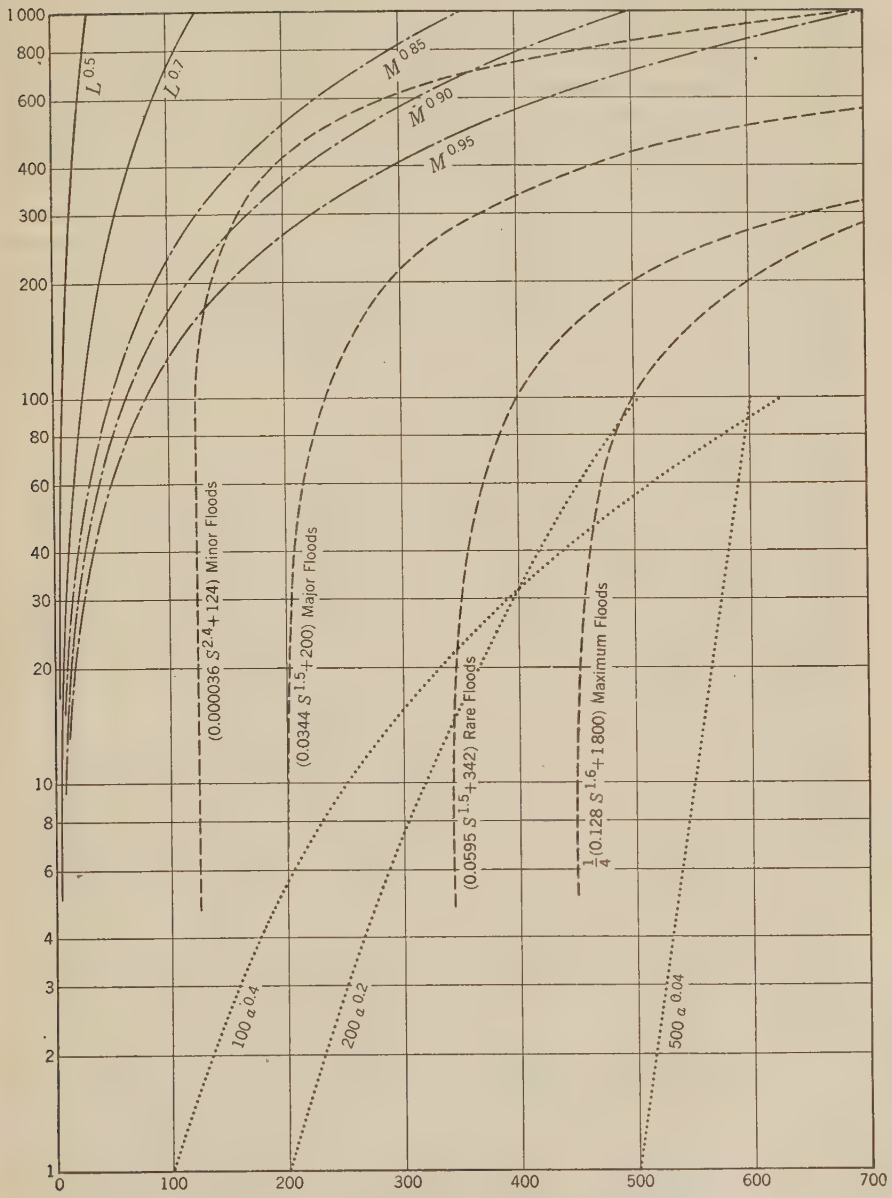

FIG. 14.—FLOOD FORMULA FACTORS

tors a, dealing with pondage to percentage values, by multiplying by 100. Furthermore, it was required to use another factor 5 for the authors' expression, to take best advantage of the chart space. The other two factors were suggested by the writer as more nearly expressive of the probable influence of pondage. It was also necessary to divide the quantities of the factor involving s in Eq. 6d by 4, to keep the right-hand curve within the limits of the drawing. The outstanding characteristics of curves relating to length of runoff travel, drainage area, and altitude above the outlet are increased curvature and divergence above 100.

3. The general form of Eqs. 6 with a fractional power of drainage area in the numerator and with a lesser power of runoff travel distance in the denominator seems to recall the derivation of the width[24] formula derived by C. R. Pettis, M. Am. Soc. C. E., directly from the Modified Myers formula,[4] Eq. 1. Through the introduction of a "compactness factor" Colonel Pettis obtained the expression,

$$Q = 328\,P\,W^{1.25} \qquad (7)$$

in which P represents the rainfall depth in inches for the critical or adopted period and W is the average width of the drainage basin in miles, or $\frac{M}{L}$.[25] (A review and summary of Colonel Pettis' paper is readily available.)

4. Within the ordinary range of observed drainage areas, where length is some multiple of the width, it is possible to convert the authors' fractional power of M divided by a lesser power of L to a power of W quite closely approaching that used by Colonel Pettis, with some advantage in the way of simplification, but with appropriate changes in coefficients.

5. With 681 station-years of record included for forty-eight items of Table 1, giving an average of 14.2 years per station and a maximum of 30 years per station, and with only four of the observed maxima exceeding the quantities listed in Col. 11 as "rare" (the amount of such excess being 25% or less), it is difficult to reconcile the idea of adding another 300% or more to attain the "maximum flood" as determined by the authors. Addition of 150% might well suffice.

6. Critically examining the various factors of Eqs. 6, graphically outlined in Fig. 14 (with such alterations as seemed essential to keep them within limits of the drawing), the following comments are submitted—

(*a*) The values of $L^{0.7}$ vary between 3.09 and 15.5 for 5 miles and 50 miles, respectively, or 77.5 for 500 miles. Thus, as the L-factor appears in the denominator of each formula, its influence would be such as to decrease flood peaks to 1/25 or 4% for such a range of variation. For the alternate Eq. 6b, with $L^{0.5}$ instead, the total range between 5 and 500 would be 10 instead of 25—a more readily defensible factor according to extensive records and observations.

---

[24] "A New Theory of River Flood Flow," by C. R. Pettis, 1927 (privately published).

[25] "Floods in the United States; Magnitude and Frequency," *Water-Supply Paper No. 771*, U. S. Geological Survey, 1936, pp. 36–37.

(*b*) The s-factor for minor floods, with added constant, amounts to 126.27 for 100 ft of altitude, or 137 for 200 ft, 237 for 500 ft, or 694 for 1,000 ft of altitude above the outlet. Thus, because of the influence of altitude in Eq. 6*a*, the flood peak is multiplied by a factor 5, in consequence of increased median altitude from 200 to 1,000 ft. All three of the other s-factors and associated constants run off the drawing before attaining an altitude of 600 ft. Their trends magnify the influence of altitude of drainage area above the outlet in a greater degree at 1,000 ft than has been noted for minor floods.

(*c*) The pondage factor, a, as used by the authors shows but slight variation between 1% and 5%, attaining a value of only 1.067 or 1.169 at 50%. In other words, the regulation afforded by ponds covering fully half of the drainage area would decrease the peak to 1/1.169 or 85.6% of its magnitude with no pondage. If the fractional power were 0.4 instead of 0.04, the corresponding values of the a-factor would become 1.90, 3.90, and 1/3.90 or 25.7%. This is more nearly in accord with the writer's experience, although 0.2 might serve somewhat better, with values of 1.38, 2.19, and 1/2.19 or 45.8%.

The proper scope of the authors' equations and formulas in this paper lies mainly if not entirely below 1,000 for both M and s—drainage area and median altitude above the outlet, respectively. Similarly, the width formula derived by Colonel Pettis was intended to serve primarily for drainage areas ranging from 1,000 to 10,000 sq miles; it occasionally served fairly well outside those limits, but more often wandered beyond control.

For many years the writer has striven for simplification of expression within the hydrologic field. One of the prime essentials seemed to be a formula capable of comparing the floods of either the Mississippi River or the Amazon River with the peaks of torrential floods at their headwaters, regardless of areal extent. Investigations covering several years led to a measure of approval and acceptance by the hydrologic and engineering profession, as demonstrated by a wide use of the square root of drainage area as a convenient first approximation to the influence of areal extent for the entire range above 4 to 7 sq miles. Essentially the same conclusion was reached as the result of a later investigation conducted by a committee of the Boston Society of Civil Engineers. This report laid some of the foundations for later development in the field of unit hydrographs, as has been tacitly acknowledged by the originators of that procedure.[26] For the usual form of drainage area, with length considerably greater than average width, introduction of the expression $\sqrt{M}$ may be regarded as equivalent to adopting the width as the governing dimension with either a coefficient or a power greater than unity; or it might be construed as being the same as using the dimension of length in the denominator, with either a coefficient or a power somewhat less than 1. These developments have been presented in considerable detail in some of the references in the paper, as well as in other publications deserving mention.[27,28,29,30,31,32,33]

---

[26] Report of Committee on Floods, *Journal*, Boston Soc. of Civ. Engrs., September, 1930, pp. 297 and 376–407.

In spite of the time-consuming mazes of complex computations involved in the authors' procedure and formulas, not to mention the occasional exceptions or divergences of opinion freely expressed by the writer as constructive suggestions, the entire investigation, together with its lucid presentation, is both profitable and enlightening to the profession. The concepts of basin characteristics for not only flood phenomena but also rainfall and runoff relations generally are not new. The late Emil Kuichling, M. Am. Soc. C. E., the late A. N. Talbot, Past-President and Hon. M. Am. Soc. C. E., Major Myers, and many other authors of formulas made special provision for accommodating the various factors throughout their probable range. The writer's modification of the Myers formula included extension of the range both above and below that originally suggested by Major Myers. The use of the Modified Myers formula is so simple and elementary as to deter its adoption by those who presumably seek the more abstruse and complicated forms. No matter how involved any preferred procedures, the results are readily translated into terms of Myers percentage ratings, as demonstrated by Table 2.

L. R. BEARD,[34] JUN. AM. SOC. C. E.—A phase of hydrology that deserves close attention from those interested in hydrologic design is treated in a practical manner in this paper. The Los Angeles (Calif.) office of the U. S. Engineer Department adapts the principles of the summation hydrograph (S-graph) as presented by Mr. Langbein[11] and Franklin F. Snyder,[35] Assoc. M. Am. Soc. C. E., for relating flood characteristics to drainage area characteristics. This relation is accomplished through the medium of "lag," which is a function similar to "time of concentration." Lag is related to the length and slope of the longest stream and the length of the stream up to the center of the drainage area. All other variations are considered negligible within a given runoff region.

The function of length used by the authors appears to be a much better measure of lag or other time functions than the length of the longest stream, which often is not a representative measure for the entire drainage system. It is interesting to note that the peak discharge of Eqs. 6*a*, 6*c*, and 6*d* is inversely proportional to the length raised to the 0.7 power. This result is in substantial agreement with Mr. Snyder's equation which relates the discharge inversely to the length raised to the 0.6 power, and is in slightly better agreement with studies made in the Los Angeles Engineer Office which relate the discharge to the length raised to the 0.76 power.

[35] "Synthetic Unit-Graphs," by Franklin F. Snyder, *Transactions*, Am. Geophysical Union, Pt. I, 1938, pp. 447–454.

The function of slope used by the authors also appears well chosen and should prove to represent the slope factor better than more simply computed functions. Although the slope factor is omitted in the ordinary application of the summation hydrograph, it is almost mandatory that a slope function be introduced into formulas that relate runoff and drainage area characteristics if such formulas are to have wide application. Heretofore, application of the S-graph has been restricted within relatively small hydrologic regions, within each of which the slope function probably does not vary sufficiently to affect results and has therefore been omitted. The lag equation derived by Mr. Snyder for Appalachian areas shows the lag to be several times as long as lags developed for Pacific slope areas where stream slopes are much greater. The slope factor should account in a large part for these discrepancies.

Variation of the shape of the unit hydrograph with flood magnitude is usually overlooked or avoided although its existence is reasonable to assume. The curves of Fig. 3 showing the relation between the peak of the unit hydrograph and peak runoff are in substantial agreement with the findings of R. L. Gregory and C. E. Arnold,[36] Assoc. Members, Am. Soc. C. E., who expressed the time of concentration as inversely proportional to the discharge raised to the one-fourth power. As stated by the authors in substantiation of the data shown in Fig. 5(*a*), the peak of the unit hydrograph is inversely proportional to the time of concentration or to lag. (E. P. Bennett, who has reviewed this discussion, has stated that this relation does not hold strictly unless the unit-rain interval is proportional to the lag. However, this relation is approximate for cases in which the unit-rain interval is short compared to the lag.) Thus, the peak of the unit hydrograph, in accordance with the equations of Messrs. Gregory and Arnold, should be directly proportional to the discharge raised to the one-fourth power, as approximated by the curves in Figs. 3(*a*), 3(*b*), 3(*c*), and 4. (Fig. 5(*b*) does not show this relation because factors other than flood discharge have an effect.) The incorporation of a function of discharge in lag equations may improve the relationships considerably, but, before application of the results shown in Figs. 3, 4, and 5, it should be ascertained whether subtraction of subsurface flows from observed hydrographs has involved sufficient error to affect the peaks of the unit graphs.

Those who work with rainfall and runoff frequency determinations for the Pacific slopes area are aware of the great variations of over-all runoff coefficients that might prevail. The curves of Figs. 1 and 2 are presented for illustration of the great variation of runoff magnitude compared to the variation of rainfall magnitude in some regions (which indicates that accuracy in the determination of rainfall magnitude does not necessarily result in accuracy in the derivation of runoff magnitude). Fig. 15 shows a duration curve of peak runoff for Big Bear Lake Dam, and Fig. 16 shows a duration curve of daily rainfall for the Santa Ana River near Mentone, Calif., which is in the tributary area above Mentone. Inasmuch as these curves are representative of hundreds of rainfall and runoff curves for the region, they serve to illustrate that the largest of 50 annual maximum occurrences of rainfall for any duration is usually about 110 times the smallest, whereas the largest of 50 annual maximum runoff occurrences is usually about 1,000 times the smallest. It is questionable whether such curves could be correlated by the analysis presented in this paper with as much accuracy as the accuracy of the duration curve of runoff.

---

[36] "Run-Off—Rational Run-Off Formulas," by R. L. Gregory and C. E. Arnold, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1058.

Regarding the great influence of rainfall-runoff relations and their erratic nature, an example will be cited. The most disastrous flood that ever struck Southern California was that of March, 1938. During that flood, hundreds of rainfall and runoff records were broken. In January, 1943, a storm occurred whose 24-hr rainfall set a record for the entire nation and which was from 30% to 50% greater than the 24-hr rainfall of the 1938 storm. However, mainly because of the difference in ground conditions, the greater storm of 1943 resulted in a comparatively small flood, which is not generally classed as a major flood.

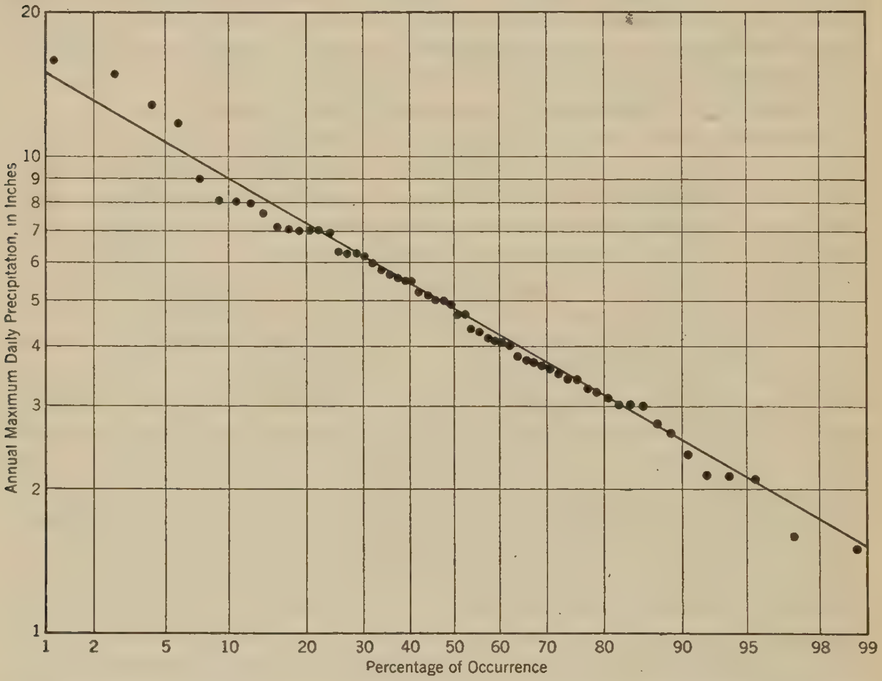

Fig. 15.—Duration Curve of Daily Precipitation, Big Bear Lake Dam; 1883–1944 (60 Years)

Of course, the over-all runoff coefficients in the Massachusetts area do not vary as much as those in Southern California, but it is possible that they do vary more than has become evident in the analysis and that curves C and D, Fig. 7, actually should agree more closely with curve A. It is not evident from the presentation just how reliable the precipitation curve of Fig. 6 may be, but it should be expected that errors of that curve and errors in rainfall-runoff relationships combine to produce the errors in curve D, Fig. 7. Curve C or D is not obviously more accurate than curve A. In fact, the occurrence, within a short period, of a flood in excess of the 1,000-yr value is so highly improbable as to cast serious doubt on the accuracy of curves C and D. The inaccuracy of curve B on this basis cannot be reasonably doubted. It would be helpful if the authors would include with their closing discussion the data that show the probability of a given depth of runoff being generated by a given depth of precipitation. Also, the criteria used in selecting 6-hr and 2-hr runoff amounts from the 72-hr volume have not been indicated.

The writer's only criticism of the analysis and results would be that the scope of the analysis might be too limited even for application within Massachusetts. Some manner of combining runoff records for the entire Atlantic coast of the United States and perhaps for some distance inland should yield results that not only would be more generally applicable but also would be more accurate for each small region as a result of the combination of many independent records. In the opinion of the writer, the advantage of resorting to rainfall-runoff analysis lies not in the superiority of rainfall data to runoff data but in that the results of such an analysis permit the combination and

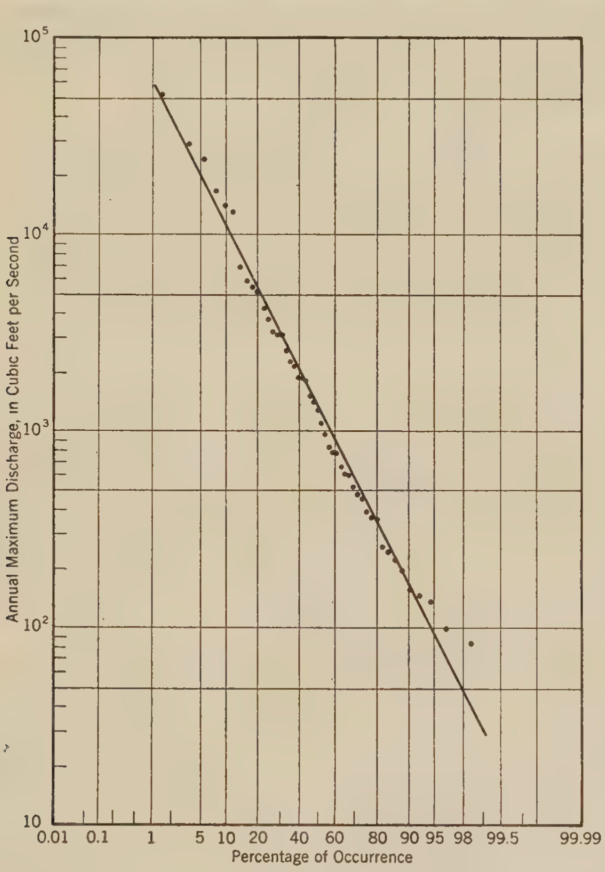

FIG. 16.—DURATION CURVE OF PEAK DISCHARGE, SANTA ANA RIVER NEAR MENTONE 1896–1943 (47 YEARS); 189 SQ MILES

correlation of runoff records. Extrapolation of individual runoff frequency curves by a study of rainfall is generally unsound because of the inadequate knowledge of the frequency variation of runoff factors and the effect of such variation on the runoff-frequency curve.

The analysis presented is straightforward and simple. It includes wisely chosen general expressions such as average elevation of an area (which includes the factors of soils, vegetal cover, temperature, and rainfall distribution) and size of area (which includes short-time variations in precipitation and diminution of average rainfall with size of area). The degree of "breakdown" into the various component factors can be too high, and often much simplified functions such as those used in this paper are adequate for application within a limited region.

M. J. ORD,[37] JUN. AM. SOC. C. E.—Flood characteristics of Massachusetts streams have been analyzed thoroughly in this paper. However, the writer questions the wisdom of presenting flood formulas based on what the authors admit to be inadequate basic data. Although limitations have been given to their formulas, once presented, such formulas are frequently used without considering their limitations. It might have been preferable to present the relationships in the form of curves together with plotted values to define the curves.

The minor, major, rare, and maximum floods given in Table 1 can be expressed as percentages of the major flood (see Table 3). In view of the fact that reasonably consistent and uniform rainfall and runoff factors were used in the development of the floods, the percentages for each magnitude flood developed by unit hydrographs should be expected to be reasonably uniform. The percentages for the minor and rare floods do show only a small variation—for the most part within 10% of the average percentage. The percentages for the maximum flood have a greater variation. The floods represented by the extreme variations should be questioned.

The average percentages for the minor, major, and rare floods (based on unit hydrographs) were plotted versus their probable recurrence intervals of 15, 100, and 1,000 years. The resulting curve is shown in Fig. 17. It is of interest to note that the percentage for the maximum flood has a recurrence interval of 1,000,000 years determined by a conservative extrapolation of the curve.

In Table 1 there are fourteen stations for which the maximum recorded flood exceeds the computed 100-yr flood. Such a condition is not reasonable considering the short period of record, without further evidence. More weight should have been given the 1936 and 1938 floods in determining the frequencies. Thus, the slope of the frequency curve should be increased. However, accepting the authors' probabilities of occurrences, Fig. 17 will give results as acceptable as those determined by the formulas presented by the authors, and it has the advantage of permitting the determination of a flood of any frequency once the 100-yr flood has been determined. The 100-yr flood can be determined by the authors' formula or, in the writer's opinion, preferably by unit hydrograph, assuming that the distribution of unit runoff amounts has been correctly defined.

---

[37] Engr., U. S. Engr. Dist., Los Angeles, Calif.

For areas having unknown rainfall-runoff relationships, synthetic unit hydrographs can be determined by any one of several methods. The writer prefers a method, developed by the Los Angeles Office of the U. S. Engineer Department, which is similar to that proposed by Mr. Snyder[35] and modified by Mr. Langbein.[11]

[a] See Fig. 10.

In this method "lag" is plotted against a factor $\frac{L \times L_{ca}}{S^{0.5}}$, in which L = length of the longest watercourse, in miles; L_{ca} = length along a watercourse, measured upstream, to a point opposite the center of area, in miles; and S = over-all slope of drainage area, in feet per mile. Lag is defined as the elapsed time (in hours) from the beginning of unit rainfall to the instant that the corresponding summation hydrograph reaches 50% of ultimate discharge. The summation hydrograph for a given stream at a given point is the hydrograph that would result from the application of the unit hydrograph for that location to a continuous uniform supply of effective rainfall over the tributary area. The **S**-graph, first introduced by Mr. Langbein,[11] is the summation hydrograph with the coordinates expressed in dimensionless form, with the discharge scale as a percentage of ultimate discharge, and with the time scale as a percentage of lag. With the lag curve and **S**-graph determined for a region, synthetic unit hydrographs can be developed easily for areas of unknown runoff characteristics from the factors L, L_{ca}, and S.

In the development of the lag relationship for mountain streams in Southern California, numerous physical characteristics were investigated, including values corresponding to M and L in the paper. The factor $\frac{L \times L_{ca}}{S^{0.5}}$ gave as satisfactory a correlation with lag as any combination of drainage basin characteristics and, in addition, had the advantage of simplicity of determination. For the mountain region of Southern California the improvement in the relationship resulting from introducing the slope factor S is small. The necessity for introducing the slope in the lag relationship is much more apparent in correlating the lag for areas of steep slope with those of gentle slope. A lag relationship applicable to all regions would probably be very complex. The factor of roughness n may be an important item, especially where there is a large variation in the hydraulic efficiency of the channels of different basins.

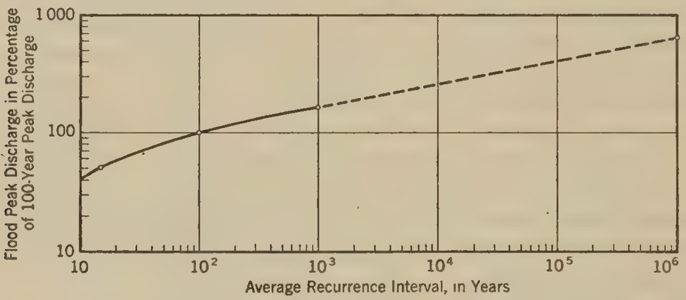

FIG. 17.—FREQUENCY CURVE OF FLOOD PEAKS, STREAMS IN MASSACHUSETTS

HOWARD M. TURNER,[38] M. AM. SOC. C. E.—The title of this interesting paper does not indicate the complete subject covered, because it omits the treatment of flood frequency which is a very interesting part. The authors have succeeded in deriving a set of formulas which take into account more characteristics of the drainage area than any others for river floods, and which show very good correlation with similar floods computed by unit hydrographs. These formulas should prove of great value for general use in regions similar to Massachusetts. Many problems arise, particularly on small drainage areas where there are not sufficient records for drawing unit hydrographs or where the problem does not justify a complete analysis. In such cases, formulas like these which take into account the factors that affect the shape of the unit hydrograph will be of great use.

The authors give the qualifications as to the use of these formulas in certain specific cases, emphasizing the fact that when there is a large storage the flood should be computed and then routed through the storage. It would be interesting to know whether they have tried to apply these formulas to any other rivers than those given in the paper and whether they consider the formulas limited to streams of less than 500 sq miles. It would seem probable that they may be generally applied to New England and similar regions, as well as Massachusetts.

---

[38] Cons. Engr., Boston, Mass.; Lecturer Water Power Eng., Harvard Univ., Cambridge, Mass.

These formulas cover four flood magnitudes described as minor, major, rare, and maximum and further defined as of 15-yr, 100-yr, 1,000-yr frequency and a maximum possible flood. Methods of computing flood frequency are open to great question due to the difficulty of extending the frequencies considered far beyond the normal records of the past. It is true that referring to floods as minor or major, rare or maximum, brings in a frequency element, but this is entirely different from assigning a definite period of years to a given sized flood. The authors recognize the unsatisfactory results of the usual methods of computation and the wide variation in results obtainable. They introduce a method of estimating frequency on a somewhat different basis from the usual figures, which are based on past records of peak flow extended by plotting or by some mathematical process.

The major differences in the authors' methods are the use of precipitation records and flood runoff figures instead of stream-flow records of peak floods to obtain frequency curves. This is, in effect, an adaptation of the rational method used for small areas. The writer believes that this method is a definite advance in the studies of flood frequency and should give more consistent results. There is, however, the same difficulty in the extension of records to periods many times in excess of their actual length and the handling of the records of major storms occurring in a short period.

There are also certain objections to the authors' method. The use of flood runoff rather than peak discharge has certain disadvantages—chiefly the question of what is to be included in the runoff for different floods. An example of this is the 1936 flood in New England where there were two peaks due to two storms, in part superimposed and combined with a large amount of melting snow. In theory, the runoff should be a better value by which to express the magnitude of floods as it would make floods on rivers with different characteristics much more comparable. By means of the unit hydrograph, flood runoff can be converted satisfactorily to peak flow, but this presupposes a normal flood due to a single storm without large base-flow complication often affected by runoff from melting snow.

It seems to the writer, also, that the use of precipitation records for frequency computation of flood flows is open to question. It is true that precipitation records are longer and thus serve better to establish frequency relations; but the other factors bring in another unknown which may more than offset the advantage of the long record—that is, the further question of the condition of the ground during any given storm. For example, there is the case of the 1936 flood cited, where the ground was frozen and the runoff from the rainfall was combined with a large runoff from melting snow. There was the 1927 flood in which two weeks of previous rainfall had filled up the level of the water in the ground; and on the other hand there is the large storm of September, 1932, in New England, which produced no serious floods, as it came after a long period without rain. The necessity of allowing the additional factor to cover the question of how much of a given storm runs off introduces an uncertainty which, it seems to the writer, more than makes up for the advantage of using the longer storm records instead of peak flood flow records.

In their use of the unit hydrograph to convert from the flood runoff to peak flow, the authors point out an interesting relation, indicating that the distribution graph should show a larger peak for large floods than for small floods. It would be advisable to investigate this further. The authors have found it so from the rivers they studied but it should be noted that these are all small rivers—with one exception less than 500 sq miles. It would be interesting to know whether they have made any study to see whether the same relation holds for larger rivers, and also whether this tendency is not greater on the smaller rivers and tends to increase as the size of the drainage area increases. The distribution graphs given in U. S. Geological Survey *Water-Supply Paper No. 772* [39] do not show this; but these are mostly for larger areas.

The authors' frequency data lead them to classify floods with definite figures of 15, 100, and 1,000 years for the minor, major, and rare floods. This frequency of the 15-yr flood can be determined definitely, and that for the 100-yr flood, fairly satisfactorily in many cases. There is no difficulty in the use of some maximum figures, provided the maximum is defined as in this paper. There is clearly an important flood value between the "major" floods of 100-yr frequency and the maximum flood. The authors have used a "1,000-yr flood" computed by their method.

It would be better to leave out the definite figure of 1,000 years and merely call the flood "rare." Frequency computations may help in obtaining comparable floods on the different rivers for these formulas as the authors have done, but other methods for obtaining comparable floods on different streams could be used. One would be on the basis of flood runoff—a rare flood could be expressed as one which produces the equivalent of a definite flood runoff of, say, 8 in. on 500 sq miles, with corresponding adjustment for larger or smaller areas; or the rare flood could be expressed in a percentage increase over the 100-yr flood, without using the definite 1,000-yr figure.

The difficulty with the 1,000-yr frequency, expressed as such, is that there are so many ways of computing frequencies. There is the authors', as given in this paper, besides numerous others, all of which give widely different results, depending not only on the method of estimating but also on the length or the period of the record, which is much more difficult. Thus, when the term "1,000-yr flood" is used, it really should be combined with the statement of how it is computed. For example, one should say, to be definite, the 1,000-yr flood according to Fuller, based on a 25-yr period, 1918–1943; or the 1,000-yr flood according to Hazen, based on a 100-yr record, 1843–1943.

Something of the difficulties involved in finding these frequency relations is shown in the paper itself. The curves in Fig. 12 show frequencies for the 1938 flood as follows: Millers River near Winchendon, 680 years; Middle

---

[39] "Studies of Relations of Rainfall and Run-Off in the United States," by W. G. Hoyt, *Water-Supply Paper No. 772*, U. S. Geological Survey, 1936.

Branch of Westfield River at Goss Heights, 1,000 years; and Housatonic River near Great Barrington, 25 years. This appears to be too wide a difference, even when the smaller rainfall on the latter area is considered.

Any one who has been through the work necessary to analyze the floods on any stream will realize the work that has gone into this paper. The authors are to be congratulated for their success in expressing the effect of the various characteristics of the drainage area on the flood peak in a formula of usable form. This should prove a valuable check on the other methods particularly where more or less special characteristics are involved.

BYRON O. MCCOY,[40] ASSOC. M. AM. SOC. C. E.—The formulas presented by the authors will be of much assistance to engineers in and around Massachusetts. A tremendous amount of time and effort has been expended on the method presented in this paper, and the engineering profession is fortunate in having this additional tool for its use. It would be desirable to make similar investigations in other states. Further correlation with other watershed characteristics may be disclosed in regions with soil, vegetal cover, temperature, and other conditions differing from those found in Massachusetts. As with all such empirical equations, it is well to observe the authors' caution that the formulas should not be applied where conditions are materially different from those on which the formulas are based.

The exponents applied to the various physical characteristics used in the formulas vary somewhat with frequency. To be entirely consistent, for a given watershed, the variation of magnitude with frequency should be a function of probabilities. It does not seem reasonable that the effect of drainage area or distance the water must travel should be less on the major flood than on the minor or rare floods.

The data on maximum possible floods are of much interest. As defined by the authors, the maximum flood is one (see heading, "Maximum Flood Runoff") "* * * that could not be exceeded under any possible * * * combination of circumstances." For all practical purposes it has a probability of occurrence of one only. As the authors state, a design based on (see heading, "Conclusions") "* * * less than a maximum flood should be expected to involve some risk * * *."

As an indication of the risk being assumed in present practice, Fig. 18 shows the probability of occurrence of the design flood for the Clarks Falls dam recently built on the Lamoille River in Vermont. The spillway drains an area, M, of 701 sq miles, with a median altitude above the dam, s, of 880 ft, and an average distance the runoff must travel, L, of 43 miles. It was assumed that the authors' formulas would apply, and the 15-yr, 100-yr, and 1,000-yr floods have been plotted in Fig. 18. A curve drawn through these three points and extended to become asymptotic to the maximum flood of 160,000 cu ft per sec at infinity indicates that the spillway design flood of 85,000 cu ft per sec has a probability of occurrence of about once in seven thousand years.

---

[40] With Charles T. Main, Inc., Boston, Mass.

The authors' method of deriving magnitude-frequency relations should prove very valuable. Heretofore, probability studies based on past records for a particular stream have been inadequate because they did not take into account the probability of occurrence on that stream of the requisite meteorological and hydrological conditions to produce a given flood.

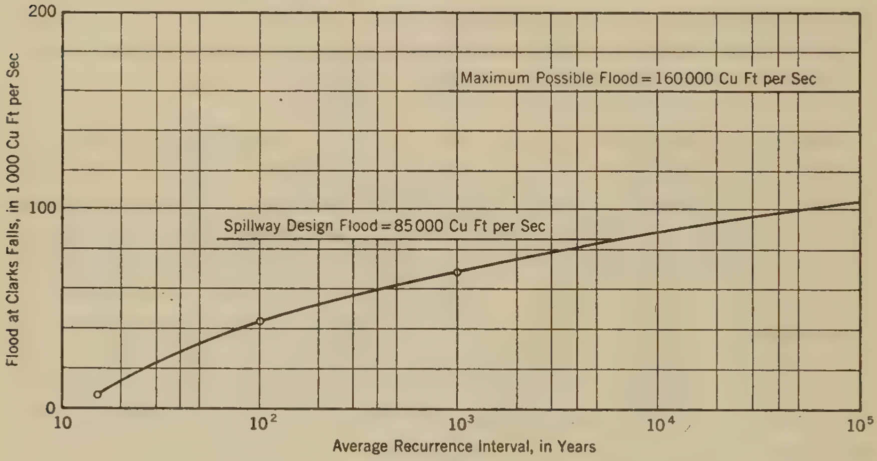

FIG. 18.—PROBABILITY OF OCCURRENCE OF CLARKS FALLS SPILLWAY DESIGN FLOOD BASED ON THE KINNISON AND COLBY FORMULAS

Magnitude-frequency relations are often used by the engineer to evaluate economic benefits of flood control projects; but, beyond a period of fifty years or so, the annual benefit becomes so small that additional expenditure for relief from such rare floods is usually difficult to justify on an economic basis. For floods of greater magnitude, the engineer becomes interested in the probability of occurrence—that is, the chances of occurrence, rather than frequency.

The authors have assumed that major floods and larger floods in Massachusetts will be caused by a 72-hr storm and that the chances of such a storm occurring over any drainage area in Massachusetts are one in one. They have also assumed that the chances are one in one that the distribution of runoff generation will follow the pattern they have used. Then, from the frequency, or probability, of a given rainfall and the probability of that rainfall producing a given runoff, the authors have obtained the probability of the resulting flood. The method is an important contribution in arriving at the true probability of occurrence of a given flood at a given station.

C. O. CLARK,[41] JUN. AM. SOC. C. E.—The expression of flood formulas in terms of drainage basin characteristics—a more comprehensive classification than drainage area—has been needed for many years. The authors' proposal that the unit hydrograph be used as a basis for the expression of flood experience is the soundest procedure yet available.

---

[41] Hydr. Engr., U. S. Engr. Office, Winchester, Va.

The authors' emphasis on the element of frequency is important. The contemplation of maximum possible floods is appropriate in extending the vision of planners to the magnitude of possible floods; but to regard such floods as truly the maximum possible is to ignore their derivation from actual rainfall and climatological data. It seems probable that, as more records of phenomenal rainfall are collected, estimates of maximum possible rainfall will be revised upward. Excellent as it is, the technique of estimating maximum possible rainfall is an infant whose horizon will be extended as it matures.

As the understanding of the possible magnitude increases, the impracticability of structural provision for it will become increasingly apparent, but the alternative of economic protection by insurance will remain, and more planners will turn to this alternative. With increasing demand for flood insurance will come a greater demand for flood formulas which express the probability of floods of various magnitude.

In applying the formulas in the paper to streams of unusual shape in Virginia and North Carolina, the writer found better correlation with the formulas for runoff depth (Eqs. 3, 4, and 5), than with the flood flow formulas (Eqs. 6*a*, 6*b*, and 6*c*). Some of the universal quality which the authors incorporated into their data by the use of unit hydrographs and runoff depths may have been lost in the later attempt to express results in terms of so few variables. The data as presented may be wholly adequate for the expression of New England flood experience. The following comments are intended to suggest a technique by which the data could be presented in a manner more easily applicable to wider geographic areas, and by which some of the influences which the authors examined but were unable to analyze possibly could be expressed.

The authors' presentation of flood formulas in terms of drainage basin characteristics and probability (or frequency) of occurrence involves combining several logical elements in the analysis. Some of these elements are much stronger than others; one appears weak. Perhaps separation of the elements will allow a stronger recombination with less dependence on the weaker elements. Basically, the logical elements appear to be:

(*a*) The expression of relative flood size for various frequencies in terms of the frequency of runoff volume—

1. Assuming runoff to vary in proportion to the combined flood experience of some streams;
2. Assuming frequency of recorded point rainfall to be indicative of frequency of flood-producing rainfall on an area and indicative of runoff volume frequency;
3. Assuming a constant chronological sequence of this rainfall or runoff to be equally critical on all watersheds;
4. Assuming runoff volume to be uniformly distributed over the watershed; and

5. Assuming variation of the runoff volume with watershed characteristics.

(*b*) The expression of the flood characteristically produced by a watershed from a given amount of runoff, in the unit hydrograph, assuming that this element is not constant but that the peak flow per unit volume increases with total runoff volume.

(*c*) The expression of the flood peaks of probable expectancy as the product of elements (*a*) and (*b*).

(*d*) The expression of element (*c*) as a flood discharge formula in terms of characteristics of drainage area.

The writer is in accord with the basic elements (*a*), (*b*), and (*c*). Possibly these steps could be strengthened if dependence on some of their subelements could be increased and extended and that on others reduced. Thus, element (*a*)1 has a basis in provable flood experience which makes it a very strong factor, whereas element (*a*)5 is likely to be obscured by many other influences and to require considerable data to prove its nature conclusively. The writer proposes to extend these logical uses by discussion and examples.

Element (*d*) tries to correlate variation in element (*c*) with watershed characteristics. This attempt can be no more successful than an expression of the unit hydrograph in terms of watershed characteristics. The writer's attempts at the latter have been only moderately useful when utilizing a graphical expression of watershed shape and depressingly inadequate if confined to terms of slope, watershed area, and watershed length—the authors' selected variables. The authors have clearly indicated the difficulties of simple correlation of flood peaks and watershed characteristics.

The writer proposes to abandon element (*d*) and to express element (*c*) as a multiple of the peak of the unit hydrograph, leaving the user free to adapt the unit hydrograph of his particular stream. This proposal is based upon the writer's experience that unit hydrographs are secured rather easily from records if time and cost permit; that, even when developed from short records, such unit hydrographs are more consistently reliable than if developed by any method of synthesis known to the writer; and that, if the flood producing characteristic of a watershed must be expressed from topographic maps, there are means available which exceed in accuracy any expression possible in terms only of s, M, and L. However, it appears that the authors have collected considerable data on watershed characteristics and unit hydrographs. Direct correlation of unit hydrograph peak with watershed characteristics may be possible. Such correlation is highly desirable, and, if possible, it would help to solve both this problem and many related problems depending on synthesis of the unit hydrograph.

The proposed modified expression would parallel the foregoing logical theory, but would place slightly different emphasis on some elements, thus:

(*A*) Relative flood size for various frequencies would be expressed in terms of frequencies of runoff volumes equal, or equivalent in peak flow produced, to multiples of a uniformly distributed unit volume generated in unit time:

1. Although this definition does not exclude the use of the applicable assumptions of element (*a*) in the authors' procedure, it by-passes numerous controversies regarding the absolute truth of these assumptions by including equivalents as well as equalities.
2. There is an opportunity to include the authors' variation of peak of unit hydrograph as the equivalent of a larger volume of runoff, and thereby to avoid the controversies between those who attribute the variation in actual flood peaks to variation in the unit hydrograph and those who attribute it to intensification and concentration of runoff volume as compared to the assumption of uniformity in unit hydrograph theory. Regardless of the merit of either viewpoint, a distinction is not essential to the problem at hand.

(*B*) The flood peak characteristically produced by a watershed would be that resulting from uniformly distributed unit volume generated in unit time.

(*C*) This would be the same as element (*c*) in the authors' procedure.

In deriving element (*A*), the authors' use of combined actual stream-flow records may be extended to include more records of similar streams, because the peak flows may be known, even though the records may not be complete enough to define the actual flood volume. The question of similarity may be perplexing, and any one can propound elements of hypothetical dissimilarity, whose influence may be easily exaggerated. The writer's technique is to assume simplicity and similarity until the preponderance of evidence indicates otherwise. Thus, it may be desirable to combine all or most data available as a single record, assuming similarity, and later to analyze smaller groups of data of more definite similarity in a particular characteristic to ascertain if that particular characteristic is significant. Thus, a large group of streams all sheltered by mountain ranges over 2,500 ft in elevation might be found to experience records 25% lower than the mean of all data. However, it takes many records to prove this kind of variation conclusively. It must be remembered that the casting of three 7's in succession is not proof that dice are loaded.

In illustration of the simplified technique, an analysis of 834 flood occurrences is presented. The aggregate record totals 734 years, collected at 56 recording stream gaging stations in the adjacent watersheds of the Potomac, James, and Roanoke rivers. The stations are listed in Table 4. All these major watersheds drain some part of Virginia east of the Allegheny Mountains. The largest stream included is the Potomac River at Point of Rocks, Md., with a watershed of 9,651 sq miles, and the smallest is Georges Creek at Franklin, Md., with a watershed of 72 sq miles. This very large range in drainage area has been included in one analysis to bring out the possibilities of this form of analysis. The group of data is then subdivided into lesser groups

TABLE 4.—FLOODS OF THE MIDDLE ATLANTIC SLOPE RIVERS

Stream	Watershed				Unit flood peak[c] (cu ft per sec)	Flood Record			
	Station	Drainage area (sq miles)	Length[a] (miles)	Fall[b] (ft per mile)		Years	Flood Ratios[d]		
							Largest	Number[e]	Number per year
Shenandoah River	Millville, W. Va.	3,040	197	5.8	37,800	28.8	6.09	23	0.80

[a] Total length of longest low water flow path. [b] Uniform slope of profile along longest flow path which would have same area under profile and above low water elevation at gage. [c] Peak discharge for 1.0-in. runoff generated uniformly in 6 hours. [d] Discharges of actual floods in analyzed record in ratio to unit flood peak. [e] Number of floods analyzed in excess of 0.9 unit peak. [f] Prior to record analyzed, flood of September 30, 1870 (relatively the largest known flood at any of the stations analyzed), reached a flow estimated as 8.0 times unit flood peak.

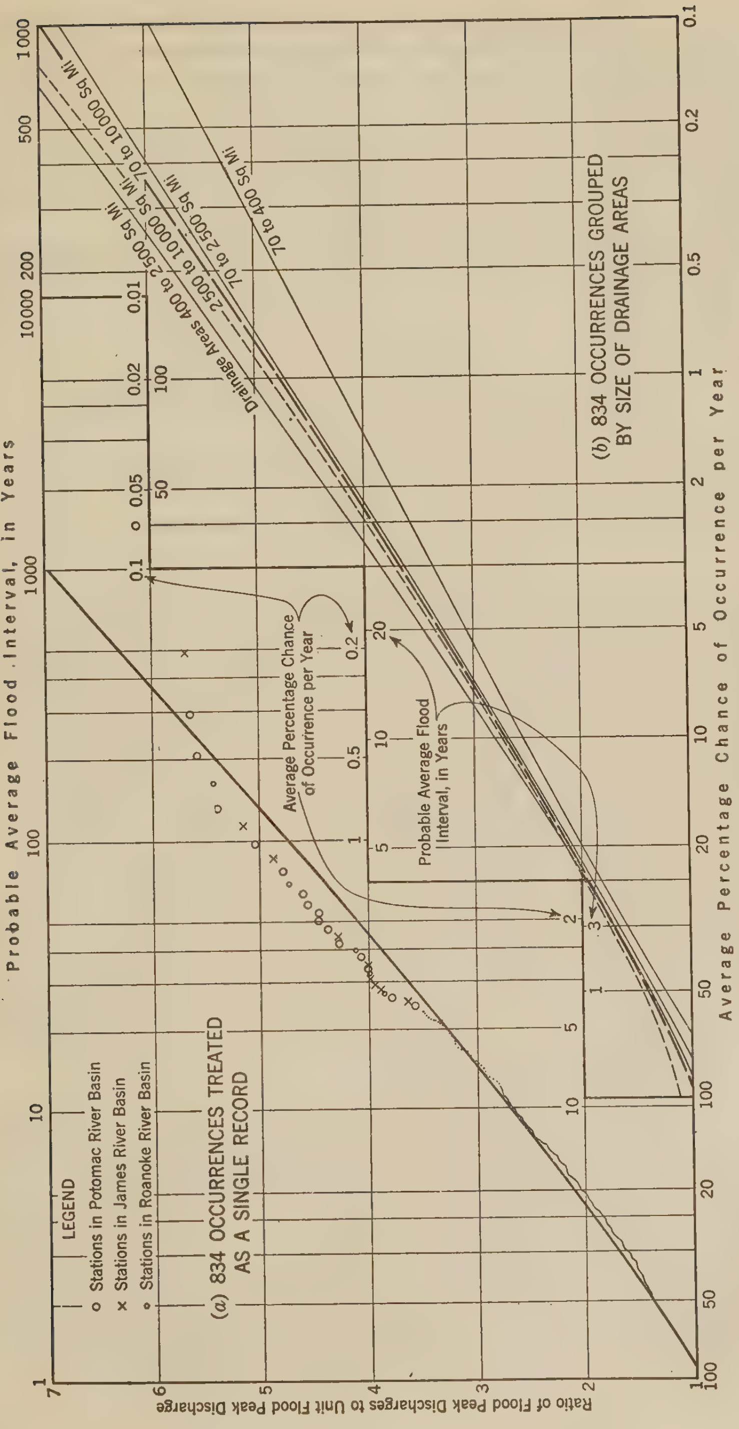

FIG. 19.—FLOOD FREQUENCIES, POTOMAC, JAMES, AND ROANOKE RIVERS, FOR DRAINAGE AREAS OF FROM 70 SQ MILES TO 10,000 SQ MILES

of more similar drainage area in an attempt to determine whether drainage area alone is a significant variable affecting relative frequency of floods.

In each analysis all peak flood discharge occurrences have been listed in order of the magnitude of the ratio by which they exceed the peak flow produced by 1.0 in. of runoff uniformly generated over the drainage area at a uniform rate during a period of 6 hours. These 834 flood ratios in descending order have been treated as a single record of 734 years in the determination of the frequency curve shown in Fig. 19(*a*).

The use of the frequency curve shown to determine flood discharge frequency on any particular small stream in the same region would involve several assumptions, namely:

I. That the frequency with which the unit flood discharge is exceeded on small watersheds is the same as that for the average of all watershed sizes in the region;
II. That the effects of other drainage area characteristics are the same as for the averages of all watersheds; and
III. That, in the region, the peak of the unit hydrograph of a single stream can be determined with suitable accuracy.

One should maintain an open mind regarding the accuracy of an hypothesis, such as assumption I, and demonstrate its correctness when the sample of data becomes large enough to be conclusive. The writer has never worked with a single flood record long enough to support a conclusive judgment. However, analysis of smaller groups of aggregate records from more assuredly similar watersheds may be qualitatively indicative. Size of drainage area alone was studied in five analyses, the results of which are represented in Fig. 19(*b*). In these analyses, the aforementioned record of 834 occurrences was divided into groups of more nearly similar watershed area as indicated in Fig. 19(*b*).

A spread in the curves results. This spread is no greater than that commonly experienced in the analysis of flood records for a single station. Furthermore, relative size in the rare frequency range does not increase or decrease consistently with increasing area, although a consistent trend does appear in the range of 1-yr to 5-yr floods. Until a contrary theory is demonstrated conclusively, the influence of watershed area would be regarded as negligible, except in the range of very frequent floods where flows would tend to be more nearly proportional to watershed area.

The accuracy of the similar assumptions with regard to other watershed characteristics might be checked similarly. An illustrative application to the aforementioned data is prohibited by the labor of evaluating the factors. However, since the authors have already evaluated more factors than they were able to report in their flood formulas, they may find re-examination of their data feasible.

Exact determination of the peak of the unit hydrograph of a single stream is not as simple as much published material might appear to indicate. As the authors have shown, different investigators using the same data will not agree, and investigators using different data from the same stream or different methods of analysis may reach quite different conclusions. Much of the variation is random in character and therefore tends to average in the analysis of a large number of streams.

The results of a general analysis like the foregoing, which is applied to a single stream, would embody any errors that might be involved in determining that particular unit hydrograph peak, and should be checked accordingly. If the record of the single stream were long enough to establish a reasonably accurate 10-yr flood, the relative size of rarer floods in proportion to the decennial flood might be used instead of the proportion of rarer floods to the unit flood. This would be tantamount to revision of the unit hydrograph peak by such an amount as would make the actual 10-yr flood and the computed 10-yr flood agree. Judgment would decide whether such an adjustment should be made. The writer knows no acceptable criterion for determining the amount of variation from mean flood experience which can occur without a stream being conclusively indicated as an exception to a stated probability law. Some records of 60 to 100 years show 10-yr periods deviating by 400% from the mean flood experience of the entire period; that is, four 10-yr floods when one would be normal for 10 years.

Some adjustment of the type mentioned in the preceding paragraphs is necessary when comparing conclusions of different investigators. Table 5 shows a comparison of frequency curves for the Middle Branch of Westfield River at Goss Heights; that is, Fig. 12 is compared with data that would develop from the frequency study of Fig. 19(*a*) (70 to 10,000 sq miles) adjusted to make the 10-yr values agree.

TABLE 5.—COMPARISON OF FREQUENCY CURVES FOR THE MIDDLE BRANCH OF THE WESTFIELD RIVER

No.	Description	Average Recurrence Interval, in Years							
		1	2	5	10	20	50	100	1,000
	Ratio of Flood Discharge; from Fig. 19(*a*):								
1	To unit flood	0.95	1.40	2.08	2.68	3.28	4.10	4.75	6.95
2	To decennial flood	0.34	0.52	0.78	1.00	1.22	1.53	1.77	2.60
	Discharge, in Cubic Feet per Second:								
3	From Fig. 19(*a*)	2,100	3,100	4,700	6,000	7,300	9,200	11,000	16,000
4	From Fig. 12	2,600	3,400	4,800	6,000	7,400	9,700	12,000	20,000

The agreement in lines 3 and 4, Table 5, is much closer than the writer had expected. However, this illustrates the fact that conclusions of many independent investigators may agree much more nearly than the techniques or assumptions that the investigators might use to reach the conclusions. For this reason the writer does not like to argue about the validity of many individual hydrological concepts and premises. Few conclusions depend on one such concept; most depend on the combination of many. Divergent theories about one premise are counterbalanced by opinionated variations on the opposite side. The writer belongs to a school of thought which denies the validity of unit hydrograph peak variation with volume of runoff and, without intending to criticize the authors' excellent analyses, he attributes such indications to an inherent fallacy in a very commonly used method for the derivation of unit graphs and to the common neglect of nonuniformity of runoff distribution in the derivation and use of unit graphs. On the other hand, his techniques for analyzing the nonuniformity of areal distribution and runoff factors are extensive. In any actual use, both techniques would be used together and seasoned with the advocates' judgment and experience. The results would be compared with a record. Presumably, neither the authors' nor the writer's analyses would agree with the record exactly, although both might be acceptably close.

Hydrology and the hydraulics of natural stream flow are complex, interrelated phenomena, too involved for practical use or exact understanding. As a result, most analyses are oversimplified explanations of an observed phenomenon in terms of a limited number of mentally conceived rational premises. The exact truths of the premises cannot be demonstrated, since only a combined result can be observed. Thus, the combination of rational concepts is the yardstick by which an individual calibrates his own judgment.

Papers of this kind present a yardstick for comparisons with other similar standards. If all yardsticks are the correct length, it is frequently presumptuous to argue the merit of the pieces. Sometimes, however, through such argument, one discovers that what he thought was an essential piece of his yardstick is either a useless piece hanging on the side, or an unnecessary piece that has been put in at one end and taken off at the other and thus adds only dead weight to the whole.

If this modified analysis is as appropriate when applied to New England stream flow records as when developed from records elsewhere, it will indicate that the same conclusions could have been reached without use of rainfall records or conversions of rainfall to runoff. It would then raise the question: "Are the premises which deal with these elements really part of the yardstick or are they computationally just extra pieces which went into the derivation at one place and out at another without really influencing the answer?"

H. B. KINNISON,[42] M. AM. SOC. C. E., AND B. R. COLBY,[43] ESQ.—The excellent discussions of this paper are deeply appreciated, and they strengthen the writers' belief that the study of the frequency and magnitude of floods should have the best efforts of many hydraulic engineers. Although records of stream flow are much more numerous than they were only a few years ago, they still are inadequate for most types of investigations; and, therefore, differences of opinion and divergent results are to be expected. The writers hope that the paper and the discussions are a constructive contribution to the field of flood studies.

The discussion by Mr. Jarvis presents a comparison between the Modified Myers formula and the writers' formulas, and states that "No matter how involved any preferred procedures, the results are readily translated into terms of Myers percentage ratings, as demonstrated by Table 2." The form of the equation, $Q = C_m \sqrt{M}$, makes it possible to convert the results of any procedure which arrives at a value of Q into a percentage rating, as the percentage rating becomes the only unknown. However, the very fact that the percentage ratings in Table 2 show so wide a variation for a flood of a given magnitude is an indication of the limitations of this type of formula. For instance, for "rare floods," the percentage rating varies from 5.4 to 51.0; and, in relation to the highest observed flood, the "rare flood" varies from 81% to more than 300% for those streams having more than 10 years of record. The engineer faced with the problem of choosing a reasonable percentage rating for a particular stream must seek another procedure rather than the Modified Myers formula to properly evaluate the flood-producing characteristics of that stream. Unit hydrographs of streams with the same drainage area show wide divergence in peak discharge, even though the basins may be adjacent to each other. The writers' formulas were developed in an attempt to evaluate the effect of those physical characteristics which cause so much divergence in the flood peaks.

---

[42] Dist. Engr., U. S. Dept. of Interior, Geological Survey, Boston, Mass.

[43] Associate Engr., U. S. Dept. of Interior, Geological Survey, Iowa City, Iowa.

In Table 2, Mr. Jarvis has given the computed peaks of the minor, major, rare, and maximum floods in percentage ratings based on the Modified Myers formula. He concluded from this table that the maximum flood peaks are too high. Mr. Clark states that they are probably too low. The maximum flood peak as defined in the paper has an infinite recurrence interval, or a probability of occurrence approaching zero. It is a computed peak representing the upper limit of possible peaks. Because ratings computed from the Modified Myers formula have been derived almost entirely from observed flood peaks or for peaks of probable or design floods, ratings computed for maximum peaks will naturally seem to be very high. The maximum peaks in Table 2 that have percentage ratings greater than 90% are not inconsistent with the other maximum peaks. They are all of the same order of magnitude in that they have the same periodicity. The largest percentage for a maximum peak (right-hand half of Col. 12, Table 2) is only 8.1 times the smallest percentage for a maximum peak; but the largest percentage for a minor peak (right-hand half of Col. 9, Table 2) is 13.2 times the smallest percentage for a minor peak.

If Mr. Jarvis means that the maximum probable flood peak should be about 150% of the rare flood peak, the writers agree that this would be a reasonable assumption. As stated in the paragraph preceding the heading, "Physical Characteristics," the peak discharge of the maximum probable summer flood might be "about 45% of the peak discharge of the maximum flood."

Mr. Jarvis found from his analysis that the formulas should not be applied to basins having characteristics that differ widely in any important physical characteristic from the basins used in the study. This limitation agrees with the stated conclusions of the writers. They are indebted to Mr. Jarvis for stressing this fact.

In his criticism of the factors included in Eq. 6, Mr. Jarvis has misinterpreted the effect of different physical characteristics on computed flood peaks, and his criticism of the use of L and a in Eq. 6 is not valid. The effect of the characteristic L on computed flood peaks must be considered in relation to the changes in other characteristics which are normally associated with changes in L. Similarly, any variation in the pondage factor a is invariably associated with changes in the slope factor s, and usually with changes in L, at least in central New England where the formulas are considered applicable.

Entirely different formulas might have been developed on the basis of Mr. Jarvis' assumptions. However, the writers preferred to develop formulas from relationships which were indicated by the basic data, and which fit the data for this particular locality closely.

The original report of the study on which the paper was based (see "Acknowledgments") was prepared for use in Massachusetts and possibly in some adjoining areas. When the paper was prepared for wider circulation, some changes might have been made. As Mr. Ord suggests, the formulas, from the original report, might well have been shown by graphs. Also, a discussion of the floods of March, 1936, and September, 1938, should have been included, so that any one not familiar with these floods on Massachusetts streams would not have questioned the fact that these were greater floods than would normally occur during the short period covered by gaging station records.

Mr. McCoy's observation that the exponents and coefficients in the formulas should be consistent for different classes of floods is a logical one. In determining the effects of the various characteristics, each of the four classes of floods was considered separately, and correlations indicated by the basic data were used without adjustment. The writers felt that, because of the limited knowledge of the influence of each characteristic, complete dependence should be placed on the basic data.

Mr. Beard and others question the accuracy of curves C and D in Fig. 7. These curves are not well defined, but they are based on logical extensions of the available data. Discussion of the derivation of these curves was considered much too lengthy to be given in the paper. However, it should be understood that runoff coefficients were not confined to a narrow range. For example, precipitation in the range from 5.6 in. to 6.0 in. (the range was expressed to the nearest tenth of an inch) was found to have about one chance in seven of generating less than 1.0 in. of runoff. Under extreme conditions of precipitation falling on snow cover, precipitation was assumed to have less than one chance in one thousand of generating more than 10 in. of runoff.

Depth of runoff was not determined solely from curve D which was based directly on incompletely defined relations between rainfall and runoff. The basis for the depths of runoff that were finally used is stated in the paragraph preceding the heading, "Maximum Flood Runoff."

In Table 3, Mr. Ord lists the minor, rare, and maximum flood peaks in percentages of the major flood peaks. Fig. 17, showing a curve drawn through the average percentages for each class of flood peak, is interesting and could be used to compute flood peaks having other recurrence intervals after the major flood peak had been computed. However, the writers do not agree that flood peaks computed from this type of average curve would be as accurate as flood peaks computed from the frequency curves for individual drainage areas. Although most frequency curves for basins in the same region probably should be approximately parallel when drawn on logarithmic paper, each one is not necessarily parallel to all the others. Also, the use of an average curve seems to be inconsistent with the suggestion made by Mr. Ord that the floods of March, 1936, and of September, 1938, should have been given more weight in the study. Figs. 1 and 11 show how difficult it would be to draw parallel curves for the three basins if much emphasis were given to the floods of March, 1936, and of September, 1938.

Mr. Ord states, "The percentages for the maximum flood have a greater variation." He then adopts the doubtful assumption that those maximum peaks which show the extreme variations from the average should be questioned. The maximum flood peaks have a greater variation only because the maximum flood peaks are farthest from the major flood peaks, which Mr. Ord makes coincide. If the maximum flood peaks were made to coincide, the peaks of the minor floods would have had the greatest variation. Table 2 shows that the ratio of the highest to the lowest maximum flood peak is less than the corresponding ratio for any other class of flood peak.

Mr. Clark and Mr. Ord prefer to make the unit hydrograph a direct basis for computations of expected flood peaks. That is a logical procedure, and the study reported in the paper was begun on a similar plan, but that plan was soon abandoned. The computed unit hydrograph is an imperfect foundation on which to build. As Mr. Clark states, the unit hydrographs obtained by investigators using different methods may not agree. For flashy streams, the peaks of the unit hydrographs computed by the same person from several flood hydrographs may differ widely. Also (on Massachusetts streams at least), the peaks of computed unit hydrographs vary with the depth of runoff. Publication of depths of runoff to be used with unit hydrographs computed by other engineers might lead to very inaccurate computations of flood peaks. Besides convenience of application, the correlation of computed peaks for each class of flood with the physical characteristics of drainage areas has the advantage of insuring at least a consistent computation and the use of unit hydrographs. Also, the peaks of floods computed from unit hydrographs having sharp peaks are not as variable as the peaks of the unit hydrographs.

The writers were reluctant, as is Mr. Turner, to assign numerical recurrence intervals to the different classes of floods because of the accuracy which numerical intervals connote. However, adjective ratings alone are indefinite and would have a wide range of interpretation. Also, some assumption of recurrence intervals was needed for plotting. Hence, numerical ratings were used as a means of precise definition only. The computed flood peaks are approximations of the peaks of floods having the definite recurrence intervals. The writers hope that the flood peaks will be understood according to these definitions.

It should be recognized that the formulas have been derived from a study of runoff from areas of less than 500 sq miles and have not been tested on larger areas. They should not be applied to drainage areas having significant physical characteristics which differ materially from those on which this study has been made, or to localities affected by storms of a different character than those in Massachusetts. Computed flood flows should be routed carefully through storage in the basin if the storage is extensive or is so located that it has an appreciable effect upon the flood peak. Before the formulas are used for areas some distance from Massachusetts, an adequate study should be made to determine their applicability. It is hoped that the method can be used in the derivation of similar formulas for other areas and, possibly, eventually for the derivation of more satisfactory formulas for general application.

ANALYSIS OF THE GENERAL TWO-DIMENSIONAL FRAMEWORK

By Yves Nubar,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Leon Beskin, Jaroslav Polivka, A. A. Eremin, and Yves Nubar.

Synopsis

A method is presented for the analysis of displacements and stresses in the general two-dimensional framework composed of rectilinear members, subjected to loading and displacement in its own plane. The joints may be articulated or rigid, or they may be a combination of such types.

The analysis is characterized by the division or decomposition of the frame into triangular elements by means of imaginary diagonals and the consideration of the axial deformations of the bars (given or imaginary) of the resulting network.

The technical literature contains descriptions of many excellent methods for the analysis of frames, some of which deal with specialized types. Most of them can be loosely classified as being based on one of the following concepts: Least work, slope deflection, fixed points, moment distribution, angle distribution, etc. The method developed in this paper has a semi-geometric basis. It is applicable to simple structures, as well as to complex systems of straight lines meeting at joints to form panels of arbitrary shape. Its value consists perhaps in the development of certain inherent properties of the general framework, helpful in the systematization of the analysis. This tends to unify, under one consistent procedure, the method of approach in a number of superficially unrelated problems, such as, for instance, the determination of deflections in a hinged truss and of moments in a rigid frame.

The application of the method is illustrated by several practical cases.

Introduction

General Description.—In this analysis, the frame is first decomposed completely into triangular elements by means of imaginary diagonals, in an arbi-

---

Note.—Published in April, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Cons. Engr., New York, N. Y.

trary but simple fashion (see dotted lines in Fig. 1). These diagonals may be conceived as infinitely thin wires stretched between the joints, carrying infinitesimal forces, but undergoing finite axial strains as a result of the deformation of the frame. The axial strains of the given members and those of the imaginary diagonals are taken as the unknowns, with the understanding that the axial strains in given or imaginary members joining supports are equivalently written in terms of the linear movements of the supports. These elements determine the relative positions of all deflected joints and supports and lead to the solution of stresses. The number of these unknowns is greatly reduced in the case (frequent in problems on rigid frames) in which the axial deformations of the given members are assumed to be negligible and the linear movements of the supports are prevented.

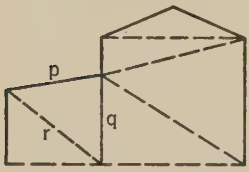

FIG. 1

The following is an outline of the procedure of the analysis:

A.—Since closed circuits must remain so after deformation, conditions of compatibility must be satisfied by the axial and lateral strains of the sides of all closed circuits. For triangular elements such as $p\ q\ r$ of Fig. 1, these conditions are written in a form involving the axial strains of the three sides and the difference $\delta_p - \delta_q$ (expressed as δ_{p-q} in this paper) between the lateral strains δ_p and δ_q of any two of them. The axial strains, adopted as unknowns in this analysis, may be interdependent; this follows from restrictions imposed by the compatibility conditions. These conditions lead to the following results:

(*a*) Expression of elements δ_{p-q} in terms of the unknowns;
(*b*) Determination of the relative displacement of any two joints of the frame in terms of the unknowns; and
(*c*) Reduction of the unknowns to a minimum number of them which are independent.

B.—Relationships between the dependent and independent unknowns are developed through a study of the topological properties of the general frame. (Topology is defined by R. Courant and H. E. Robbins[2] as "the study of the properties of geometrical figures that persist even when the figures are subjected to deformations so drastic that all their metric and projective properties are lost." In a framework, the numbers of members, joints, regions, etc., are thus topological elements, and relations between them represent topological properties of the framework.) Such a study discloses the degree of freedom of the frame in joint displacements and relates it to the number of independent axial strains.

C.—The boundary conditions are translated into relations which exclude the support reactions and involve the unknowns of this analysis.

D.—All end moments (and consequently tranverse end forces) are expressed, by means of recurrence formulas, in terms of δ_{p-q}; that is, in terms of the independent unknowns (see A(*a*) and A(*c*)).

---

[2] "What is Mathematics?" by Richard Courant and Herbert E. Robbins, Oxford Univ. Press, London and New York, p. 235.

E.—The independent unknowns are determined. This results from the consideration of a conjugate frame obtained by removing all bars corresponding to dependent unknowns (see A(*c*)) and substituting hinges for all the joints. This conjugate frame is statically determinate; its solution yields the exact number of conditions for the determination of the independent unknowns. In general, the number of these unknowns is rather small; for instance, in the case of a one-story bent of n columns on rigid supports, with the axial deformations of given members assumed to be negligible, this number is 1.

F.—All stresses and joint displacements are now found using the values of the unknowns just determined.

NOTATION

The letter symbols in this paper are defined when they first appear and are assembled for convenience of reference in the Appendix.

ASSUMPTIONS

All assumptions leading to the validity of the well-known equation,

$$\frac{d^2y}{dx^2} = \mp \frac{M}{E\,I} \quad \text{(1)}$$

which relates displacements to applied loads, are adopted in this analysis. (In Eq. 1, x and y are the coordinates of a point on the deflected member, M is the bending moment, E the Young modulus, and I the moment of inertia—all referred to this point.) In particular, the assumption is made that all deformations are very small in comparison with the dimensions of the members.

It is further assumed that:

(1) The moment of inertia of each member is constant along its length, although not necessarily the same for all members;

(2) The joints in the frame are either perfectly rigid, free to rotate, or belong to both categories; in other words, flexible joints are not considered. No such restriction is imposed upon the supports; and

(3) For the purpose of this analysis, the given frame may be replaced by an idealized system formed by the gravity axes of the members.

These assumptions are common to most methods for the analysis of frames. With some modifications, the method presented here may be extended to remove restrictions (1) and (2).

COMPATIBILITY EQUATIONS

The axial strains and unit deflections of members resulting from the displacements of the joints are subject to conditions of compatibility derived in the following manner.

Let AB and A′B′ in Fig. 2 represent any member in a frame, respectively, before and after displacement. From point A′, draw a line A′B″ parallel to AB and equal to it in length. Point B‴, the foot of a perpendicular from B′ on A′B″, defines the change in length e_1 of member AB and the transverse movement Δ_1 of joint B. In Fig. 2, these elements are indicated in their positive directions, that is, elongation for e_1 and clockwise rotation for Δ_1.

Let δ_1 designate the unit deflection of the member, defined by $\delta_1 = \dfrac{\Delta_1}{l_1}$; ϵ_1 its axial strain, defined by $\epsilon_1 = \dfrac{e_1}{l_1}$; and let λ_1 be the inclination of AB on

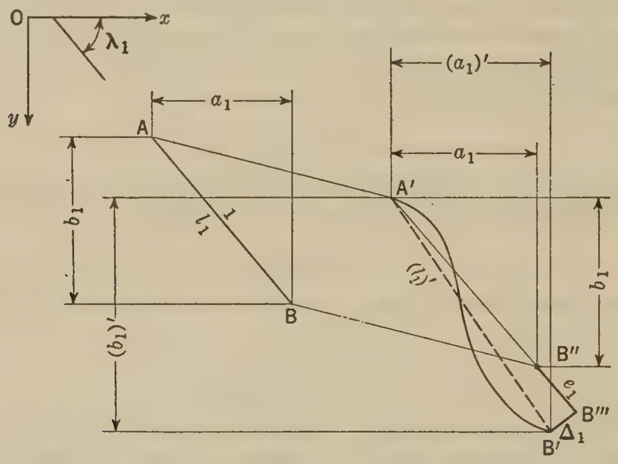

FIG. 2

the x-axis. The following relations may be written between the rectangular projections of AB and A′B′:

$$(a_1)' = a_1 + e_1 \cos \lambda_1 - \Delta_1 \sin \lambda_1 \ldots\ldots\ldots\ldots (2a)$$

and

$$(b_1)' = b_1 + e_1 \sin \lambda_1 + \Delta_1 \cos \lambda_1 \ldots\ldots\ldots\ldots (2b)$$

or, in terms of δ_1 and ϵ_1:

$$(a_1)' - a_1 = a_1\,\epsilon_1 - b_1\,\delta_1 \ldots\ldots\ldots\ldots (3a)$$

and

$$(b_1)' - b_1 = b_1\,\epsilon_1 + a_1\,\delta_1 \ldots\ldots\ldots\ldots (3b)$$

Eqs. 2 and 3 apply to any member of the frame, regardless of its position or orientation, provided its rectangular projections are taken with the proper signs in relation to the reference axes. Apply these relations to a closed circuit of bars (given or imaginary); denote by $\sum_o$ a complete summation around this circuit, continuously in a clockwise direction. Since, for a closed circuit, $\sum_o a = 0$; $\sum_o a' = 0$; $\sum_o b = 0$; and $\sum_o b' = 0$, the following relations may be derived from Eqs. 3:

$$\textstyle\sum_o(a\,\epsilon) - \sum_o(b\,\delta) = 0 \ldots\ldots\ldots\ldots (4a)$$

and

$$\textstyle\sum_o(b\,\epsilon) + \sum_o(a\,\delta) = 0 \ldots\ldots\ldots\ldots (4b)$$

These relations simply mean that the axial and lateral strains of the bars are compatible in maintaining a closed circuit. It seems appropriate, therefore, to call Eqs. 4 "compatibility equations."

Consider a closed circuit, ABCDA, Fig. 3(*a*), in which the sides may be some of the given members in a frame or simply imaginary diagonals connecting two joints. Designate any two consecutive sides by the letters p and q. Eqs. 4 may be written in a simpler manner if the differences $\delta_p - \delta_q = \delta_{p-q}$ and $\epsilon_p - \epsilon_q = \epsilon_{p-q}$ are introduced instead of the elements δ and ϵ. At the joint where members p and q meet, apply the orthogonal vectors δ_{p-q} and ϵ_{p-q} in the direction of the arbitrary axes x and y. Treat all other joints in the same manner, as indicated in Fig. 3(*a*). It will be shown that the resultant moment of all these vectors about point O is zero if the compatibility equations are satisfied.

FIG. 3

This moment is

$$M = x_a\,\epsilon_{0-1} + x_b\,\epsilon_{1-2} + x_c\,\epsilon_{2-3} + x_d\,\epsilon_{3-0} - (y_a\,\delta_{0-1} + y_b\,\delta_{1-2} + y_c\,\delta_{2-3} + y_d\,\delta_{3-0}) \ldots\ldots\ldots\ldots (5)$$

in which x_a, y_a, etc., are the coordinates of joints A, etc.; and ϵ_{0-1}, δ_{0-1}, etc., are equal, respectively, to $\epsilon_0 - \epsilon_1$, $\delta_0 - \delta_1$, etc. Similarly, if $x_a - x_d$, etc., are expressed as x_{a-d}, etc., Eq. 5 may be transformed as follows:

$$M = x_{a-d}\,\epsilon_0 + x_{b-a}\,\epsilon_1 + x_{c-b}\,\epsilon_2 + x_{d-c}\,\epsilon_3 - (y_{a-d}\,\delta_0 + y_{b-a}\,\delta_1 + y_{c-b}\,\delta_2 + y_{d-c}\,\delta_3) \ldots\ldots\ldots\ldots (6)$$

or again

$$M = \sum\nolimits_o (a\,\epsilon) - \sum\nolimits_o (b\,\delta) \ldots\ldots\ldots\ldots (7)$$

Eq. 7, which represents the moment about O of the vectors δ_{p-q} and ϵ_{p-q}, directed as in Fig. 3(*a*), is equal to zero by virtue of Eq. 4*a*.

If all these vectors are rotated bodily 90° clockwise, as in Fig. 3(*b*), it may be shown in a similar manner that their resultant moment about O reduces to the expression

$$M' = \sum\nolimits_o (b\,\epsilon) + \sum\nolimits_o (a\,\delta) \qquad (8)$$

which is also equal to zero because of Eq. 4*b*.

It is thus seen that, if a certain number of the joints of a frame are considered as forming a closed circuit (by drawing imaginary diagonals, if necessary), the two moments (about any point) of the vectors δ_{p-q} and ϵ_{p-q}, directed first as in Fig. 3(*a*), then as in Fig. 3(*b*), reduce to zero if the compatibility conditions are satisfied; and vice versa. In addition, these vectors satisfy the two self-evident relations, $\sum_o \delta_{p-q} = 0$; and $\sum_o \epsilon_{p-q} = 0$.

The system formed by these two moment equations and the relation $\sum_o \delta_{p-q}$ is equivalent to a more symmetrical system obtained by equating three resultant moments to zero. These moments are taken about three arbitrary points, of the orthogonal vectors δ_{p-q} and ϵ_{p-q}, directed along three arbitrary directions. In each moment operation, all δ_{p-q}-vectors are made parallel, pointing in the same direction. This applies similarly to vectors ϵ_{p-q}.

Compatibility equations, expressed in the form of a system of three moment equations as described herein, can be written conveniently when applied to triangular elements, the vertices of which are used as centers of moments (see Example 1).

The compatibility equations developed in this section apply to any frame, regardless of the nature of the joints—rigid, hinged, or flexible.

Example 1.—After a frame has been decomposed into its hypothetical triangular elements, the compatibility conditions are applied to one of these elements. Fig. 4(*a*) represents a triangle ABC, formed by any three joints of a frame. The orthogonal vectors δ_{p-q} and ϵ_{p-q} are applied at the respective joints as shown. Equate their moment about point A to zero; thus:

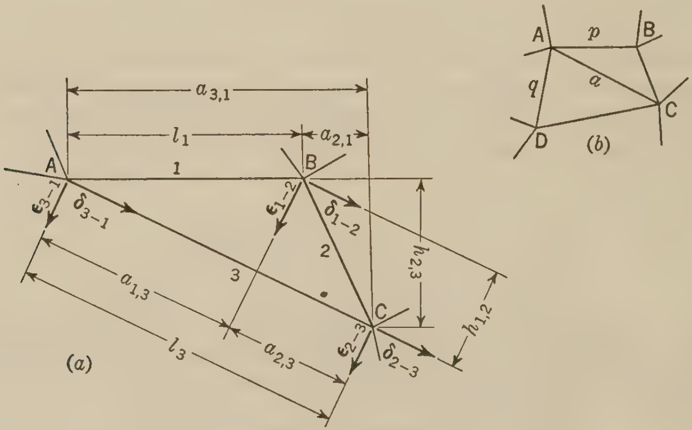

FIG. 4

$$M = h_{1,2}\,\delta_{1-2} + a_{1,3}\,\epsilon_{1-2} + l_3\,\epsilon_{2-3} = 0 \qquad (9)$$

or

$$\delta_{1-2} = \frac{l_3\,\epsilon_3 - a_{1,3}\,\epsilon_1 - a_{2,3}\,\epsilon_2}{h_{1,2}} \qquad (10a)$$

If these vectors, fixed at right angles to each other, are rotated to bring the δ_{p-q}-vectors parallel with line BA, and their moment about point B is equated to zero:

$$\delta_{2-3} = \frac{l_1 \epsilon_1 + a_{2,1} \epsilon_2 - a_{3,1} \epsilon_3}{h_{2,3}} \quad \text{.................} \quad (10b)$$

A third expression of a similar type is obtained by equating to zero the moment about point C of the vectors δ_{p-q} and ϵ_{p-q}, rotated so that δ_{p-q} becomes parallel to line CB.

It may be concluded that δ_{p-q} at any angle formed by two given members in a frame meeting at a joint may be written in terms of the axial strains of the members forming the angle and that of the diagonal opposite. When the members are not contiguous, such as AD and AB in Fig. 4(*b*), δ_{p-q} may be written as $\delta_{p-a} + \delta_{a-q}$, in which each term may be expressed using the axial strains ϵ of the lines forming the triangles ABC and ACD.

If one (or several) of the sides of a triangular element happens to be a bar joining two supports, the δ-terms and ϵ-terms of this side will represent, respectively, the unit deflection and the axial strain of the line of supports. Both of these elements can be expressed easily as functions of the linear movements of the supports. In the development of this analysis, it will be found expedient to assume that the unit deflection and axial strain of bars (given or imaginary) joining two supports have been replaced in terms of the support movements. As a result, the compatibility equations will contain these movements explicitly, when applied to panels adjacent to support lines.

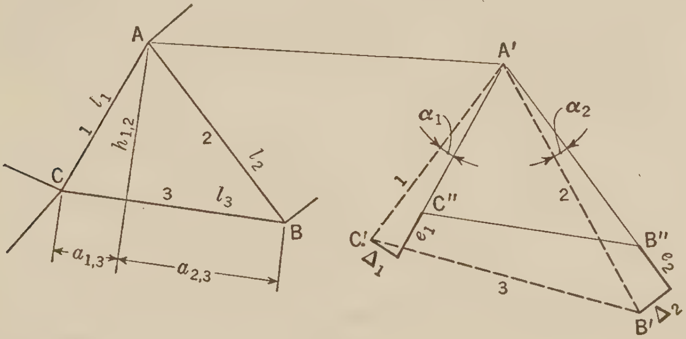

FIG. 5

A geometric representation of δ_{p-q} and ϵ_{p-q} may be drawn in terms of the deformation of a triangle. Let ABC, Fig. 5, be a triangular element in the frame; A′B′C′ is the triangle formed by joining the deflected positions of the vertices; and A′B″C″ the position of ABC translated until joint A coincides with joint A′. By definition,

$$\delta_{1-2} \; (= \delta_1 - \delta_2) = \frac{\Delta_1}{l_1} - \frac{\Delta_2}{l_2} \quad \text{..................} \quad (11)$$

but $\frac{\Delta_1}{l_1}$ and $\frac{\Delta_2}{l_2}$ are respectively equal to angles α_1 and α_2. Therefore, $\delta_{1-2} =$

$\alpha_1 - \alpha_2$ = angle C′A′B′ − angle CAB = ΔA, in which ΔA is the variation of the original angle at joint A compared to that formed by straight lines connecting the new positions of the joints. Again, by application of compatibility equations, ϵ_{1-2} may be written easily as

$$\epsilon_{1-2} = \frac{a_{1,3}\,\delta_{1-3} + a_{2,3}\,\delta_{2-3}}{h_{1,2}} \qquad (12)$$

If δ_{1-3} and δ_{2-3} are referred to their appropriate angles C and B (Fig. 5) as $-\Delta C$ and $+\Delta B$, respectively, Eq. 12 can be expressed as:

$$\epsilon_{1-2} = \frac{\Delta B}{\tan B} - \frac{\Delta C}{\tan C} \qquad (13)$$

Example 2.—An important function of the compatibility conditions consists in determining the relative displacement of two arbitrary joints in a frame in terms of elements δ_{p-q} and axial strains ϵ, assuming that the unit deflection δ of one of the bars in the frame is given. For instance, referring to Fig. 6, let it be required to find the displacement of joint D with respect to joint A. Two cases are distinguished:

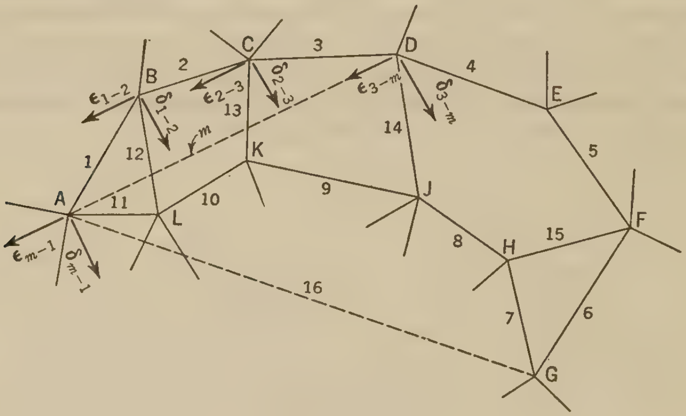

FIG. 6

Case 1.—The bar whose unit deflection δ is given is an actual member in the frame, say, member 8, Fig. 6. Draw line AD (or, as a subscript, simply m). At the joints of the closed circuit ABCDA apply the corresponding vectors δ_{p-q} and ϵ_{p-q}, with the ϵ_{p-q}-vectors parallel to AD, as shown. Equate to zero the moment of these vectors about joint A; ϵ_{3-m} will disappear and δ_{3-m} will be given as a linear function of the vectors applied between joints A and D, such as,

$$\delta_{3-m} \quad \text{or} \quad \delta_3 - \delta_m = F(\delta_{1-2}\ ,\ \epsilon_{1-2}\ ,\ \delta_{2-3}\ ,\ \epsilon_{2-3}) \qquad (14a)$$

In Eq. 14*a*, δ_3 may be expressed in terms of δ_8 (assumed given) and some δ_{p-q}-elements, as follows:

$$\delta_3 = \delta_{3-14} + \delta_{14-8} + \delta_8 \qquad (14b)$$

Substitute this value of δ_3 in Eq. 14*a* and obtain δ_m. The product $l_m\,\delta_m$ is then the movement of joint D at right angles to line AD. Rotating the vectors, in Fig. 6, 90° clockwise and again taking their moment about joint A, δ_{3-m} will disappear and ϵ_{3-m} (or, $\epsilon_3 - \epsilon_m$) will be found as a linear expression of the vectors between joints A and D. The movement of joint D along line AD is then given by $l_m \epsilon_m$.

Case 2.—The bar whose unit deflection δ is given is an imaginary diagonal, say, line 16, Fig. 6, drawn between two joints. Eq. 14*a* holds also for this case; Eq. 14*b* will have to be replaced by:

$$\delta_3 = \delta_{3-14} + \delta_{14-8} + \delta_{8-7} + \delta_{7-16} + \delta_{16} \quad \text{(14c)}$$

In Eq. 14*c*, δ_{16} is assumed known; all the terms in the second member, except δ_{7-16}, refer to actual angles in the frame, these being the only ones which will be necessary to consider in this analysis; δ_{7-16} can be found, and then eliminated in Eq. 14*c*, by locating the orthogonal vectors δ_{p-q} and ϵ_{p-q} at the joints of the closed circuit ALKJHGA (with the ϵ_{p-q}-vectors parallel to line AG) and equating to zero their moment about joint A. The movement of joint D along line AD is found as in case 1.

Corollary to Example 2.—Assuming that the given frame is completely decomposed into triangles by means of imaginary diagonals, the δ_{p-q}-elements at all angles in the frame may be written, as shown in Example 1, in terms of the axial strains of the bars (given or imaginary), and the linear movements of the supports. Therefore, as a corollary to Example 2, it may be concluded that the relative displacement of any two joints may be found in terms of the axial strains of the actual members, those of the imaginary diagonals, and the linear movements of the supports, knowing the unit deflection of any one bar in the frame (for this bar, one joining two supports may be used).

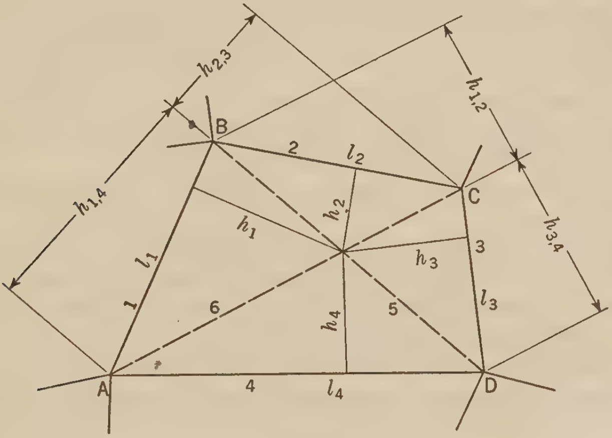

FIG. 7

Example 3.—Compatibility equations may be applied to quadrilateral elements, or polygons of any number of sides, either for the study of their deformation, or, more immediately, as a preliminary for the analysis of redundant polygonal panels. A quadrilateral element is shown in Fig. 7. Imagine it divided into the four triangles ABC, BCD, CDA, DAB. Express δ_{1-2}, δ_{2-3}, δ_{3-4}, and δ_{4-1} by applying the method of Example 1 to each of these triangles, and equate their sum to zero; the following relation is obtained after simplification:

$$2\,A_e\left(\frac{\epsilon_5}{h_{1,4}\,h_{2,3}}+\frac{\epsilon_6}{h_{1,2}\,h_{3,4}}\right)=\frac{l_1\,\epsilon_1}{h_1}+\frac{l_2\,\epsilon_2}{h_2}+\frac{l_3\,\epsilon_3}{h_3}+\frac{l_4\,\epsilon_4}{h_4}\,\ldots\ldots(15)$$

In Eq. 15, A_e represents the area of the quadrilateral and ϵ_5 and ϵ_6 the axial strains of the diagonals. If the axial deformations of the sides are negligible, it takes the form

$$\frac{\epsilon_5}{h_{1,4}\,h_{2,3}}+\frac{\epsilon_6}{h_{1,2}\,h_{3,4}}=0\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(16)$$

which correlates the axial strains of the diagonals in a quadrilateral with rigid sides.

Example 4.—The results of Example 3 will be used for an outline of the determination of the axial forces in the pin-connected truss with one redundant member, shown in Fig. 8. If the redundant member BD is replaced by a pair of opposite forces X, the symbol X being the unknown force in the member, the axial strains in each of the members 1, 2, 3, 4, and 5 will be of the form $\frac{T^1\,X+T^0}{E\,A}$; in this expression, A is the cross-sectional area of the member, and T^1 and T^0 are, respectively, the axial forces found, first, by assuming $X = 1$ and all external loads removed, and second, by assuming $X = 0$ and allowing the external loading to act. The axial strain in the redundant member itself is $\frac{X}{E\,A}$. Substitute these axial strains in the compatibility equation (Eq. 15) for panel ABCD, and solve for the unknown X.

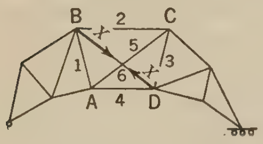

FIG. 8

It may be noted that only the members bounding the panel which contains the redundant member enter into the calculations.

The case in which several redundant members are present may be treated in a similar manner.

Example 5.—The procedure outlined in Example 2 will be applied to a statically determinate frame. Let it be required to find the vertical deflection of joint D with respect to joint A, in the Pratt truss of Fig. 9. (This truss has been analyzed elsewhere by means of Williot-Mohr diagrams.[3])

In this symmetrical truss, symmetrically loaded, $\delta_{11} = 0$. The procedure of case 1, Example 2, applied to the closed circuit ABCDA, reduced to a straight line in this case, gives

$$\delta_{8-m} = -\tfrac{1}{75}\,(25\,\delta_{2-4} + 50\,\delta_{4-8})\ldots\ldots\ldots\ldots\ldots\ldots(17)$$

corresponding to Eq. 14*a*; in Eq. 17, the subscript m designates the imaginary line drawn between joints A and D. The elements ϵ_{p-q} of the circuit do not appear because their moment about A is zero. Also

FIG. 9

All δ_{p-q}-terms in Eq. 19*b* are now expressed as functions of the axial strains of the members, using the method of Example 1 in the several triangles forming the truss; their expressions are:

$$\delta_{8-9} = -\frac{30\,\epsilon_7 - 30\,\epsilon_9}{25} \qquad (20a)$$

$$\delta_{9-11} = -\frac{25\,\epsilon_{10} - 25\,\epsilon_9}{30} \qquad (20b)$$

$$\delta_{2-3} = -\frac{39\,\epsilon_1 - 16\,\epsilon_2 - 23\,\epsilon_3}{19.2} \qquad (20c)$$

$$\delta_{3-4} = -\frac{39\,\epsilon_5 - 23\,\epsilon_3 - 16\,\epsilon_4}{19.2} \qquad (20d)$$

$$\delta_{4-5} = -\frac{30\,\epsilon_3 - 30\,\epsilon_5}{25} \qquad (20e)$$

$$\delta_{5-7} = -\frac{25\,\epsilon_6 - 25\,\epsilon_5}{30} \qquad (20f)$$

and

$$\delta_{7-8} = -\frac{39\,\epsilon_9 - 23\,\epsilon_7 - 16\,\epsilon_8}{19.2} \qquad (20g)$$

The substitution of these values in Eq. 19*b* will give δ_m; thus:

$$\delta_m = -0.68\,\epsilon_1 + 0.28\,\epsilon_2 + 0.28\,\epsilon_4 + 0.68\,\epsilon_5 - 0.56\,\epsilon_6 - 0.40\,\epsilon_7 + 0.56\,\epsilon_8 + 0.68\,\epsilon_9 - 0.83\,\epsilon_{10} \qquad (21)$$

In this problem, the axial forces T in the members can be found immediately by statics; the corresponding axial strains are of the form $\epsilon = \dfrac{T}{EA}$.

Substituting the numerical values[3] for the ϵ-terms, $\delta_m = \dfrac{27{,}820}{29{,}000{,}000} = \dfrac{9.55}{10{,}000}$. The vertical movement of joint D is then $75 \times 12\,\delta_m = 0.86$ in.

Topology of Frameworks

The given frame having been completely decomposed into triangular elements by drawing imaginary diagonals, the axial strains of these diagonals, those of the given members, and the linear movements of the supports (see Example 1 for the reason of their introduction), are used as elements for the determination of the displacements and stresses in the frame. Their immediate connection with some of the important aspects of the problem has been illustrated in preceding sections. Their essential rôle will be further disclosed as the analysis proceeds.

These elements—axial strains and support movements—may be interdependent. This may be noted, for instance, by considering the plane deformation of a quadrilateral panel with two diagonals; evidently, the axial strains of any five of the six bars will determine that of the sixth.

The reduction of these elements to a minimum number which are independent, the determination of this number, the exposition of other properties connected with the configuration of the frame (such as relations between number of regions, members, joints, etc.) and leading ultimately to the solution of the independent elements—all result from a study of the topology of the frame.

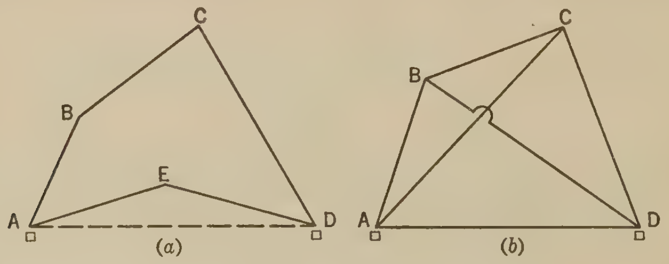

Fig. 10

A region in a framework is defined in this paper as the space within a closed circuit formed by some of the given members; or, within a closed circuit formed by some of the given members and an imaginary line joining two supports. For instance, the frame in Fig. 10(*a*) has three regions—ABCDEA, ABCDA, AEDA; that of Fig. 10(*b*) has five—namely, ABCA, ACDA, BCDB, ABDA, and ABCDA. A distinct region is defined as one whose boundary contains at least one bar (not joining 2 supports) which has not already been used in circumscribing other regions; on this basis, the first frame has only two distinct regions, and the second only three, among the several regions enumerated for each of them. It is immaterial which particular regions are considered as distinct among all others resulting from the configuration of the frame; for reasons of simplicity, it is well to choose those with the smallest number of sides. In this analysis, only distinct regions will be considered.

Let:

n_r = total number of distinct regions in a frame, exclusive of those with all their vertices at supports;

n_m = total number of given members, exclusive of those connected to a support at each end;

n_p = total number of joints, exclusive of the supports.

(The reason for the exclusion from this list of members joining two supports, is that their axial strains and unit deflections are assumed to be expressed in terms of the linear movements of the supports. Similarly, the supports are not included among the number of the joints for the reason that the equilibrium and displacement requirements at the supports will be disposed of in the establishment of boundary conditions. The limitation imposed upon the number of regions is due to similar conditions.)

Proposition (*a*).—Between the numbers of regions, members and joints as defined above there exists the following relation:

$$n_r = n_m - n_p \qquad (22)$$

(Compare Eq. 22 to Euler's equation[2] relative to the number of faces, edges, and vertices of polyhedra.)

Eq. 22 is, of course, evident in the case of a rudimentary system composed of one member and one support ($n_r = 0$, $n_m = 1$, $n_p = 1$). It will be sufficient to show that it remains true when successive members, joints, and supports are added to it to form an arbitrary frame. For instance, at the free end of this system attach a closed region of n members. Then $n_r = 1$, $n_m = n + 1$, $n_p = n$, and Eq. 22 is satisfied. Next, add one member between two of the joints, or between one of the joints and the support, or between one of the joints and a new support: There are now one more region and one more member; the number of the joints has not changed; and the relation still applies. Add a member between two supports: The number n_r does not change; neither does n_m, nor n_p; and the relation is again valid. It will remain valid after the addition of a new member connecting a joint or a support with some point on one of the members, thus creating a new joint at that point and converting one member into two (this will result in one more region, two additional members, and one new joint).

Similarly, it may be shown that Eq. 22 remains valid at each stage of growth resulting from any other type of addition to the frame.

For example, in Fig. 9, $n_m = 21$, $n_p = 10$, $n_r = 21 - 10 = 11$, these regions being the ten triangles subdividing the truss, and the space between the bottom chord and the line of supports (which coincides in this case with the bottom chord).

Proposition (*b*).—From Eq. 22, the total number of distinct triangular elements n_t (excluding those with all their vertices at supports) into which the frame is decomposed by diagonals is given by:

$$n_t = (n_m + n_{mt}) - n_p \ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

In this relation n_{mt} represents the total number of imaginary diagonals required for the complete decomposition of the frame into triangles, exclusive of those joining two supports.

After the frame has been divided into triangles, a total of $2\,n_t$, compatibility equations (Eqs. 4) may be written for the n_t triangular elements forming the transformed frame. These equations will be in terms of the unit deflections δ and δ_t, and the axial strains ϵ and ϵ_t of the given members and the imaginary diagonals, respectively. They will also involve the linear movements of the supports. Consider the $(n_m + n_{mt})$-elements δ and δ_t eliminated between these $2\,(n_m + n_{mt} - n_p)$ equations; and there will remain $2\,(n_m + n_{mt} - n_p) - (n_m + n_{mt}) = n_m + n_{mt} - 2\,n_p$ linear relations between the elements ϵ and ϵ_t and the linear movements of the supports; call n_i the number: $n_m + n_{mt} - 2n_p$.

Proposition (*c*).—As a result of Proposition (*b*), calling n_σ the number of the support movements, it may be concluded that a number n_i of the $n_m + n_{mt}$ axial strains ϵ and ϵ_t are dependent upon, and may be determined as functions of, the remaining $n_m + n_{mt} + n_\sigma - n_i = n_m + n_{mt} + n_\sigma - (n_m + n_{mt} - 2\,n_p) = 2\,n_p + n_\sigma$ elements (axial strains and linear movements of supports), considered as independent. This last number reduces to $(2\,n_p - n_m) + n_\sigma$ in the assumption of negligible axial strains for the n_m given members. In other words, the degree of freedom of a frame in joint displacement is $2\,n_p + n_\sigma$ in the general case, and $(2\,n_p - n_m) + n_\sigma$ if the axial deformations of the n_m given members are assumed to be negligible; (this is, of course, in addition to its displacement as a whole).

In most cases, these n_i-relations may be obtained easily by expressing the value of δ_{p-q} for each angle at an interior joint or interior support, in terms of the ϵ-elements and ϵ_t-elements of the neighboring bars and the linear movements of the supports (see Example 1), and writing the self-evident relation $\sum \delta_{p-q} = 0$ at these points.

An illustration is afforded by the frame in Fig. 13 (given subsequently), in which $n_m = 5, n_p = 3, n_t = 4, n_{mt} = 2$; number of regions $n_r = n_m - n_p = 2$; number of triangles $n_t = n_m + n_{mt} - n_p = 4$; $n_i = n_m + n_{mt} - 2\,n_p = 1$ ($\sum \delta_{p-q} = 0$ at support F, Fig. 13); degree of freedom in joint displacement, $2\,n_p = 6$, or $2\,n_p - n_m = 1$.

The application of this analysis to articulated frames leads to their classification as statically determinate, redundant, unstable, and redundant-unstable, and to criteria for such classification.[4]

BOUNDARY CONDITIONS

In preparing to find end moments in terms of the unknowns adopted in this analysis, boundary conditions will be expressed in a form excluding the reactions of the supports; their expression will involve only axial strains, linear and angular movements of supports, and end moments.

---

[4] "Displacements and Stresses in the General Two-Dimensional Framework," by Yves Nubar; submitted in partial fulfilment of the requirements for the degree of Doctor of Philosophy, Faculty of Pure Science, Columbia Univ., New York, N. Y., 1941. On file for reference in Engineering Societies Library, New York, N. Y.

A support of a general type is shown at point a in Fig. 11. Let X_a, Y_a, and M_a be the reactions at the support and e_{xa}, e_{ya}, ω_a the corresponding linear and angular movements. At this support, boundary conditions in their general form may be represented by three expressions between these six elements, such as

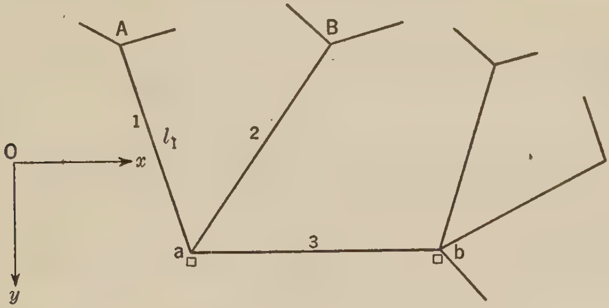

FIG. 11

$$\left.\begin{aligned} F_1(X_a, Y_a, M_a, e_{xa}, e_{ya}, \omega_a) &= 0 \\ F_2(X_a, Y_a, M_a, e_{xa}, e_{ya}, \omega_a) &= 0 \\ F_3(X_a, Y_a, M_a, e_{xa}, e_{ya}, \omega_a) &= 0 \end{aligned}\right\} \quad (24)$$

In practical cases, these expressions are of much simpler type; for instance, at a hinged, immovable joint, they reduce to: $e_{xa} = 0$, $e_{ya} = 0$, $M_a = 0$; and, at a support on rollers, they may be written as: $e_{ya} = 0$, $X_a = 0$, $M_a = 0$.

Reactions X_a, Y_a, and M_a can be eliminated from Eqs. 24 as follows: The moments and forces in each of the members (for instance, member 1) meeting at the support are of the form: Axial force, $E A_1 \epsilon_1$; end moments, M_{1a} and M_{1A}; transverse end force, $\dfrac{M_{1a} + M_{1A}}{l_1}$ (this expression will also involve lateral loads on the member, if any). Using these expressions, the equilibrium conditions at the support are:

$$X_a + \sum(E A_1 \epsilon_1)_x + \sum\left(\frac{M_{1a} + M_{1A}}{l_1}\right)_x = 0 \quad (25a)$$

$$Y_a + \sum(E A_1 \epsilon_1)_y + \sum\left(\frac{M_{1a} + M_{1A}}{l_1}\right)_y = 0 \quad (25b)$$

and

$$M_a + \sum M_{1a} = 0 \quad (25c)$$

Solve for X_a, Y_a, and M_a and introduce the result in Eqs. 24. These relations will represent the boundary conditions at support a, Fig. 11, but will involve only the linear and angular movements of the support, the axial strains and end moments in the members connected there.

If line 3, Fig. 11, is only an imaginary diagonal joining two supports, the forces and moments corresponding to it will naturally disappear from Eqs.

24 and 25. If it is an actual member, its end moments, transverse and axial forces may be assumed to have been written in terms of the angular and linear movements of the supports, using the slope deflection[5] equations of the member.

DETERMINATION OF END MOMENTS

The proposition will be established that the end moments in the members of a rigid frame can be found as linear functions of the δ_{p-q}-elements at the angles formed by the given members of the frame and the linear movements of the supports.

It was shown in Example 1 that, if the frame is completely decomposed into triangular elements, these δ_{p-q}-terms themselves may be expressed as functions of the axial strains ϵ and ϵ_t of the bars (given members and imaginary diagonals) and the linear movements of the supports. Consequently, the aforementioned proposition will result in a linear dependence of all end moments upon the unknowns, ϵ, ϵ_t, and the support movements.

When such a dependence is established, it will follow that the axial strains ϵ and ϵ_t, together with the linear movements of the supports, can specify completely the system of displacements and stresses in the general two-dimensional frame; this conclusion is valid, because:

(1) The axial force T in a member equals $E\,A\,\epsilon$;

(2) The transverse forces at the ends of a member may be found from the end moments by means of the equilibrium conditions of the member;

(3) The relative displacement of any two joints can be determined in terms of the axial strains ϵ and ϵ_t and the linear movements of the supports (see "Corollary to Example 2");

(4) The relative rotation of two joints may be found from the end moments of the members by application of slope deflection[5] equations (see, for instance, Eqs. 28, given subsequently);

(5) The boundary conditions, as written in the preceding section, furnish the angular and linear movements of the supports in terms of axial strains, and end moments.

The aforementioned proposition is demonstrated by first establishing the following property of rigid joints:

I.—If, at a joint of n members, there exists one linear relation between the end moments of each of $n - 1$ members (a total of $n - 1$ relations), another linear relation may be found between the end moments of the nth member. This expression involves the coefficients of the $n - 1$ linear relations and the terms δ_{p-q} at the joint.

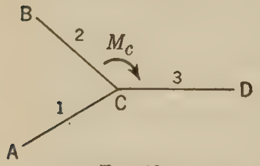

FIG. 12

A joint of three members will be considered for simplicity, the demonstration being similar for a joint of any number of members. Let M_{1A} and M_{1C} designate the moments exerted by member 1, Fig. 12, upon joints A and C, respectively; m_{1A} and m_{1C} designate the same moments if joints A and C do not rotate, and if member AC does not deflect laterally (fixed end moments);

---

[5] "Analysis of Statically Indeterminate Structures by the Slope Deflection Method," by W. M. Wilson, F. E. Richart, and Camillo Weiss, *Bulletin No. 108*, Eng. Experiment Station, Univ. of Illinois, Urbana, 1918.

ω (with the subscript of a joint) represents the rotation of the joint common to all members connected to it. These moments and rotations are taken as positive in a clockwise direction.

For members 1 and 2, Fig. 12, assume given two linear relations:

$$M_{1A} + C_{1C}\, M_{1C} = D_{1C} \quad \text{(26a)}$$

and

$$M_{2B} + C_{2C}\, M_{2C} = D_{2C} \quad \text{(26b)}$$

C_{1C}, D_{1C}, C_{2C}, D_{2C} representing given coefficients.

It is proposed to derive a similar relation

$$M_{3C} + C_{3D}\, M_{3D} = D_{3D} \quad \text{(26c)}$$

for member 3—that is, to determine coefficients C_{3D} and D_{3D}.

With the adopted sign conventions, the slope deflection equations[5] for member 1 are

$$M_{1A} = -2\, E\, K_1\, (2\, \omega_A + \omega_C - 3\, \delta_1) + m_{1A} \quad \text{(27a)}$$

and

$$M_{1C} = -2\, E\, K_1\, (2\, \omega_C + \omega_A - 3\, \delta_1) + m_{1C} \quad \text{(27b)}$$

in which K_1 is the stiffness $\frac{I_1}{l_1}$ of member 1. Solving for ω_A and ω_C:

$$\omega_A = \delta_1 + \frac{[(M_{1C} - m_{1C}) - 2\, (M_{1A} - m_{1A})]}{6\, E\, K_1} \quad \text{(28a)}$$

and

$$\omega_C = \delta_1 + \frac{[(M_{1A} - m_{1A}) - 2\, (M_{1C} - m_{1C})]}{6\, E\, K_1} \quad \text{(28b)}$$

Consideration of members 2 and 3 will furnish the following additional expressions for ω_C:

$$\omega_C = \delta_2 + \frac{[(M_{2B} - m_{2B}) - 2\, (M_{2C} - m_{2C})]}{6\, E\, K_2} \quad \text{(29a)}$$

and

$$\omega_C = \delta_3 + \frac{[(M_{3D} - m_{3D}) - 2\, (M_{3C} - m_{3C})]}{6\, E\, K_3} \quad \text{(29b)}$$

Subtract Eq. 29b from Eq. 28b and Eq. 29b from Eq. 29a:

$$\begin{aligned} 6\, E\, \delta_{1-3} &+ \frac{1}{K_1}\, (M_{1A} - 2\, M_{1C}) + \frac{1}{K_3}\, (2\, M_{3C} - M_{3D}) \\ &= \frac{1}{K_1}\, (m_{1A} - 2\, m_{1C}) + \frac{1}{K_3}\, (2\, m_{3C} - m_{3D}) \quad \text{(30a)} \end{aligned}$$

and

$$\begin{aligned} 6\, E\, \delta_{2-3} &+ \frac{1}{K_2}\, (M_{1B} - 2\, M_{2C}) + \frac{1}{K_3}\, (2\, M_{3C} - M_{3D}) \\ &= \frac{1}{K_2}\, (m_{2B} - 2\, m_{2C}) + \frac{1}{K_3}\, (2\, m_{3C} - m_{3D}) \quad \text{(30b)} \end{aligned}$$

By Eqs. 26*a* and 26*b*:

$$\frac{C_{1C}+2}{K_1} M_{1C} = \frac{1}{K_3}(2\,M_{3C} - M_{3D}) + 6\,E\,\delta_{1-3} + \frac{D_{1C}}{K_1}$$
$$- \frac{1}{K_1}(m_{1A} - 2\,m_{1C}) - \frac{1}{K_3}(2\,m_{3C} - m_{3D}) \ldots\ldots\ldots\ldots (31a)$$

and

$$\frac{C_{2C}+2}{K_2} M_{2C} = \frac{1}{K_3}(2\,M_{3C} - M_{3D}) + 6\,E\,\delta_{2-3} + \frac{D_{2C}}{K_2}$$
$$- \frac{1}{K_2}(m_{2B} - 2\,m_{2C}) - \frac{1}{K_3}(2\,m_{3C} - m_{3D}) \ldots\ldots\ldots\ldots (31b)$$

If M_{1C} and M_{2C} from Eqs. 31 are substituted in the equilibrium equation of the joint—

$$M_{1C} + M_{2C} + M_{3C} + M_C = 0 \ldots\ldots\ldots\ldots\ldots\ldots (32)$$

in which M_C represents, for generality, an external couple applied at joint C, the following is the result:

$$2\,M_{3C}\left(\frac{K_1}{C_{1C}+2} + \frac{K_2}{C_{2C}+2} + \frac{K_3}{2}\right)$$
$$- M_{3D}\left(\frac{K_1}{C_{1C}+2} + \frac{K_2}{C_{2C}+2}\right) = -K_3\,U \ldots\ldots\ldots\ldots (33)$$

in which

$$U = +M_C + \frac{K_1}{C_{1C}+2}\left[6\,E\,\delta_{1-3} + \frac{1}{K_1}(D_{1C} - m_{1A} + 2\,m_{1C}) - \frac{1}{K_3}(2\,m_{3C} - m_{3D})\right]$$
$$+ \frac{K_2}{C_{2C}+2}\left[6\,E\,\delta_{2-3} + \frac{1}{K_2}(D_{2C} - m_{2B} + 2\,m_{2C}) - \frac{1}{K_3}(2\,m_{3C} - m_{3D})\right] \ldots\ldots\ldots\ldots (34)$$

Coefficients C_{3D} and D_{3D} in Eq. 26*c* are found by comparing this equation to Eq. 33; thus:

$$C_{3D} = -\frac{\dfrac{K_1}{C_{1C}+2} + \dfrac{K_2}{C_{2C}+2}}{2\left(\dfrac{K_1}{C_{1C}+2} + \dfrac{K_2}{C_{2C}+2} + \dfrac{K_3}{2}\right)} \ldots\ldots\ldots\ldots (35a)$$

and

$$D_{3D} = -\frac{K_3\,U}{2\left(\dfrac{K_1}{C_{1C}+2} + \dfrac{K_2}{C_{2C}+2} + \dfrac{K_3}{2}\right)} \ldots\ldots\ldots\ldots (35b)$$

This establishes the property stated in paragraph I.

The relations developed in this section may be considered to represent compatibility conditions in joint rotations, since they imply members rigidly connected to each other.

In case another member CE (numbered 4) is hinged at joint C of Fig. 12 (this member not shown), it is to be considered as nonexistent, so far as the operations of this section are concerned; its coefficients C_{4E} and D_{4E} are evidently zero.

The generalization of Eqs. 35 for application to joints of any number of members is obvious by inspection of the structure of these formulas. Coefficients C depend only upon the stiffness of the members. Therefore, they may be written once and used for all cases of loading and lateral deflections in the frame.

Eqs. 35 represent recurrence relations which make it possible to correlate end moments in a series of members by passage from one group of members to adjacent ones. The process of determining the successive coefficients C and D for consecutive members may be described as follows:

The determination of coefficients C and D may start at a member connected to a support. Two cases will be considered, depending on the type of this support, taken as the origin.

Case 1.—In the first case, the origin is a simply connected support; that is, only one member is connected to it. If this member is hinged at the origin, its coefficients C and D equal zero; if this is not the case, to find its coefficients C and D, consideration is given to Eq. 28*a* relative to this member. In this equation, the support rotation ω (if not zero) can be replaced by the end moments and the linear movements of the support, using the appropriate boundary condition therein which correlates these elements. The lateral deflection δ in Eq. 28*a* can also be written in terms of some adjacent δ_{p-q}-elements and some support movements (this is true for even more complex types of supports, such as support a of Fig. 11, in which $\delta_1 = \delta_{1-2} + \delta_{2-3} + \delta_3$). The resulting expression will be a linear relation involving the end moments of the member; its coefficients are the required values of C and D for this member; coefficients D will be in terms of the δ_{p-q}-elements and the support movements.

Case 2.—In the second case, the origin is a multiply connected support; that is, it is situated on the periphery of one or more closed circuits, such as joint a of Fig. 11. The rotation of the support ω (if not zero), common to all members meeting it, is maintained in equations such as Eq. 28*a* corresponding to each one of these members. Their lateral deflections δ can be replaced, the same as in case 1, using neighboring δ_{p-q}-elements and linear movements of adjacent supports. The resulting linear equations, involving the end moments, will again furnish the coefficients C and D for each member, except that, in this case, coefficients D will also be functions of the support rotation ω as a parameter, used for "opening up" the closed circuits at the origin. It will be eliminated in the remaining operations which will be described in the next paragraph. In case all members are hinged at the common origin, their coefficients C and D naturally vanish.

Coefficients C and D for one or several starting members having been found, operations may proceed continuously in one direction, using Eqs. 35. Successive sets of C and D coefficients for each span are written as functions of those preceding, all coefficients D in linear terms of δ_{p-q}-elements. Each set signifies one linear relation between the end moments of a member. A span will be reached finally where the end moments are already correlated by another equation resulting from a given boundary condition. This will mean two equations in terms of two end moments. Their solution will yield these moments which then can be carried backward toward the origin, for the determination of all end moments in preceding spans. For case 2, all these moments will contain the rotation ω of the origin as a parameter. This rotation can now be determined by writing $\sum M = 0$ at the origin; then it can be replaced in the expressions of the moments.

The operations are similar to the foregoing when both the origin and terminal support are multiply connected, or when the frame contains closed regions. In such cases, a joint or support rotation can again be maintained in the formulas for the purpose of "opening up" closed regions; later it can be eliminated. Several adjacent closed regions may be "opened up" by the use as a parameter of a single joint rotation.

The general approach presented herein may be greatly simplified in each individual case of practical application.

The principal conclusion to be drawn from this discussion is that the end moments in a frame can be found as linear functions of the δ_{p-q}-elements at the angles and the linear movements of the supports. This proves the proposition stated at the head of this section.

A geometric interpretation of the property of rigid joints stated in paragraph I is the following: If, at a joint of n members, the moment lines of all but one of the members pass through known fixed points ($n - 1$ in all), the moment line of the remaining member will also pass through a fixed point which may be located using the coordinates of the known points, and the δ_{p-q}-elements at the joint. Upon this interpretation, a generalized theory of fixed points may be based for the determination of end moments by means of semi-graphical operations.[4] (See also the work[6] of L. H. Nishkian, and D. B. Steinman, Members, Am. Soc. C. E.)

DETERMINATION OF AXIAL STRAINS AND THE LINEAR MOVEMENTS OF SUPPORTS

The essential function of the group of the axial strains ϵ and ϵ_t of the given and imaginary members and the linear movements of the supports, in specifying the system of displacements and stresses in a frame, has been described in the preceding part of this paper. The determination of this group of elements is the object of this section.

In some problems, the displacements of the joints and the supports are supplied as part of the data; in such cases, the analysis of the frame is comparatively simple: All δ_{p-q}-elements appearing in Eqs. 34 and 35 assume known values; and all end moments, axial forces, and shears are found at the conclusion of the operations of the preceding section. In other problems, all joints are hinged, and the axial forces in the members may be determined by simple statics; the axial strains are then available and can be used for the determination of all deflections (see "Corollary to Example 2" and "Example 5"). In general, however, the frame is rigid and the joints and supports are subject to unknown displacements. The determination of axial strains ϵ and ϵ_t and support movements is then necessary, so far as the present analysis is concerned.

---

[6] "Moments in Restrained and Continuous Beams by the Method of Conjugate Points," by L. H. Nishkian and D. B. Steinman, *Transactions*, Am. Soc. C. E., Vol. 90 (1927), pp. 1-206.

At this stage of the analysis, end moments, hence transverse end forces in all given members, are assumed to have been written as functions of $n_m + n_{mt} + n_\sigma$, axial strains ϵ and ϵ_t, and support movements. More precisely, they may be assumed to be expressed in terms of the quantity $2\,n_p + n_\sigma$ of these elements considered as independent (see "Topology of Frameworks: Proposition (*c*)").

In the given frame decomposed completely into triangular elements by means of n_{mt} imaginary diagonals, the axial strains in n_i of the bars are considered to be dependent upon the others (see Proposition (*c*)). Remove from the resulting figure n_i bars judiciously chosen, and replace all joints and supports by perfect hinges. The structure thus obtained will be called a conjugate frame (see Fig. 13, given subsequently). This frame has the same n_p joints as the original; but the number of its bars is $(n_m + n_{mt}) - n_i = n_m + n_{mt} - (n_m + n_{mt} - 2\,n_p) = 2\,n_p$. At the joints of the conjugate frame apply the corresponding joint loads of the original, and, in addition, load them with the transverse end force exerted by each given member. So far as the forces in the bars are concerned, the conjugate frame is statically determinate since it has $2\,n_p$ bars and n_p joints, each furnishing two equilibrium equations, $\sum X = 0$ and $\sum Y = 0$. The solution of this frame will yield $2\,n_p$ axial forces as functions of the $2\,n_p + n_\sigma$ independent unknowns. Equate to zero the axial forces corresponding to the imaginary diagonals; equate to $E\,A\,\epsilon$ of the corresponding member, those belonging to the given members; the result is a system of $2\,n_p$ equations for the determination of $2\,n_p$ unknown axial strains in terms of n_σ support movements. These movements can then be found by the use of the corresponding boundary conditions.

In case the axial strains of the given members are assumed to be negligible—a very frequent case in rigid frames—the number of independent axial strains decreases from $2\,n_p$ to $2\,n_p - n_m$. It will then be sufficient to solve only for the axial forces in the $n_{mt} - n_i$ $(= 2\,n_p - n_m)$ imaginary diagonals and to equate them to zero. Often, a convenient way of doing this is to apply the equilibrium equation $\sum(M) = 0$ to a portion of the conjugate frame on one side of some line X–X, treated as a free body; if this line is drawn to intersect one of the imaginary diagonals, and if the center of moments is chosen with care, this equation may contain none (or only a few) of the axial forces in the members (these forces are of no immediate interest in this case). The result will be a relation involving only the loads at the joints of the conjugate frame, that is, a relation between the $(2\,n_p - n_m) + n_\sigma$ independent unknowns. By varying the line X–X and the center of moments, additional relations of the same type may be obtained (see Illustrative Problem, and Fig. 13, given subsequently).

The treatment of the case (mentioned at the beginning of this section), in which the joints of a frame are subjected to given displacements rather than loads, can now be amplified further. These displacements immediately specify all elements δ, δ_{p-q}, ϵ, ϵ_t. If the movements of the supports are also assumed given, all end moments, axial and transverse end forces throughout the frame will be known in terms of these displacements; the $2\,n_p$ equations of equilibrium at the joints of the conjugate frame will then furnish the $2\,n_p$ components X and Y of the n_p joint constraints corresponding to, and resulting in, the joint displacements impressed upon the frame.

APPLICATION TO THE GENERAL CASE

The method presented in this paper will be applied to the general case of a frame in which axial deformations are not negligible; the actual solution is best described by decomposing it into the following sequence. This will help to recapitulate the procedure of the analysis.

Step 1.—Divide the frame completely into simple triangular panels by means of imaginary diagonals. For the $2\,n_p + n_\sigma$ independent unknowns (see "Topology of Frameworks: Proposition (*c*)"), choose (in addition to the n_σ linear movements of supports) the axial strains of $2\,n_p$ of the given members, if $2\,n_p \leqq n_m$. Choose the axial strains of all n_m given members and $2\,n_p - n_m$ of the imaginary diagonals, if $2\,n_p > n_m$. Some judgment must be exercised in this choice, with a view to convenience in the operations of step 2.

Step 2.—Proceeding as in Example 1, express all δ_{p-q}-elements, one at each angle formed by given members, in terms of the independent unknowns. This is done conveniently by first writing these δ_{p-q}-values using the axial strains of all the bars in the vicinity, and then eliminating the dependent axial strains by means of the n_i-relations (see "Topology of Frame-work: Proposition (*c*)").

Step 3.—By application of the procedure described under the heading, "Determination of End Moments," express all end moments as functions of δ_{p-q}-elements (hence, as functions of the independent unknowns); if the end moments determined thus involve also the rotations at some of the multiply connected supports (or at joints on the periphery of closed regions), these rotations may be found and eliminated by the use of $\sum M = 0$ at such supports or joints.

Step 4.—Using these end moments, express all transverse end forces as functions of the independent unknowns; load the conjugate frame and solve for the $2\,n_p$ independent axial strains in terms of the n_σ linear movements of the supports (see heading, "Determination of Axial Strains and the Linear Movements of Supports").

Step 5.—Use the boundary conditions and determine the displacements of the supports. Of three boundary conditions at each support, one, relating to the support rotation and equivalent to $\sum M = 0$, will yield the rotation of the support, if not already found in step 3 of this sequence. The remaining two boundary conditions will furnish the linear movements of the support, and Eqs. 25 will give the reactions.

All stresses and displacements throughout the frame may now be found using the $2\,n_p + n_\sigma$ independent unknowns just determined.

The general solution outlined herein can be simplified appreciably if one chooses to analyze a rigid frame, as a preliminary step, under the assumption of negligible axial deformations in the members. Such an analysis (outlined under a subsequent heading, "Application to a Less General Case") will yield axial forces in the given members which, in general, are correct enough for a first approximation. The axial strains of these members may then be computed and used in the compatibility equations of step 2 (this sequence), which will then contain a small constant term (corresponding to these axial strains), in addition to the axial strains ϵ_t of imaginary diagonals and the movements of the supports. The solution can then proceed, yielding another set of axial forces, which may be used for a second cycle of the same operations, each cycle altering the small constant term in the compatibility equations to a still smaller extent. The procedure may be repeated as many times as desired. In general, one cycle is ample when dealing with most rigid frames.[4]

Application to a Less General Case

The analysis of a rigid frame in which the axial deformations of the n_m given members are assumed to be negligible proceeds along steps similar to those involved in the general case. The number of independent unknowns becomes $(2\,n_p - n_m) + n_\sigma$, comprising $(2\,n_p - n_m)$ axial strains (this is also the number of imaginary diagonals in the conjugate frame) and n_σ support movements; $2\,n_p$ must be greater than n_m, otherwise, the axial deformations of the given members may not all be assumed negligible. The determination of the independent unknowns is much simpler than in the general case, since, as has been noted before, it will be sufficient to write only that the axial forces in the imaginary diagonals vanish.

If they are of interest, the axial forces in the given members may be found by the solution of the conjugate frame, in the same manner as in any statically determinate frame.

Illustrative Problem

Although somewhat different from the ordinary type of structures, the following case was chosen in order to illustrate as many points of the preceding analysis as possible.

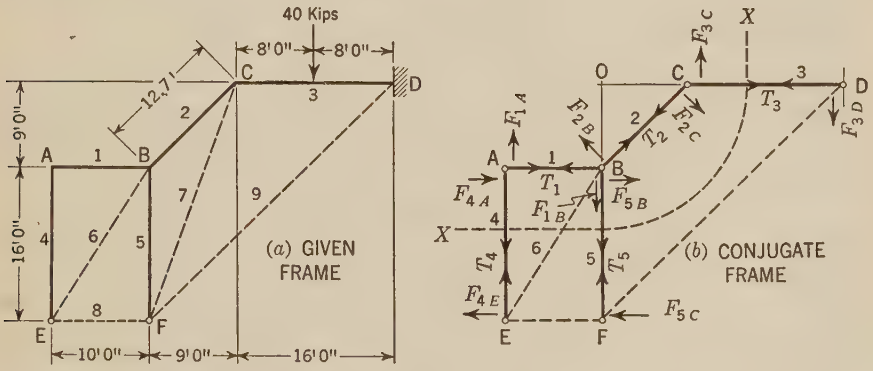

FIG. 13.—(STIFFNESS FACTORS: $K_1 = K_4 = 1$; $K_2 = K_5 = 2$; AND $K_3 = 3$)

The rigid frame of Fig. 13(a) is to be analyzed for moments and deflections. Linear movements of the supports are prevented, supports E and F are hinged, and support D fully restrained; axial deformations of the members are assumed to be negligible; units are in feet and kips. The steps in the procedure correspond to those in "Application to the General Case."

Step 1.—Draw imaginary diagonals 6, 7, 8, and 9. Due to the nature of the supports, $\delta_8 = \delta_9 = 0$, $\epsilon_8 = \epsilon_9 = 0$; and, because of negligible axial deformations, $\epsilon_1 = \epsilon_2 = \epsilon_3 = \epsilon_4 = \epsilon_5 = 0$. The number of independent unknowns is $2\,n_p - n_m + n_\sigma = 2 \times 3 - 5 + 0 = 1$. The axial strain ϵ_6 of imaginary diagonal 6 will be taken as this unknown.

Step 2.—By application of Example 1, the expressions for the several δ_{p-q}-elements (using scaled dimensions) are as follows:

$$\left.\begin{array}{rl} \delta_{8-4} = \delta_{8-6} + \delta_{6-4} = & -\,2.22\,\epsilon_6 \\ \delta_{4-1} = & +\,2.22\,\epsilon_6 \\ \delta_{1-5} = \delta_{1-6} + \delta_{6-5} = & -\,2.22\,\epsilon_6 \\ -\,\delta_{8-5} = \delta_{5-8} = & +\,2.22\,\epsilon_6 \end{array}\right\}\ldots\ldots\ldots\ldots(36)$$

$$\left.\begin{array}{rl} -\,\delta_{5-9} = \delta_{9-5} = \delta_{9-7} + \delta_{7-5} = & -\,1.78\,\epsilon_7 \\ \delta_{5-2} = & +\,4.92\,\epsilon_7 \\ \delta_{2-3} = \delta_{2-7} + \delta_{7-3} = & -\,4.92\,\epsilon_7 \\ \delta_{3-9} = & +\,1.78\,\epsilon_7 \end{array}\right\}\ldots\ldots\ldots\ldots(37)$$

The number of n_i-relations is $5 + 2 - 2 \times 3 = 1$. This is the equation $\sum \delta_{p-q} = 0$ at the interior support F, or $\delta_{8-5} + \delta_{5-9} = 0$; that is, $-\,2.22\,\epsilon_6 + 1.78\,\epsilon_7 = 0$. Hence: $\epsilon_7 = 1.245\,\epsilon_6$. Substituting this value of ϵ_7 in Eqs. 37:

$$\left.\begin{array}{ll} \delta_{9-5} = -.2.22\,\epsilon_6; & \delta_{5-2} = +\,6.12\,\epsilon_6 \\ \delta_{2-3} = -\,6.12\,\epsilon_6; & \delta_{3-9} = +\,2.22\,\epsilon_6 \end{array}\right\}\ldots\ldots\ldots\ldots(38a)$$

and

$$\delta_{1-2} = \delta_{1-5} + \delta_{5-2} = 3.90\,\epsilon_6\ldots\ldots\ldots\ldots\ldots\ldots(38b)$$

Step 3.—The coefficients C and D in each successive member are determined by Eqs. 34 and 35, in which all δ_{p-q}-elements are replaced by their equivalents, Eqs. 36 and 38. Operations begin at joint E and proceed toward joint D $\left(\text{note that } m_{3C} = +\dfrac{16 \times 40}{8} = +\,80,\ m_{3D} = -\,80\right)$:

Since $M_{4E} = 0$—
in member 4, $C_{4A} = 0$; and

$$D_{4A} = 0\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(39a)$$

in member 1, $C_{1B} = -\,0.25$; and

$$D_{1B} = -\,3.33\,E\,\epsilon_6\ldots\ldots\ldots\ldots\ldots\ldots\ldots(39b)$$

Since $M_{5F} = 0$—
in member 5, $C_{5B} = 0$; and

$$D_{5B} = 0\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(40a)$$

in member 2, $C_{2C} = -\,0.305$; and

$$D_{2C} = -\,18.75\,E\,\epsilon_6\ldots\ldots\ldots\ldots\ldots\ldots\ldots(40b)$$

in member 3, $C_{3D} = -\,0.22$; and

$$D_{3D} = +\,30.4\,E\,\epsilon_6 + 52.8\ldots\ldots\ldots\ldots\ldots\ldots(40c)$$

Using the values for C_{3D} and D_{3D} from Eqs. 40*c* in the equation $M_{3C} + C_{3D} \times M_{3D} = D_{3D}$, for member 3:

$$M_{3C} - 0.22\, M_{3D} = +\,52.8 + 30.4\, E\, \epsilon_6 \tag{41a}$$

Making $\omega_D = 0$ in the slope deflection equation for member 3 (corresponding to Eq. 28*b*), a second relation is obtained between M_{3C} and M_{3D}:

$$M_{3C} - 2\, M_{3D} = +\,240 - 39.96\, E\, \epsilon_6 \tag{41b}$$

Solving Eqs. 41:

$$M_{3C} = +\,29.7 + 39.15\, E\, \epsilon_6 \tag{42a}$$

and

$$M_{3D} = -\,105 + 39.53\, E\, \epsilon_6 \tag{42b}$$

All end moments may now be found in terms of ϵ_6 by proceeding backward and using the C-values and D-values in Eqs. 39 and 40; thus:

$$M_{2C} = -\,M_{3C} = -\,29.7 - 39.15\, E\, \epsilon_6 \tag{43a}$$

and $M_{2B} + C_{2C}\, M_{2C} = D_{2C}$; or,

$$M_{2B} = -\,9.06 - 30.75\, E\, \epsilon_6 \tag{43b}$$

At joint B, Eq. 31*a* should be applied to member 5, giving $\frac{C_{5B} + 2}{K_5} M_{5B} = \frac{1}{K_2} (2\, M_{2B} - M_{2C}) + 6\, E\, \delta_{5-2}$; or,

$$M_{5B} = +\,5.79 + 25.81\, E\, \epsilon_6 \tag{44}$$

Continuing:

$$M_{1B} = -\,M_{2B} - M_{5B} = +\,3.27 + 5.21\, E\, \epsilon_6 \tag{45a}$$

$M_{1A} + C_{1B}\, M_{1B} = D_{1B}$; or,

$$M_{1A} = +\,0.82 - 2.03\, E\, \epsilon_6 \tag{45b}$$

and

$$M_{4A} = -\,M_{1A} = -\,0.82 + 2.03\, E\, \epsilon_6 \tag{45c}$$

Step 4.—The transverse forces exerted on joints A and B by member 1 will be designated by F_{1A} and F_{1B}, respectively. Similar symbols will be selected for the transverse end forces of other members. The positive directions of these reactions will be such as to create a clockwise couple. Then:

$$\left.\begin{array}{ll} F_{4E} = F_{4A} = -\dfrac{M_{4A}}{16}; & F_{1A} = F_{1B} = -\dfrac{M_{1A} + M_{1B}}{10} \\[2ex] F_{5F} = F_{5B} = -\dfrac{M_{5B}}{16}; & F_{2B} = F_{2C} = -\dfrac{M_{2B} + M_{2C}}{12.7} \\[2ex] \multicolumn{2}{c}{F_{3C} = -\dfrac{M_{3C} + M_{3D} + 320}{16}} \end{array}\right\} \tag{46}$$

Load the conjugate frame with these forces, as shown in Fig. 13(*b*), and equate to zero, the moment about point O of all forces on the free body above line X–X:

$$-\,10\, T_4 + 10\, F_{1A} - 9\, F_{4A} - 9\, F_{5B} + 6.35\, F_{2B} + 6.35\, F_{2C} - 9\, F_{3C} = 0 \tag{47}$$

The force T_4 may be eliminated by the condition $\sum Y = 0$ at joint A, giving $T_4 = F_{1A}$. Use Eqs. 42 to 46, inclusive, and, in Eq. 47, replace all F-elements by their equivalents in terms of ϵ_6; the following equation is the result:

$$+ 318.67 + 224.51\, E\, \epsilon_6 = 0 \qquad (48)$$

or, $E\, \epsilon_6 = - 1.37$.

The substitution of this value of ϵ_6 into the expressions of the several unknowns in terms of ϵ_6 will give all unknowns explicitly: For instance, $M_{3C} = + 29.7 + 39.15\ (- 1.37) = - 24.4$; and $M_{3D} = - 105 + 39.53\ (- 1.37) = - 159.5$.

All rotations and displacements of joints may now be found by using the end moments, the axial strains, and the unit deflections determined as a result of the preceding analysis. It is necessary, however, to use the actual K-values of the members; if member 4, for example, is a 10-in., 72-lb, H-section, its actual K is $\frac{420}{12^4 \times 16}$ ft³, while its relative K was assumed as 1. Using feet and kips, the actual value of ϵ_6 (Eq. 48), is therefore: $\epsilon_6 = -\frac{1.37}{30{,}000 \times 12^2} \div \frac{420}{12^4 \times 16} = -\frac{1}{3{,}994}$.

If the vertical displacement of joint C is desired, Eq. 38a yields: δ_{3-9} or $\delta_3 = -\frac{2.22}{3{,}994}$. Then: $\Delta_3 = -\frac{2.22 \times 192}{3{,}994} = - 0.11$ in. (clockwise about joint D) or, + 0.11 in. downward.

CONCLUSION

A complete analysis of the general two-dimensional framework is achieved through the consideration—and use as principal unknowns—of the system of the axial strains in the members and those in the imaginary diagonals which divide it into triangular elements. The paper brings into evidence the compatibility conditions and topological properties of the frame and establishes a correspondence between it and a conjugate frame which is statically determinate. These considerations lead to the determination of all unknowns.

The adaptability of the general theory to different types of problems, and its workability as a practical method of approach, are demonstrated by several illustrative applications.

ACKNOWLEDGMENT

This paper was prepared from a dissertation presented by the writer at Columbia University, New York, N. Y., in 1941, in partial fulfilment of the requirements for the degree of Doctor of Philosophy. The writer wishes to acknowledge his great indebtedness for valuable suggestions and guidance to Professors J. K. Finch and J. M. Garrelts, Members, Am. Soc. C. E., and R. D. Mindlin and M. G. Salvadori, Assoc. Members, Am. Soc. C. E., of the Faculty of the School of Engineering at Columbia University.

APPENDIX

NOTATION

The following symbols, used in this paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering, and Testing Materials,[7] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932. In the text, subscripts are used with these symbols, to relate them to the corresponding member or joint.

A = area; cross-sectional area of a member: A_e = the area of a quadrilateral element (Eq. 15); in Eq. 13, A, B, and C are used to designate the interior angles at joints A, B, and C of a triangle;

a = linear dimension in a triangle (see also b and h):
    a_1 = linear projection of the line AB (see Fig. 2) on the x-axis;
    $(a_1)'$ = linear projection of the line A′B′ (see Fig. 2) on the x-axis;
    $a_{1,3}$, etc. (see Fig. 4) = linear projection of member 1 on member 3, etc.;

B = (see angles A, B, and C in Eq. 13);

b = linear dimension in a triangle (see also a and h):
    b_1 = linear projection of the line AB (Fig. 2) on the y-axis;
    $(b_1)'$ = linear projection of the line A′B′ (Fig. 2) on the y-axis;

C = coefficient in the general linear relation between the end moments of a member; see Eqs. 26 (see also coefficient D); in Eq. 13, A, B, and C are used to designate the interior angles at joints A, B, and C of a triangle;

D = coefficient in the general linear relation between the end moments of a member; see Eqs. 26;

E = Young's modulus;

e = total axial deformation of a member, elongation being positive: In Eqs. 24, e_{xa} denotes the linear movement of support a in the x-direction and e_{ya} in the y-direction;

F = transverse end force in a member (also, where indicated, F = "function of"): F_{1A}, etc., in Eqs. 46, designate the transverse forces exerted by member 1 upon joint A, Fig. 13;

h = linear dimension of a triangle (see also a and b); in Eq. 9, $h_{1,2}$ is the perpendicular drawn on member 3 from the intersection of members 1 and 2;

I = moment of inertia;

K = stiffness ratio I/l;

l = length of a member from center to center of joints: l_1 is the length of member 1 = AB, Fig. 2; $(l_1)'$ is the corresponding length of the deformed member A′B′, Fig. 2;

M = moment: M_{1A}, etc. = the moment exerted by member 1 upon joint A, the clockwise direction assumed positive; M_a = the moment at support a, Fig. 11;

---

[7] ASA—Z10a—1932.

m = moments similar to M when the end rotations and the lateral deflection of the member are zero;

n = a number:

  $n_i = n_m + n_{mt} - 2\, n_p$;

  n_m = total number of given members, excluding those connected to a support at each end;

  n_p = total number of joints, excluding the supports;

  n_r = total number of distinct regions in a frame, excluding those with all their vertices at supports;

  n_t = total number of distinct triangles resulting from the division of the frame by imaginary diagonals, excluding those with all their vertices at supports;

  n_{mt} = total number of imaginary diagonals required for the complete division of the frame into triangles, excluding those joining two supports;

  n_σ = total number of linear movements of the supports in a frame;

T = axial force in a member, positive for tension:

  T^0 = axial force found by assuming $X = 0$ and allowing the external loading to act (Fig. 8);

  T^1 = axial force found by assuming $X = 1$ and all external loading removed (Fig. 8);

U = a substitution factor used to simplify Eq. 33;

X = reaction: X_a, Y_a, and M_a are the horizontal, vertical, and moment reactions at support a, Fig. 11;

x = coordinate distance parallel to the x-axis; x and y are the coordinates of a point on a deflected member; x_a, y_a are the coordinates of joint A;

Y = (see X);

y = (see x);

α = angles shown in Fig. 5;

Δ = relative lateral displacement at one end of a member with respect to the other, measured at right angles to the member, positive if either end moves clockwise about the other;

δ = unit deflection of a member, defined by $\delta = \dfrac{\Delta}{l}$; δ_t = unit deflection of an imaginary diagonal; $\delta_{p-q} = \delta_p - \delta_q$, the difference in unit deflection between two adjacent members p and q;

ϵ = axial strain of a given member defined by $\epsilon = \dfrac{e}{l}$; ϵ_t = axial strain in an imaginary diagonal; $\epsilon_{p-q} = \epsilon_p - \epsilon_q$, the difference in axial strain between two adjacent members p and q;

λ = the angle of a given line referred to the x-axis;

ω = angular rotation of a joint or support measured from its position before deformation or displacement, positive when clockwise;

$\sum_o$ = sign of summation around a closed region continuously in a clockwise direction, including all joints (or all members) on the boundary.

DISCUSSION

Leon Beskin,[8] Assoc. M. Am. Soc. C. E.—To clarify this discussion, the method of framework analysis presented by the author is summarized as follows:

1.—The redundant unknowns are divided into two groups—(*a*) linear displacements of the joints; and (*b*) rotations at the joints, for which the moments at the joints can be substituted in the case of relatively simple structures.

2.—Group (*a*), Item 1, is represented by the relative variations of lengths (strains) of the sides of a statically determinate triangulated system which "maps" the actual structure according to a method well known in surveying.

3.—Group (*b*), Item 1, can be calculated in a relatively simple manner as a function of group (*a*) when the framework is of the "open" type; that is, when the computer progresses along the framework in a definite direction without intersecting hinges (free rotation) or fully restrained multiple supports (no rotation), no member can be encountered twice. In this special case, moments can be considered directly, instead of rotations. The procedure becomes increasingly complicated when multiply-connected frames are considered and it becomes necessary to introduce a third group of redundant unknowns, which must be added to the moments and which includes the rotations of some of the joints.

4.—The equilibrium of moments at the joints is obtained without considering the equilibrium of the longitudinal and transverse forces. These forces can be defined in terms of the moments at the joints. Then the structure can be replaced by an equivalent hinged structure and the conditions of stability and equilibrium of forces corresponding to that structure give the equations necessary to define the unknowns of group (*a*), Item 1.

A profitable comparison can be made between this paper and the simple and direct analysis presented by David M. Wilson,[9] M. Am. Soc. C. E., who admits "that no new method of analysis is proposed." For example:

(1) Divisions of the unknowns into two groups is the basis of both methods.

(2) For group (*a*), Item 1, Mr. Wilson uses rotations and Mr. Nubar uses strains. The two groups are similar, and only practical considerations can indicate the superiority of one group. Mr. Wilson limits himself to structures in which axial deformations are negligible, which is the "less general case" treated by Mr. Nubar; but the treatment of the more general case by successive approximations is well known; it is the conventional method for the analysis of trusses. A good example can be found in a study by K. A. Calisev,[10] who examines trusses, beams on continuous supports, and frameworks.

(3) For group (*b*), Item 1, Mr. Wilson uses rotations or moments, and applies slope deflection and moment distribution methods. Mr. Nubar uses

moments wherever possible and applies the method of fixed (conjugate) points. All these methods are well known and the special conditions of each problem or, more often, the habits of the analyst, dictate the choice between these methods. However, for multiply-connected circuits, the moment distribution method has the definite advantage of being well developed, available with numerous examples in any textbook. On the contrary, the fixed points method, developed many years ago in a straightforward manner for open circuits only, is far from being perfected (as shown by the author's statements) for use in analyzing multiply-connected circuits. The author indicates, in substance, that some rotations must be introduced as auxiliary unknowns and that the system of equations containing these unknowns must then be solved. This is known and is a condition that must be applied to any statically indeterminate structure. A method is new and useful essentially in the extent to which it presents a definite and straightforward manner of choosing unknowns and of solving systems with a high degree of indeterminacy.

(4) The determination of group (*a*), Item 1, when group (*b*) is defined in terms of group (*a*), is identical in the Nubar and the Wilson methods.

From the foregoing, it appears that the Nubar method follows closely the pattern of conventional methods. It remains to be decided whether the method introduces an element of newness and simplification over conventional procedures.

As indicated, the division of unknowns in two groups is conventional. Generally the unknowns of group (*a*) are: The horizontal displacements for multi-story frames; the vertical displacements for Vierendeel beams; and the axial loads (or strains) for triangulated trusses.

The author replaces unknowns that result from a choice adapted to the nature of each problem, by a system of arbitrary unknowns which are the same in all cases. This attitude can be compared to that of an analyst who would always use rectangular coordinates, even if other sets of coordinates (polar, cylindrical, spherical, etc.) are more adapted to the problem. Such an approach is utterly unsatisfactory; and sometimes the main difficulty in the solution of a problem is in the choice of a proper system of coordinates. In the present case, since it is always necessary to calculate the angular displacements δ of the straight lines connecting the ends of each member (called unit deflections by the author), it appears logical, wherever possible, to use the latter as principal unknowns. For instance, in Fig. 13 no advantage results from the use of ϵ_6 as an unknown, against the use of either the horizontal displacement of AB or the common rotation of EA, BF, and CD. Defining δ as this rotation, Eqs. 36, 37, and 38 become:

$$\left.\begin{aligned} -\delta_{8-4} = -\delta_{1-5} = \delta_{3-9} = \delta_{4-1} = \delta_{5-8} = \delta \\ \delta_{1-2} = \frac{16}{9}\delta = 1.777\,\delta \qquad\qquad\qquad \\ \delta_{5-2} = -\delta_{2-3} = (\delta_{3-9} + \delta_{1-2}) = 2.777\,\delta \end{aligned}\right\}\ldots\ldots\ldots\ldots(49)$$

The simplification is obvious and clearly demonstrates, by means of the example given by the author himself, that the method is of very little practical interest for frameworks, even of an unconventional type.

For a conventional framework, there is no doubt that the linear displacements of the various stories, defining the rotations at a glance or (even better) the rotations of each line of columns between stories, are the logical unknowns to be used (Fig. 14). If axial strains are considered, they are added to the rotations to form the first group of unknowns.

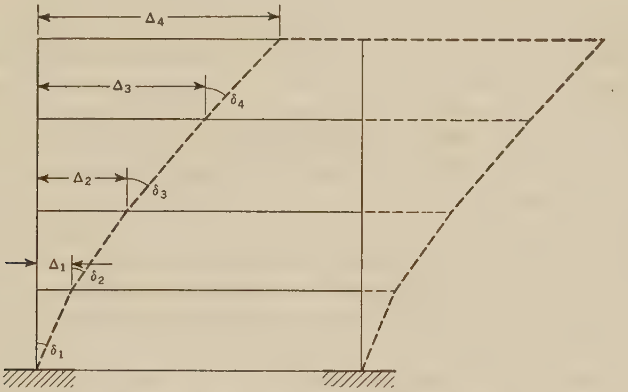

FIG. 14

His illogical choice of the unknowns for rectangular frames has forced the author to use, in all cases, what he called "equations of compatibility" which relate axial strains to angular displacements. These equations are well known under other names. Eqs. 4 are the equivalent of the Williot-Mohr construction. The condition expressed in terms of moments (Eq. 5) is the equation used for the calculation of deflections of curve beams, the sole difference being that the quantity $\sum x_k (\epsilon_{k,k+1} - \epsilon_{k-1,k})$ is replaced by the equivalent quantity $\sum \epsilon_{k,k+1} (x_{k+1} - x_k) = \sum \frac{P}{E\,A} (x_{k+1} - x_k)$, whereas the quantity $\sum y_k \left(\frac{\Delta_{k,k-1}}{L_{k,k-1}} - \frac{\Delta_{k-1,k}}{L_{k-1,k}} \right)$ is generally replaced by the integrated expression:

$$\int y_k \frac{d^2\Delta}{ds^2}\, ds = \int y \frac{M}{E\,I}\, ds \ldots\ldots\ldots\ldots\ldots\ldots (50)$$

Eq. 10*a* is well known, in English[11] as well as in French[12] literatures under the equivalent form (see Fig. 15):

$$\frac{\Delta_b}{b} - \frac{\Delta_c}{c} = \delta\,\alpha = \frac{\epsilon_b - \epsilon_a}{\tan\gamma} - \frac{\epsilon_c - \epsilon_a}{\tan\beta} \ldots (51)$$

Topology of Frameworks.—The purpose of the section entitled "Topology of Frameworks" appears to be the establishment of Proposition (*c*) which appears several times in the paper. However, this proposition is self-evident without any preliminary proof: The n_p-joints each

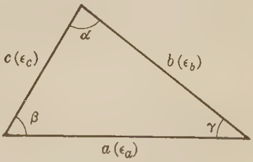

FIG. 15

---

[11] "Airplane Structures," by A. S. Niles and J. S. Newell, Vol. I, 3d Ed., 1943, New York, N. Y., p. 402.

[12] "Résistance des Matériaux," by B. de Fontviolant. Vol. II, 1927, Paris, p. 148.

have two degrees of freedom in the plane; the entire framework in joint displacement has $2\,n_p$ degrees of freedom, plus n_σ degrees of the n_σ linear displacements of support, minus $n^r{}_m$ degrees for the $n^r{}_m$ rigid (nondeformable) members. Thus:

$$\text{Degree of freedom} = 2\,n_p + n_\sigma - n^r{}_m \qquad (52)$$

In Eq. 52, $n^r{}_m$ (in which r is an index and not an exponent) may vary from zero to n_m, the total number of members. It appears that this entire section is extraneous to the subject of the paper.

Boundary Conditions.—Since moments and axial strains are used as unknowns, and, perforce, they define the stresses and loads in the structure completely, it is obvious that the boundary conditions can be expressed in terms of such elements, and general Eqs. 24 do not clarify the problem for practical applications.

End Moments.—The method used to determine in succession the moments in a structure of the "open" type is the well-known method of "conjugate points" (English terminology), "focal points" (French terminology), "fixed points" (German terminology).

The development of Eqs. 35 can be presented in a simpler and more symmetric manner: Using the author's notation, and with r denoting any member, it can be shown that, if n members meet at a joint J and if, for $n - 1$ members, there exist relations of the type

$$M_{rR} + C_{rJ}\, M_{rJ} = D_{rJ} \qquad (53)$$

(R being the joint at the end of the member r), a relation of the same type holds for the nth member.

This fact is obvious from the general relations of linearity between moments and rotations. The coefficients C_{n-J}, D_{n-J} of the nth member can be related to the other coefficients. The equation of equilibrium of a joint is:

$$M_J + \sum M_{rJ} = 0 \qquad (54)$$

in which M_J is a couple applied at the joint. Expressing the rotation of any member at the joint in terms of the loads and couples,

$$\omega_J = \delta_r + \frac{1}{6\,E\,k_r}\,(2\,m_{rJ} - m_{rR} + M_{rR} - 2\,M_{rJ}) \qquad (55)$$

All rotations ω_J are equal. Replacing M_{rR} in terms of M_{rJ} by means of Eq. 53, the value of M_{rJ} can be expressed as follows:

$$M_{rJ} = -\,\omega_J\,\frac{6\,E\,k_r}{C_r + 2} + \frac{6\,E\,k_r\,\delta_r + 2\,m_{rJ} - m_{rR} + D_{rJ}}{C_r + 2} \qquad (56)$$

Substituting in Eq. 54:

$$M_J + \sum \frac{6\,E\,k_r\,\delta_r + 2\,m_{rJ} - m_{rR} + D_{rJ}}{C_r + 2} - \omega_J\,6\,E \sum \frac{k_r}{C_r + 2} = 0 \qquad (57)$$

When M_J, δ_r, m_r, and D_r are all equal to zero, there may be a rotation ω_J under the action of moments M_{rR}. This shows that the coefficient of ω_J is equal to zero (except for a completely restrained joint for which $\omega_J = 0$ and $C_r = -2$). Thus

$$\sum \frac{k_r}{C_r + 2} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (58)$$

Also

$$M_J + \sum \frac{6\,E\,k_r\,\delta_r + 2\,m_{rJ} - m_{rR} + D_{rJ}}{C_r + 2} = 0 \ldots\ldots\ldots\ldots (59)$$

Eqs. 58 and 59 are absolutely symmetrical and are equivalent to Eqs. 34 and 35, provided it is noted that $C_{rR} = 1 : C_{rJ}$ and $D_{rR} = D_{rJ} : C_{rJ}$. The method developed from Eqs. 58 and 59 is a mere extension of the method of fixed points for continuous beams, adapted to "open" structures. In that form it was presented by Prof. M. Ritter[13] as early as 1936.

For multi-connected circuits, it is necessary to introduce the rotations of some of the joints, which cannot be eliminated directly. Very rapidly, the method becomes extremely complicated, due to the number of simultaneous unknowns, and loses its value, at least in its present stage. Moreover, the author limits himself to a simple suggestion of the method, without attempting to develop it into a practical procedure. For a conventional truss, the number of rotations to be introduced is the integer equal or immediately superior to one third of the number of the circuits. In Fig. 16(*a*), the "opened" joints are represented by hinges. For a conventional Vierendeel structure (Figs. 16(*b*) and 16(*c*)), the corresponding ratio is one half. The last result also applies to a one-span, multi-story portal, and to a two-story, multi-span

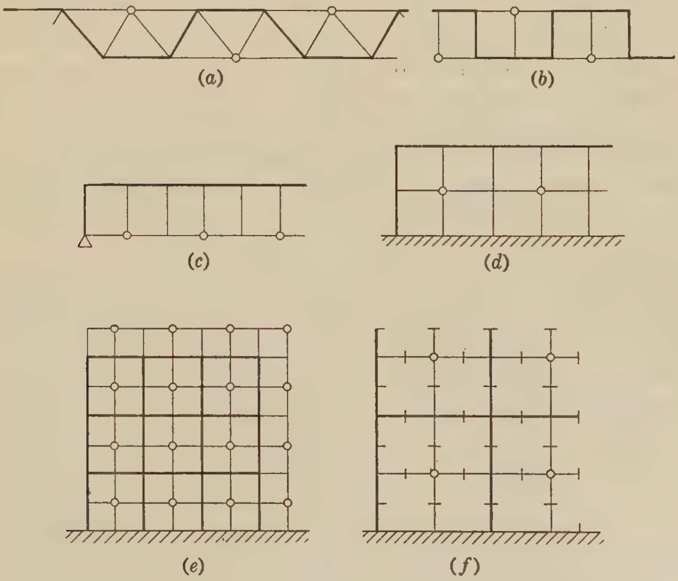

FIG. 16

---

[13] "Continuous Beams on Compressible Supports," by M. Ritter, *Publications*, International Assn. for Bridge & Structural Eng., Vol. IV, 1936, Zurich, p. 509.

portal (Fig. 16(*d*)). For a multi-span, multi-story portal, the number will be approximately two thirds to one half of the order of multiplicity of the portal. For instance, the portal represented in Fig. 16(*e*) is of 42d order. It can be reduced to the 6th order as shown, and then to the "open" type as shown in Fig. 16(*f*). Thus a total of twenty-eight rotations are needed for a framework of the 42d order, and four rotations are required for a framework of the 6th order. It is obvious that in such cases only iteration methods are of practical interest, and in these methods it may be advantageous to use all the rotations of joints in a symmetric manner, avoiding the separation of any that may be considered as fundamental unknowns in order to calculate the remainder in terms of the segregated unknowns.

When the author states (see heading, "Determination of End Moments") that "The proposition will be established that the end moments in the members of a rigid frame can be found as linear functions of the δ_{p-q} elements * * * and the linear movements of the supports," he simply states that to solve a system of linear equations the following procedure can be followed:

Solve the equations in terms of the given constants, some of the unknowns being considered as fundamental unknowns. The remaining unknowns will be expressed as linear functions of the fundamental unknowns and the constants. Thus, the author's statement, presented as a new proposition, does not reflect any new light on the problem. Moreover, the proposition is incomplete, since the end moments are functions, not only of the δ-elements, but also of the rotations that must be introduced in multi-connected circuits. However, for "open" structures, that procedure, which could be designated as Ritter's method, is of great interest because: (1) The number of fundamental variables is small; and (2) the secondary variables can be expressed in a relatively simple manner in terms of the fundamental variables.

If similar methods were available for multi-connected circuits, a great step would be made toward the general direct analysis of structures of that type. It appears that such methods do not yet exist.

Determination of the Axial Stresses and Linear Movements of the Supports.—As indicated by Mr. Wilson,[9] the conventional procedure is to consider appropriate free bodies and to determine the transverse forces in the members. The conditions of stability and equilibrium of the totally hinged structure, or the conditions of equilibrium of several free bodies that are statically independent of one another, define all the conditions required to find the fundamental unknowns. For instance, in the simple case of the frame of Fig. 17, the hinged structure is unstable. Thus, the equilibrium of two free bodies must be examined: The condition of equilibrium of body I defines the load acting on body II. Then the equilibrium of body II can be expressed, defining the load acting on the vertical member.

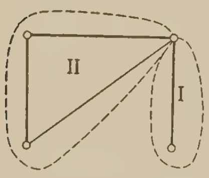

Fig. 17

In order to solve the same problem, the author introduces a fictitious diagonal and stipulates that the load in that diagonal must be equal to zero, which appears as a useless complication. Actually, the author, in Fig. 13, does not use that diagonal, and his method, somewhat artificial, does not give the required equation directly. It is possible to find the result directly. For example, projecting the forces as shown in Fig. 18, in order to eliminate the loads along 3 and 5:

$$F_{2B} + F_{2C} - (F_{4A} + F_{5B} + F_{3C})\sqrt{2} = 0 \qquad (60)$$

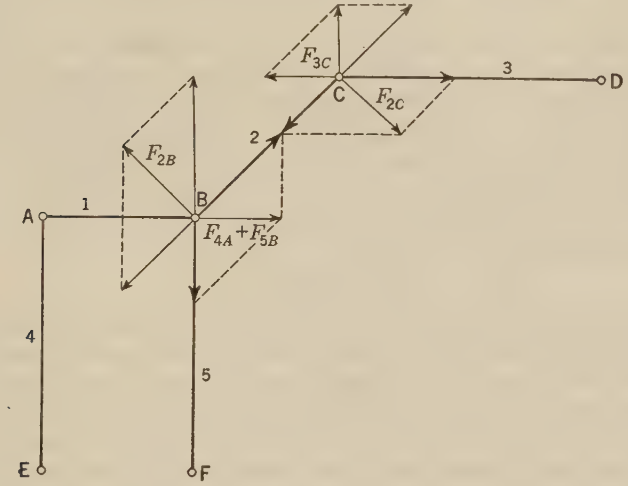

FIG. 18

which is strictly equivalent to Eq. 47 after the subsequent elimination of T_4 from the latter equation.

Conclusions.—The following conclusions deserve emphasis:

1.—The author does not present a substantially new method of analysis of redundant structures; he merely gives a somewhat different presentation of existing methods. The presentation shows a tendency to generalize the field of application of some methods. In the case presented, this approach is erroneous, since absolutely general methods are available (least work). The trend of future research must be toward the development of special methods well adapted to each category of problems, since absolutely general methods are impracticable in highly redundant structures, because of long numerical computations.

2.—The author introduces conditions that create undue complications in the presentation of simple and well-known processes, such as his introduction of conjugate frames and his treatment of the subject "Topology of Frameworks." He also presents well-known concepts with a changed and special terminology, such as compatibility equations, boundary conditions, the incomplete proposition relative to the determination of end moments as linear functions of the δ_{p-q}-elements, and the fundamental relation of the fixed-point method.

3.—Precisely at the point where the method seems to suggest new developments (in the introduction of a minimum of additional rotations), the author merely states that these quantities must be introduced and then eliminated.

4.—An incorrect interpretation is given to the number of the principal unknowns. Actually, to the unknowns defining the joint displacements must be added the unknowns defining the joint rotations in multi-connected frameworks.

5.—The author has repeated a summary in two places of his paper—first in the "Introduction" and again in the "Application to the General Case." The second summary is much more intelligible than the first but, when compared with the outline given by Mr. Wilson,[14] it appears that both summaries are practically identical step by step, as far as principles are concerned. From a practical standpoint, however, there is no doubt that Mr. Nubar's paper will prove much less valuable to the engineer who is desirous of finding a simple and rapidly applicable method.

Jaroslav Polivka,[15] M. Am. Soc. C. E.—An interesting and original general method of analyzing a two-dimensional framework, based on the superposition principle, is presented by the author. The method has the same advantages and disadvantages as some of the other methods of superposition, such as the method of moment distribution by successive approximation. Superposition methods require more accuracy because of the many calculations involved and extreme caution is necessary to avoid confusion in sign conventions.

A greater simplification is attained by methods permitting a better visualization of the elastic deformations under the given load, such as, for example, column analogy, the method of fixed points, and a method based on the ellipse of elasticity.

The author's method and the method of characteristic (fixed) points are similar in some ways. To demonstrate the common features of both methods, and for purposes of checking, the writer has solved the problem illustrated in Fig. 13, using the method of characteristic points, as shown in Fig. 19. The results were checked by the slope deflection method, involving the following equations:

$$\left.\begin{aligned} 7\,B + 2\,C - 18\,R &= 0 \\ 9\,C + B + 2\,E + 46\,R &= 0 \\ 5\,E + C + 5\,R &= 80 \\ 27\,B - 138\,C - 30\,E - 6{,}526\,R &= 11{,}520 \end{aligned}\right\} \quad \cdots\cdots\cdots\cdots (61)$$

Solving: $B = -\dfrac{605{,}460}{821{,}199}$; $C = +\dfrac{6{,}181{,}120}{821{,}199}$; $E = +\dfrac{13{,}570{,}720}{821{,}199}$; and

Fig. 19.—Check Solutions of Illustrative Problem (Fig. 13)

$R = -\dfrac{1{,}667{,}760}{821{,}199}$. The slope deflection equations are:

$$\left.\begin{aligned}
&M_{AE} = \frac{3}{4}B - \frac{9}{2}R;\quad M_{AB} = B + \frac{C}{2};\quad M_{BA} = C + \frac{B}{2};\\
&M_{BF} = 2\left(\frac{3}{4}C - \frac{9}{2}R\right);\quad M_{BC} = 2\left(C + \frac{E}{2} + 16\,R\right);\\
&M_{CB} = 2\left(E + \frac{C}{2} + 16\,R\right);\quad M_{CD} = 3\,(E - 9\,R) - 80;\\
&\qquad\text{and}\quad M_{DC} = 3\left(\frac{E}{2} - 9\,R\right) + 80
\end{aligned}\right\}\ldots(62)$$

The shear equations are:

$$\left.\begin{aligned}
&M_{EA} + M_{AE} = 16\,H_E;\quad M_{BF} + M_{FB} = 16\,H_F;\\
&M_{BC} + M_{CB} = 9\,(H_E + H_F) - 9\,(V_E + V_F);\\
&\text{and}\quad M_{CD} + M_{DC} = -\,16\,(V_E + V_F) + 8 \times 40
\end{aligned}\right\}\ldots\ldots\ldots(63)$$

Furthermore,

$$\left.\begin{aligned}
&\frac{16}{9}\,(M_{BC} + M_{CB}) = M_{AE} + M_{BF} + M_{CD} + M_{DC} - 320;\quad\text{and}\\
&\qquad 36\,M_{AE} + 36\,M_{BF} + 36\,M_{CD} + 36\,M_{DC}\\
&\qquad\quad - 64\,M_{BC} - 64\,M_{CB} = 11{,}520
\end{aligned}\right\}\ldots(64)$$

and the joint equations are:

$$\left.\begin{aligned}
&4\,M_{AE} + 4\,M_{AB} = 0;\quad 2\,M_{BA} + 2\,M_{BF} + 2\,M_{BC} = 0;\\
&\qquad\text{and}\quad M_{CB} + M_{CD} = 0
\end{aligned}\right\}\ldots\ldots(65)$$

The solution (computation machine values) yields:

$$M_{AE} = -\,M_{AB} = +\,\frac{2{,}964{,}000}{821{,}199} = +\,3.60;\qquad M_{BA} = +\,\frac{3{,}153{,}840}{821{,}199} = +\,3.84;$$

$$M_{BF} = +\,\frac{24{,}281{,}520}{821{,}199} = +\,29.56;\quad M_{BC} = -\,\frac{27{,}435{,}360}{821{,}199} = -\,33.40;$$

$$M_{CB} = -\,M_{CD} = \frac{20{,}045{,}760}{821{,}199} = -\,24.41;$$

$$\text{and}\quad M_{DC} = +\,\frac{131{,}081{,}520}{821{,}199} = +\,159.62.$$

The same results were obtained by using the method of ellipse of elasticity, substituting for the frame EABF an imaginary ellipse of support at joint B, and combining this ellipse of support with the ellipse of the section BCD. The graphic results of this analysis are shown in Fig. 19(*c*). Comparing both methods the following statements may be made:

(1) The values C in the author's paper are the carry-over factors of the individual members of the framework (Fig. 19(*a*)): $C_{1B} = -\dfrac{1}{4}$, $C_{1A} = -\dfrac{11}{27}$, $C_{2C} = -\dfrac{11}{36}$, $C_{3D} = -\dfrac{24}{109}$, etc.

(2) The coefficients of $E\,\epsilon_6$ in Eqs. 42, 43, 44, and 45 are the moments due to axial strain $E\,\epsilon_6$ of the imaginary member 6 (Fig. 13) and are proportional to the moments of the framework when subjected to a horizontal displacement (translation) along AB equal to Δ_B.

(3) The other values of Eqs. 42 and 45 are the bending moments of the framework subjected to the given load when the lateral displacement Δ_B is equal to zero.

A. A. Eremin,[16] Assoc. M. Am. Soc. C. E.—An interesting method for computing stresses and deformations in continuous frames is presented by Mr. Nubar. Like Prof. O. Mohr,[17] Mr. Nubar considers the geometric and loading factors as forces applied at the joints of the frame, although, regrettably, his illustrative example (Fig. 13) fails to demonstrate any superior simplicity in practical application. By graphical methods, the moments in the frame, shown in Fig. 13, can be determined with less effort and time.

Graphically, the writer would proceed in two steps:[18] The first step is to determine the physical properties of the frame by locating the characteristic points, termed "central points," "inflection points," and "elastic points." The relative location of the characteristic points is determined by constructing a "three-line polygon," as described briefly by the writer elsewhere.[19] The second step is to determine the moments produced by the given loading and the distortion of the frame.

Referring to Fig. 20, which is an analysis of the frame shown in Fig. 13: The central moments in member CD with a load of 40 kips are $M_1 = M_2 = 80$ kip-ft. If the joints are fixed horizontally, the moments in the frame are determined by drawing "cross lines," as in Fig. 20(c). A distortion diagram with a unit displacement at joint C is shown in Fig. 20(b). The basic bending moments due to distortion in member CD are

$$M_{CD} = N\,a\,k_1 = 42.3\,k_1 \qquad \text{(66a)}$$

and

$$M_{DC} = N\,b\,k_1 = 78.2\,k_1 \qquad \text{(66b)}$$

in which

$$N = \frac{600\,K\,\Delta}{L\,(L - a - b)} \qquad \text{(67)}$$

and k_1 is a distortion coefficient; a and b are the distances to the points of inflection (shown in the parentheses, Fig. 20(a)); Δ is transverse displacement of member ends (Fig. 20(b)); and K (= I/L) is the basic stiffness of member, shown in the circles in Fig. 20(a). The numerical factor 600 in Eq. 67 is introduced for convenience of computations. The basic moments in each member are determined by Eqs. 66 and 67 and distributed, as shown in Fig. 20(d).

As a condition of static equilibrium, the reaction at joints E, F, and D is:

$$H_E + H_F - H_D = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (68)$$

Using the moments in Figs. 20(*c*) and 20(*d*) to determine the values of H_E, H_F, and H_D in Eq. 68, a value of $k_1 = 0.48$ is computed.

FIG. 20.—GRAPHIC DISTRIBUTION OF MOMENTS

Superposing the moments in Fig. 20(*c*) and the moments in Fig. 20(*d*), the final bending moments in the frame are $M_{DC} = 161.5$ and $M_{BF} = 29.1$, which differ slightly from those computed by the algebraic formulas introduced by the author.

Contrary to Mr. Nubar's method, the operations in the graphic distribution of moments may easily be visualized. Therefore, the moments may readily be checked. Furthermore, graphics may be used in checking the analytical computations of moments. The constant C used by the author in Eq. 35*a* may be checked by the inflection point distance in the graphical method. Thus, for member CD, Fig. 20(*a*): $C_{3D} = \frac{a}{L - a} = 0.22$, which is the same as that computed by the author. Computation of the inflection point distances, *a* and *b*, in members with variable sections may be simplified by using the constants given by the writer elsewhere.[18]

YVES NUBAR,[20] M. AM. SOC. C. E.—Some of the comments reflect a misunderstanding—namely, that the primary object of the paper was the presentation of another method for the quick solution of special types of frames. Apparently with this thought in mind, Messrs. Polivka and Eremin recommend different procedures for such solutions. Mr. Beskin expresses a similar misunderstanding in his conclusion 5. The primary purpose of the paper, described in the "Synopsis," was an investigation of the basic properties of the general framework. Rapid solutions may be obtained as by-products, after the proper simplifications (many of them obvious) are made in the general relations to fit special cases. The writer has avoided presenting simplifications of limited application for the sake of concentrating on the general approach applicable to all cases.

---

[20] Director of Research and Development, Hub Industries, Inc., Long Island City, N. Y.

Some of Mr. Beskin's comments originate from his predilection (see his conclusion 1) for "* * * special methods well adapted to each category of problems, since absolutely general methods [such as least work] are impracticable * * *." This opinion is not generally accepted. Scientific progress might be promoted best by a search for methods elastic enough to apply to the most general systems (even if processes of approximation are necessary for numerical solutions) and at the same time immediate enough to permit visualization of the geometric relationships between component elements. The method of least work meets the first requirement, but not the second. The paper has attempted to meet both requirements. Preferences are a matter of opinion, however, and it is idle to argue about them.

More of Mr. Beskin's comments seem to reflect an almost personal reaction, arising either from the fact that a few of the results which can be easily derived from the writer's general relations as special consequences have been presented directly by others under one name or another (mostly in connection with the analysis of continuous beams) or simply from the fact that sometimes Mr. Beskin himself can bring a solution of limited application to one of the isolated phases of the problem. This attitude permeates his discussion. The fact is (and Mr. Beskin chooses to ignore it) that an integrated and coherent method of analysis, applicable to very general frameworks, has been presented in this paper, based on concepts which are new, to the best of the knowledge of the writer and of all those connected with the preparation and examination of the paper.

Mr. Beskin derives Eq. 60 from a simple consideration of Fig. 13; it is indeed equivalent to Eq. 47, established in a more roundabout way. Mr. Beskin uses this fact as an argument purporting to show the "useless complication" of the method. However, his approach is quite specially applicable to the frame of Fig. 18; for a more complex frame he would find it impossible to proceed by such simple analysis. On the other hand, in this case as in every other one treated in the paper, a formal approach has been adopted consistently in order to conform to the routine of the general procedure applicable to all cases.

Mr. Beskin advances Eqs. 50 and 51 as arguments for denying the originality of the writer's compatibility relations, Eqs. 4, and their consequences, Eqs. 7 and 8. Mr. Beskin's equations can indeed be found in many textbooks; but, far from being the equivalents of Eqs. 7 and 8, they represent only very special (and easily derivable) consequences of these compatibility relations applied to curved beams and to triangular frames, respectively. As a matter of fact, that is precisely the way Mr. Beskin establishes his Eq. 50. He then refers to the Williot-Mohr construction, which, as he correctly implies, also has been known for years; but this again is one more particular result of these same compatibility relations (Eqs. 7 and 8) applied to articulated frames. Example 5 of the paper shows clearly the analytical translation of this construction as an application of the method. Eqs. 4, 7, and 8 are general and they are original; by his comments, Mr. Beskin unwittingly furnishes additional proof that they are also fertile.

Mr. Beskin analyzes the frame of Fig. 16(*c*) quite correctly; it is indeed of the 42d order and a rather complex structure. As adverse criticism of the method, he advances the fact that this frame requires twenty-eight rotations to be considered in the general relations. In reply, the writer would state that, comparatively, the conventional slope deflection method requires sixty-four unknown rotations, plus seven story deflections, and that, with the method of least work, the analyst must deal with some 170 unknowns. The writer had no reason for preferring the use of "arbitrary unknowns which are the same in all cases," beyond the very simple reason that the number of unknowns is appreciably less here than that in other methods. Mr. Beskin's own example is proof. Naturally, for the actual numerical solution of frames of this character, any experienced engineer will resort to processes of approximation, whether he uses one of the many existing methods, or the writer's method.

Mr. Beskin's opinions of the section under the heading, "Topology of Frameworks," are based on the fact that he can establish Eq. 52 directly, instead of deriving it, as in Proposition (*c*) of the paper, from a general analysis. It is necessary to proceed with such an analysis in order to establish, among other important relationships, the n_i-equations required by this method for the elimination of dependent axial strains. In addition, a study of the topological properties of two-dimensional frameworks will be found a helpful steppingstone when a general analysis of space structures is attempted.

As regards Mr. Beskin's conclusions 3 and 4, the writer agrees that the unknown joint rotations that help to "open up" multi-connected frames may properly be included in the set of axial strains used by the writer as principal unknowns. However, in conformity with the general procedure of the method, these joint rotations themselves may be written in terms of the axial strains of the imaginary diagonals of some of the component parts of a frame, such as shown in Figs. 16(*e*) and 16(*f*). Therefore, the writer's introductory description of his method and the process of operations remain valid.

The method presented in this paper deals with the two-dimensional frame in its general, almost symbolized form; hence, a penalty must be paid (see Mr. Beskin's conclusion 5) in the form of more deliberate approaches for the inclusion of complex features which seldom appear in everyday frames. Mr. Beskin's own simple derivation of Eq. 60 for use in the structure of Fig. 13 proves that the method can be simplified quickly for the treatment of special cases. His several references to the excellent paper[9] by D. M. Wilson, M. Am. Soc. C. E., are irrelevant, since the writer's paper and Professor Wilson's paper have different aims.

The semigraphical method of characteristic (fixed) points described by Mr. Polivka has merit; the writer referred to an identical method in the concluding paragraph of the section under the heading, "Determination of End Moments." This method has been developed at great length as one of the steps in a previous analysis.[4] In this paper, an analytical, instead of semigraphical, approach was preferred as being simpler to present. The method described by Mr. Eremin is based on similar concepts. Either Mr. Polivka's or Mr. Eremin's method will lead to quick solutions in the case of simple frames.

DEEP SOLUTION CHANNEL, KENTUCKY DAM, KENTUCKY

By James B. Hays,[1] M. Am. Soc. C. E.

Synopsis

An unusual method of constructing a cutoff in a solution channel nearly 200 ft deep in the foundation at Kentucky Dam, together with an accurate picture of the results of grouting in the clay-filled and rock-filled channel, is described in this paper. The cutoff wall was constructed in the form of an arch dam except that it was built from the top down rather than starting from the bottom and working upward.

So little is known about grouting in clay that it is thought the results presented herein would be of interest to many engineers engaged in similar work.

Kentucky Dam, a Tennessee Valley Authority (TVA) project, is on the Tennessee River, in Kentucky, 22 miles from its confluence with the Ohio River at Paducah, and is one of the series of flood control, navigation, and power dams that will maintain a 9-ft navigation channel to Knoxville, Tenn.

The over-all length of the combined earth and concrete structure is 8,700 ft, and the maximum height of the concrete spillway section is 165 ft. The spillway section has twenty-four fixed roller gates 40 ft wide by 50 ft high, each in three sections. The normal head is 57 ft with a maximum of 73 ft. The lock chamber is 110 ft wide by 600 ft long. The power house will ultimately have five units. Turbines are of the adjustable-blade Kaplan type. A general plan of the dam is shown in Fig. 1.

The dam was constructed in three stages. The lock, built first, was completed and placed in temporary operation early in 1942. Because of the topography of the site, the lock was built in an open excavation on the east, or right, bank flood plain, surrounded by an earth-dike cofferdam to hold back flood waters. This permitted the starting of the second stage, the building of the cofferdam in the river for the power house and part of the spillway, without waiting for the completion of the lock. The third stage involves the remainder of the spillway.

Foundation drilling and exploration of several sites began in the summer of 1935, with the selection of the final site in 1937. Closer and more detailed investigations continued even after construction was started on July 1, 1939. The rock was known to be limestone of the Fort Payne formation, but very little was exposed at the site. A few outcrops occurred on the right bank above the flood plain. The overburden was deep. The shallowest depth, 20 to 30 ft, to rock was in the area covered by the lock. In the river section, rock was 50 ft below the bed of the river, and, on the left bank, under the long earth-fill section, the depth was from 85 to 110 ft.

---

[1] New York, N. Y.; formerly Project Mgr., South Holston and Watauga Projects, TVA, Bristol, Tenn.

After considerable study of the cores and near-by formations, the geologists advised that most of the cavities in the foundation would probably be in the form of vertical solution channels along joints or fractures in the rock. For this reason considerable exploratory drilling was done by using 45° overlapping angle holes. This revealed many defects in the foundation that had been missed in the earlier vertical drilling. It later developed that the geologists' interpretations were generally correct, with a few exceptions.

At the time the construction department took charge, the general exploration had been nearly completed. It was necessary, however, to continue the drilling to fill in gaps and develop the conditions in more detail.

Many of the cavities or defects in the foundation were located before actual excavation had uncovered them. The drill records merely located the cavities but did not indicate their actual shape or the condition of such material as might be in them. The upper cavities were known to be generally filled with clay; those at lower elevations were often only partly filled or open.

The Fort Payne formation is a dark limestone interbedded with layers and large flat lenses of chert. The chert layers were generally from 2 in. to 6 in. thick with the limestone between varying from 4 in. to 12 in. The bedding varied from nearly flat, under a part of the lock, to a 6° dip toward the left bank. The limestone, in weathering, turned to a clay, but the chert layers remained unaltered, although generally found broken or cracked into small pieces. A large part of the area excavated to rock was covered with a thick layer of residual clay and chert varying from 8 ft to 10 ft in thickness. The clay and chert layers over solution channels had often slumped down, and the extent of this slumping generally indicated the extent of the cavity.

Several vertical solution channels in the lock had been located by the time excavation had reached full swing. The deepest and most extensive channel was found at the junction of the earth dam and the river wall of the lock just downstream from the lower lock gate. A study of the trend of the joint system in the rock, together with the earlier drilling records, indicated that this channel extended under the river and angled across the dam at about 45° to the axis and into the lower lock channel.

A line of drill holes was put down from the top of the lock cut on the side toward the river, with the idea of further developing the trend and extent of the channel. These holes were also grouted to prevent excessive leakage into the excavation. The drill records indicated layers of rock and clay with the deep cavities open or partly filled. Since the open cavities were water bearing, there was the danger that they might connect directly with the river and be a source of trouble. As a result of the grouting, there was practically no leakage through the rock or the solution channels into the lock excavation.

An intensive program of drilling was undertaken in the area of the lock foundation with holes on 20-ft centers each way to develop the extent of the solution channel (see Fig. 2). Two problems were involved: One was how the lock-wall would be supported over the channel; the other was what treatment would be required in the channel itself to make an adequate cutoff under the dam and prevent possible serious damage in the future. This paper deals with the second problem. All holes were grouted soon after drilling was completed..

Fig. 1.—General Plan, Kentucky

These preliminary drill records (Fig. 3) indicated that there was one wide channel and a near-by smaller one probably parallel to it. The main channel at the narrowest point was approximately 70 ft wide down to a depth of 100 ft below the floor of the lock, which was at El. 289 (sea-level datum). At that point it narrowed to about 30 ft and continued another 110 ft to El. 70, with a few small cavities on one side, as shown in Fig. 3. The narrow channel was not exposed at the rock surface under the river-wall of the lock, but there was evidence of it just downstream from the land-wall. The problem of supporting the lock-walls was solved by spanning the wide channel with deep, heavily reinforced-concrete slabs, shown in Fig. 4.

The method of making a satisfactory cutoff in the channel was discussed at considerable length. The proposal of ordinary grouting of the clay-filled channel was considered. It was felt that this would probably prove satisfactory for a time, but there would remain the uncertainty that the clay might eventually soften and be washed out by water, or pushed out by the pressure, and produce a disastrous blow.

The part of the earth dam between the power house and the lock, built on original ground, had a sheet-pile cutoff driven to rock that was originally intended to tie in to the lock-wall just downstream from the solution channel.

The final decision was to construct a definite concrete cutoff by drilling a series of holes, 36 in. and 48 in. in diameter, along a circular arc as shown in the plan, Fig. 5. These holes would be used as shafts for successively excavating small chambers and backfilling with concrete, thus creating an arch dam underground with the convex side against the water pressure. The plan view in Fig. 5 is an assumed stage in the procedure of constructing the cutoff walls. The outline of the working slab is not shown. The location was chosen to permit the underground work to proceed without delaying the construction of the lock-walls. The 48-in. holes were located over the deepest part of the solution channel since this particular drill was equipped for deep drilling. A single 48-in. hole was located to cut off the narrow channel.

The area had been grouted as well as possible. The grouting record is shown in Table 1 and Fig. 3. Previous experience had proved that it was practically impossible to drill large holes and excavate in clay-filled channels or cavities without preliminary grouting. The grout, besides filling open cavities, has a tendency to force out soft clay and to compact any that remains. On the lower two thirds of the zone, grout pressures as high as 80 to 100 lb per sq in. were used. On the upper part, pressures of from 10 to 20 lb would often blow out due to lack of sufficient cover for resistance.

To give the drillers a suitable place to work and to furnish the preliminary support for the first sections of concrete backfill, a thick reinforced-concrete slab was placed over the area. The surface of this slab was at El. 265. Reinforcing steel stubs were driven down into the clay, or into jackhammer holes drilled through loose rock slabs or boulders directly over the proposed concrete cutoff, to be used for anchoring the lower concrete blocks in position and prevent them from settling into the soft clay or dropping into the next excavation below. Reinforcement inserted in jackhammer holes drilled in rock was packed with clay to prevent any bond to rock that might later need to be removed. As the work progressed downward there was never any certainty that rock in the floor of a chamber would or could be allowed to remain, since any such rock might be a loose slab or boulder that would have to be removed in the next operation. The side-walls of the channel were tested with jackhammer holes at frequent intervals.

One 48-in. and two 36-in. shot drills were set up on alternate holes. The plan, as shown in Fig. 6 (see step I), was to drill 5 ± ft below the concrete slab and excavate a chamber 6 ft wide normal to the line of the holes and halfway to the next regular hole on each side. As soon as each unit of excavation was completed, reinforcing steel stubs were driven laterally toward the two adjacent holes into the clay or into jackhammer holes drilled in boulders, and another set was driven into the floor of the chamber, lapped and tied to the steel extending down from the roof that had previously been driven into the clay below the heavy concrete mat and was exposed when the excavation was made (see dowels A, Fig. 6). The lateral steel was used to tie the blocks together and assist in arch action, since the vertical joints between blocks were quite irregular in shape. No steel was placed to come directly under the drill hole. The chamber was then filled with concrete and the drill moved to another location while the concrete hardened, to repeat the process, after which it was moved back to the first hole. The concrete that filled the first chamber was drilled through and a similar excavation was made directly under it (step II, Fig. 6). Reinforcing steel was again installed, as before, and the chamber again was filled with concrete. In filling each excavation, the concrete was placed to a depth of 2 or 3 ft in the shaft above the roof and vibrators used to force the concrete to fill the space completely.

The cycle of operations was repeated (steps III, etc.), moving the drills from one hole to another to keep up a continuous operation for the drillers and permit the concrete to harden. In some clay pockets no drilling was done, in which case the drill was used only for hoisting out the muck that was excavated by hand into buckets. When contact was made with rock, a test hole was drilled by jackhammer in the center of the 36-in. or the 48-in. hole; then addi-

tional holes were drilled for dowels if the rock was found to be satisfactory. If a cavity was encountered, holes were drilled and dowels were extended into it, as before. After the first group of holes had been extended down four or five stages, the intermediate holes were started and carried down, alternating with the first set. The chambers excavated through the intermediate holes had concrete on two sides, with dowels projecting from the walls as well as from the roof. Frequently these chambers were narrower than the first set, due to overbreak on the latter. In the narrow channel, the depth of excavation in each section of the hole was dependent on the conditions indicated in Figs. 7 and 8.

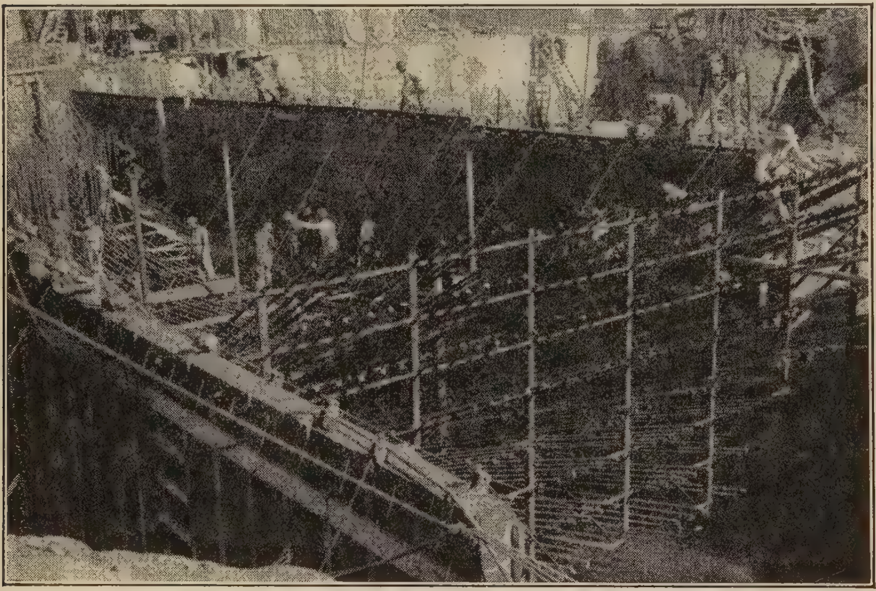

Fig. 4.—View of Heavy Reinforced Concrete Slab

This series of large drill holes was started on November 16, 1940, and hole No. 6 (Fig. 8), the last one to be completed, was finished July 2, 1941. The first concrete pours were made under the slab through the large drill holes, and the drilling, mucking, and concreting proceeded in sections 5 ft to 10 ft high until the bottom was reached. To complete this cutoff required 1,763.4 lin ft of large drill holes, including holes B and C, Fig. 8.

Water leakage into the excavated chambers, which was relatively small in volume, gradually increased as the work deepened. Part of the leakage came from the drills working on other holes which usually drained into the deepest hole. Small air-driven centrifugal pumps were adequate until the head became too great. To take care of this condition, a larger chamber was opened up in hole No. 6 between El. 108 and El. 90 to be used as a relay pumping station. Hole No. 12 had followed a narrow channel and below El. 140 had been drilled deeper than the usual 6 ft before concreting and was completed earlier. In the pump room in hole No. 6 the side-walls, along the line of the cutoff, were solid

clay began to push up from below. As the digging continued, the movement increased. Realizing that this might be dangerous, the contractor disconnected the pump and hoisted out, and the workmen then went up themselves, only a little ahead of a slowly rising column of water. The water soon flowed out of the top of the hole. The first measurement, made by pumping, gave a flow of 50 gal per min. Two hours later it had increased to 80 gal per min.

Before further work could be done on the cutoff through this hole, it was necessary to plug it and grout the lower part of the channel. To do this a 4-in. pipe was installed in the shaft, extending from the lowest point in the bottom of the 48-in. hole, at El. 87, to 3 ft above the top, at El. 268. The large chamber was filled with 3-in. crushed rock. A pump was installed with its suction inserted in the 4-in. pipe, and the water was lowered a few feet below the top of the hole to approximately El. 260. Concrete was placed over the crushed rock and well up in the 48-in. hole to seal it off, while the pump pulled the water through the 4-in. pipe.

A diamond-drill hole previously bored at approximately El. 130 between holes Nos. 4 and 5, to check and grout contact zones between blocks of concrete in the cutoff, was extended into the rock-filled chamber. Another diamond-drill hole was bored through the concrete plug to the top of the crushed rock to be used as a vent.

Grouting was started through the 4-in. pipe, from which the water had been flowing, using thick grout, 0.6 water-cement ratio by volume. In a short time the grout gate indicated no pressure. The 180-ft column of grout in the 4-in. pipe was heavier than the water pressure and created a vacuum. Eventually back pressure developed and grouting was continued until 2,297 bags of cement had been injected to a refusal pressure of 100 lb per sq in. The diamond-drill hole between holes Nos. 4 and 5 was next grouted and required 693 bags. The vent hole drilled through the concrete was deepened to El. 80 and grouted, using 3,493 bags of cement with 150-lb refusal pressure. A total of 6,483 bags of cement was used.

Drilling with the 48-in. equipment was resumed after the grout had set sufficiently. The core in the shaft had to be broken out with paving breakers, due to the 4-in. pipe which prevented breaking the core in the usual manner. The grouted broken rock below the concrete was found to be a solid mass. Jackhammer test holes indicated no pockets; hence, this material was not removed. Many of the stones were found coated with thin films of clay, but there were no continuous seams to cause leakage. The 48-in. hole was finally driven to the bottom and concreted. As a final check, diamond-drill holes were put down midway between each of the 36-in. or 48-in. holes and grouted. Fig. 7 shows the outline of each block of concrete placed in the cutoff. In the secondary channel, only one hole was drilled except where it was necessary to drill a second hole through the concrete slab at the top to fill a shallow clay-filled pocket.

The location of the sheet-pile cutoff was changed to follow directly over the underground curtain. The backfill was rolled earth and its width at this depth permitted the change.

During the process of constructing the cutoff, a detailed examination was made of the undisturbed walls and floor of each chamber just prior to backfilling with concrete. A sketch was made of the upstream face showing the rock with its dip and strike, the residual clay, sand pockets, grout, and other rock formations. The assembly of this information to El. 200 is shown in Fig. 9. The original drawing extends downward to El. 80. There were many very thin seams and stringers of grout that were too small to indicate, and many thin seams are exaggerated in thickness. Fig. 10 is a photograph of a typical face, with arrows indicating many of the grout seams. Where diamond-drill holes were encountered, they have been shown in Fig. 9.

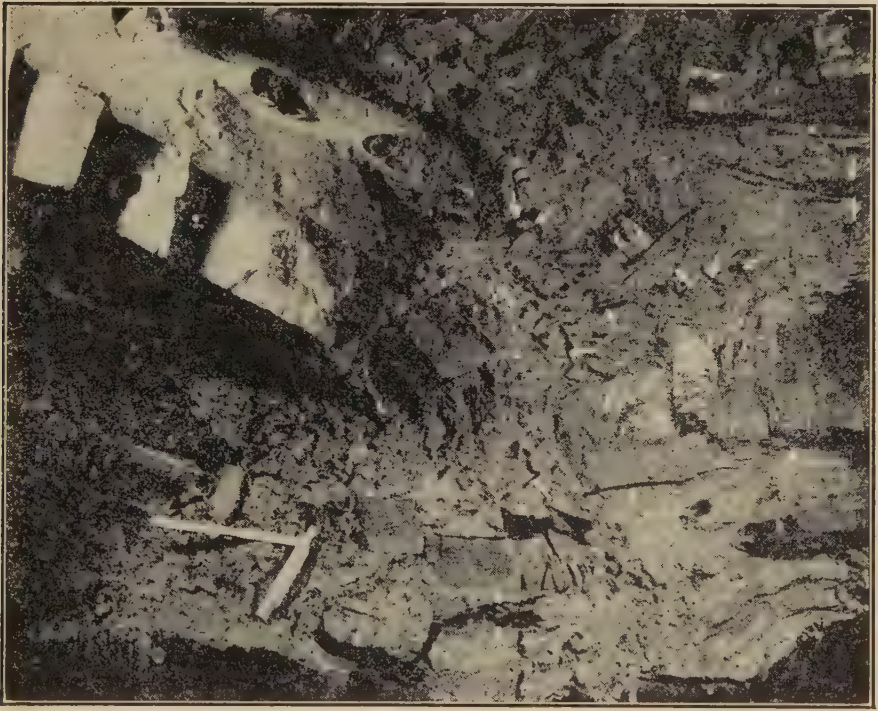

Fig. 10.—Face of Excavation on the River Side of the Line of Cutoff; Hole No. 6 at El. 120

By means of this chart it was possible to develop the geology of the deep vertical solution channel, to compare the actual conditions with the original interpretations of the diamond-drill holes, and also to illustrate the results of grouting in the clay and rock-filled channel.

There is no evidence of faulting. Diamond-drill holes had been driven to 320 ft below sea level on both sides of this channel about 700 ft to the south of the cutoff. The next formation that can be identified accurately at the contact is the Chattanooga black shale at El. − 307.

The rock that was exposed in the foundation excavation had numerous vertical joints, most of which had been recemented with calcite. The general trend of most of the weathered joints is north and south, with a secondary set at right angles. Weathered joints of all degrees of alteration have been found, and practically all of them start and develop in the same manner. Ground water readily entering the joint slowly dissolves various layers of the limestone, but does not affect the chert layers which at first remain as rigid shelves or projections, often carrying the weight of the clay above. The residual clay at first does not completely fill the voids in the limestone. Drill holes, encountering these openings, often develop flowing water at the surface if the area has not been grouted, indicating a connection with a higher source of water. As the load on the chert, or chert and limestone, shelves becomes greater, due to the continued weathering of the lower limestone and the widening of the channels, they break down and a general slumping occurs. Strata of chert that have sagged, due to slumping, often can be traced across the weathered channel. Since the limestone is variable in its solubility, some layers dissolve more rapidly than others and many narrow seams extend outward some distance into the solid rock. These, being only partly filled, carry active waters of solution. The diamond-drill records, shown in Fig. 3, indicated open cavities near the bottom or at the sides in narrow seams with several feet of sound rock above them. No open cavities were found in the upper areas due to the slumping action in the wide part of the weathered zone, which forced clay into the horizontal lateral cavities.

A study of the effect of grout in this material is interesting. The cavities were grouted in stages, from the bottom up. Seams in massive rock were generally grouted individually. In the main body of the clay and boulders, grouting was done through the bottom of the casing which was jacked up at intervals, a foot or two at a time, until within 20 to 30 ft from the surface, where it was generally impossible to use any pressure without a blowout and no spread of grout could be obtained. It will be noted that the grout generally was found in measurable quantities adjacent to rock surfaces with main feeders often extending in a horizontal direction from one boulder to another, frequently following the layers of undissolved chert in the clay. In hole No. 6, from El. 220 to El. 225, a column of grout from 8 in. to 18 in. in diameter was found with evidence of a filled drill hole in the center. Another was found in the same hole from El. 100 to El. 108. In hole No. 7 a similar condition was found between El. 240 and El. 246.

Thin seams and isolated bulbs of grout were found in many areas. Many of the larger pieces of excavated grout were found to have pockets of clay in them. There was ample evidence that the grout had solidified the clay and packed the seams sufficiently to permit the walls to stand vertical, and without slumping, at least during the construction period.

The total work with the large drills was listed as 1,763.4 lin ft. The drills had to penetrate each section of concrete, so that the actual drilling was about twice this value. The total volume of grout used in the immediate vicinity of the cutoff was 47,198 bags before the cutoff was made, and 2,657 bags afterward. This is in addition to the amount used to stop the aforementioned sand and water flows.

ACKNOWLEDGMENT

T. B. Parker, M. Am. Soc. C. E., was chief engineer of the TVA, and A. L. Pauls, M. Am. Soc. C. E., is chief construction engineer. At Kentucky Dam, George P. Jessup is project manager; B. S. Philbrick, M. Am. Soc. C. E., is construction superintendent; and the writer was construction engineer, until January, 1942, when he was transferred to another project.

FLOWING WATER IN UNDERGROUND CHANNELS, HALES BAR DAM, TENNESSEE

By L. A. Schmidt, Jr.,[2] M. Am. Soc. C. E.

Synopsis

Hales Bar Dam on the Tennessee River was built by private interests (1905–1913) and is one of the classics in the annals of early dam building in the United States. Since its completion it has presented a foundation leakage problem which remained unsolved at the time the property was acquired by the Tennessee Valley Authority (TVA) in 1939. Previous efforts to correct the leakage were varied and numerous and inevitably resulted in only temporary improvement. Leakage has been progressively greater until a flow of 1,700 cu ft per sec was measured as ungainfully passing just before the present work by TVA was begun in 1940. A cutoff wall was placed in the foundation leakage area just upstream of the dam to reduce flows, and the foundation was stabilized by placing concrete, cement, and asphalt grout in the foundation under the structure. Special equipment and methods were required and devised to do this work without interrupting the hydroelectric power operations.

Among the more unique core drilling projects in the United States to date is the foundation treatment given to Hales Bar Dam on the Tennessee River, thirty-three river miles downstream from Chattanooga, Tenn. Fig. 11 is a general view of the spillway, facing upstream from the top of the south control house on the river-wall of the lock.

On heavy construction core drills are frequently used for exploration and for determining excavation requirements both as to equipment and to yardage involved. At Hales Bar core drills were used for excavation, cutting out some 35,000 lin ft of 18-in. hole and removing several thousand cubic yards of badly leaking foundation rock. This material was replaced by concrete specially placed in a predetermined pattern to effect a cutoff wall under this historical river barrier.

Stories describing many previous attempts to stop leakage at Hales Bar are legend, and the colloquial narratives are sufficiently enigmatical to intimidate engineering efforts that challenge the flow of water in the underground channels. To understand this leakage problem one must delve back to 1905–1913, the time the dam was built by private interest for hydroelectric power and for navigation improvement in the Tennessee River to Chattanooga. Even then foundation leakage into cofferdams under only nominal differential heads was great enough to force the constructors to build a part of the dam by the use of pneumatic caissons. After the reservoir was filled, leakage in the foundation was detected from water boiling up on the downstream side of the dam.

---

[2] Acting Constr. Engr., TVA, Hales Bar Dam, Chattanooga, Tenn.

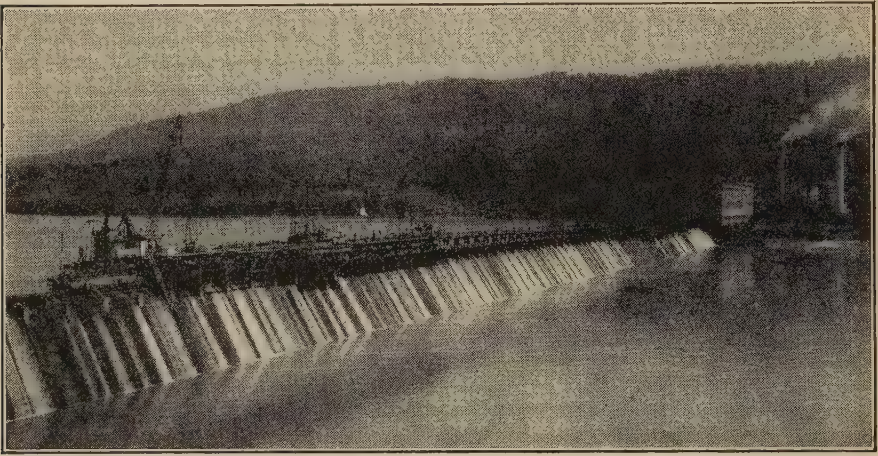

FIG. 11.—SPILLWAY OF HALES BAR DAM

The dam is built on the Mississippian limestone formations of this vicinity (see Fig. 12). Leakage at Hales Bar exists principally in the foundation under the dam. Noticeable points of suction have been found in the reservoir and the path of flow from these points to the visible boils downstream has been traced with dye. Leakage is caused by three principal foundation defects:

1. Washing out of the shales in horizontal bedding planes, causing horizontal openings (note, in Fig. 12, at El. 503.3 a piece of typical quartz with Golconda shale sticking to it was found where it had fallen from above);
2. Solution of calcites, forming vertical solution channels; and
3. Faulting.

Defect 3 probably caused very little leakage and was handled fairly easily. Defect 1 contributed considerable leakage, but when such planes were found they were readily corrected. Leakage from this cause also seemed to exist in serious quantities only in the upper foundation reaches from 2 ft to 30 ft below the foundation rock level. Defect 2 contributed greatly to leakage and through its far-reaching labyrinth of passages, some of which extend to considerable depth, large quantities of water eluded the engineer's plans and efforts to stop this waste of potential hydroelectric energy.

As early as 1915, L. C. Glenn,[3] wrote as follows:

FIG. 12.—COMPARISON OF MISSISSIPPIAN FORMATIONS IN LOOKOUT MOUNTAIN AND AT HALES BAR DAM

> "No better illustration of the serious dangers from solution channels in limestones could be given than to cite the Hale's Bar dam on the Tennessee River near Chattanooga. The Bangor limestone, very pure, highly soluble and generally noted for its caves, forms the bed rock, and extends downward for some hundreds of feet beneath the river channel. This limestone was honey-combed with intercommunicating solution channels, some of which were choked with sand, gravel and cobbles, while others carried water under pressure. Excavation was carried some distance down into this rock and the foundation was thoroughly drilled and grouted, several hundred thousand barrels of cement being pumped into these openings. This honeycombed foundation caused a delay of several years in the completion of the project and increased by five or six million dollars, or more, the cost of construction.
>
> "The writer is by no means certain that the troubles there from leakage are ended, since geological examination shows the dam to be located on a syncline, or trough, in the Bangor limestone, and this means that the lower portion of this limestone there is the stretched member of the curved mass, and this tension, caused by the folding, undoubtedly opened joints in the lower part of the limestone and these filled with water under very considerable pressure would yield to solution more rapidly than the part up near the surface, so that the lower part is probably more open than the upper part that has been grouted, and the tendency will be, with the added head above the dam, for the water to work its way beneath the dam through these lower lying fissures and channels in constantly increasing quantities."

The reasons for correcting the leakage condition at Hales Bar were twofold:

1. To save water for power during periods of low flow; and
2. To protect the investment in this property against failure of the foundation.

The value of lost energy can be capitalized to determine a sum that may be expended economically, but economic considerations for the latter may range from the extreme of laissez-faire to that for a complete new project, in accordance with the individual opinions as to the urgency of this work.

From October 1, 1940, to October 1, 1941, there were 277 days during which river flow at Hales Bar was less than turbine capacity. Assuming that the demand for electrical energy existed during that period, a total of more than 26,500,000 kw-hr was lost. Similarly, between October 1, 1941, and October 1, 1942, the equivalent of nearly 21,000,000 kw-hr was lost. No one can gainsay but that, during these two years, the drought and then the war have demanded the conservation of every potential kilowatt-hour available.

Besides stopping leakage to increase the quantity of water available for power, it was essential that these large openings be filled to secure the bearing value of the rock foundation for permanent stability to the dam structure itself. This work was also a necessary step preparatory to raising the headwater level to El. 634, which will provide a 9-ft navigation channel to Chickamauga Dam in Tennessee, when the dam is raised after the war.

The first efforts to stop the flow in the foundation consisted of placing inert materials of many descriptions into the upstream suction inlets. These inlets were discovered when exploring for the cause of boils which appeared in the tailwater under full hydrostatic pressure as a result of filling the reservoir to dam-crest level; but any success in this effort was short lived since flow broke out elsewhere.

In the early 1920's, corrective work was attempted by pumping more than 11,000 bbl of asphalt into the foundation by way of the newly invented hot electric wire process on which a patent was later granted. This treatment was partly effective in stopping some of the flow, but was of doubtful value for bearing purposes. Leakage increased again later to the 1940 flows, so that evidently these leaks broke out in other places, probably by additional washing of clays and shales which the asphalt could not displace or penetrate. Some credence to this theory is available from the logs of the present drill holes. Invariably open cavities either above or below, or both, were found to exist when the old asphalt was encountered. It is now believed that, if an intensive cement grouting program had followed the asphalt grouting to effect consolidation of the foundation and to confine the asphalt, the leakage problem might have been solved at that time. The years that elapsed following the completion of this work enhanced the obstacles to be overcome in effecting a barrier to this leakage so that the methods used in the decade 1920–1930 no longer were effective, at least in some areas. The predominant leakage occurred in two areas as indicated in the elevation in Fig. 13. To some extent cavitation, as shown in this figure, is hypothetical since these cavities were projected from drill logs of holes all drilled in the same vertical plane, and since much of the predication of these cavities was based on core loss, probably due to drilling through vertical seams in many cases (see Fig. 14). However, the interlocking and water-carrying connections of these cavities are well established and the openings, as they are shown, are at least representative. The general pattern of cavitation is verified by 13-in. and 3-in. holes drilled later through the dam, and downstream from the upstream face.

The approach of the TVA to the problem has been based on placing a watertight diaphragm across the valley in the bedrock below, and just upstream from the upstream face of the dam. To secure this effect, it was proposed to drill and grout the foundation wherever feasible by conventional methods. Where the openings were not groutable, special grouts were developed, and, if these failed, recourse was had to a lined cutoff trench filled with concrete to cut off the through passage of water.

Water in the reservoir stands at about El. 628.5. Overburden is at approximately El. 583, foundation rock, 573, and apparent lowest cavities 481. To maintain a full reservoir for power, which is indispensable for war industries, it was necessary to devise some means of excavating for the cutoff through 55 ft of water and for depths as great as 92 ft below that point.

The first step was to sink NX size diamond-drill holes 20 ft on centers, and approximately 125 ft in solid rock, across the entire length of the dam. These holes were water tested, air tested, and dye tested by stages, using a $1\frac{1}{2}$-in. pipe extending down the hole, and a unique quick-breaking and quick-sealing packer at the bottom. This packer was developed on other TVA work and operated so satisfactorily that its adoption at Hales Bar was a natural consequence.

UNDER HALES BAR DAM, FACING UPSTREAM

The water tests were made to determine the level to which grouting would be feasible and the type of grout to be used. Air and fluorescein dye tests established the paths of the underground connecting channels. Cavities, penetrated by holes at different levels, each connecting with different boils in the tailwater were found. The intensity of the coloring was a measure of the quantity of flow, and the travel time from the time the coloring was placed in the hole until it appeared downstream was noted carefully to establish a velocity index. Figs. 13 and 15 show the outlets and leakage paths established by these tests.

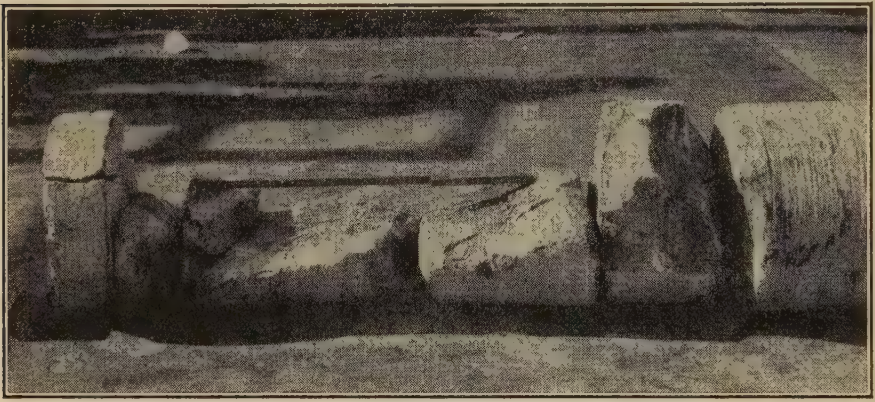

FIG. 14.—TYPICAL CAVITY, AS REVEALED BY 18-IN. DRILL HOLE CORES

These NX holes were then grouted to as high a level as feasible under pressure varying from 30 to 70 lb per sq in., depending on the depth of rock penetrated. Grouts of consistencies varying in water-cement content from 1.0 to 0.5 were used progressively, made from neat cement, neat cement mixed with as much as 6% calcium chloride by weight of cement to accelerate the set, grouts with cottonseed hulls added, grouts "sweetened" with quick-setting property admixtures, and asphalt, depending on the characteristics of the holes. Asphalt was used only when cement grouts proved to have been lost, and then only in seams carrying water and in holes that were apart from the cutoff trench areas where it would not be feasible to extend this cutoff trench to the seam penetrated. Wherever asphalt was used it was followed immediately by cement grout for confining and consolidating the asphalt, and adjacent holes were cement grouted to assure this effect. Excellent results have been achieved by hot asphalt grouting where stoppage of flowing water is the only consideration, bituminous material being very effective for this purpose.

Wherever holes could be grout-filled to the rock surface, secondary holes were drilled midway and grouted. Additional holes at still closer spacing were drilled and grouted, as required, until the area was tight. The average volume of grout taken by the foundation per foot of hole drilled for the various hole spacings in groutable areas was as follows:

Spacing of holes (ft)	Cu ft grout per ft drilled hole
20	6.25
10	5.20
5	3.60
2½	1.60

Diamond-drilling speeds varied greatly due to difficulties encountered in setting the casing and other features of drilling through 60 ft of water, many of which were not comparable with other jobs. In good operating, after the casing was set, 20 to 30 ft were drilled easily in one 8-hr shift. Cast-set bortz

bits were used for the most part although some work was done with tungsten-carbide-faced blank bits. The bit cost on this job was high—approximately 60¢ per foot—but it was caused by drilling in old construction territory, where it was common experience to drill through reinforcing bars, old pipe, timber, bolts, caving holes, asphalt, concrete, and many other burdensome inert materials.

The only effective and permanent cutoff across the leakage areas was felt to be a continuous concrete wall in the foundation under the dam. It was desirable to do this work without lowering the reservoir so that some novel excavating process had to be devised to accomplish this desired result.

Numerous ideas were studied. In the first experimental drilling, the plan was to core drill large diameter holes and line them with fabric and rubber bags, line-drilling the overlapping holes; but numerous defects developed which led to the evolution of the method of drilling 18-in. holes 24 in. on centers, lining them with asbestos-cement pipe, and concreting inside the asbestos-cement pipe by tremie. This step was followed by drilling intersecting holes $8\frac{3}{4}$ in. upstream and midway between the other two, again lining and concreting, using the velocity of the water to draw the liner against the previously concreted holes for a seal (see Fig. 15(*c*)). Thus a continuous cutoff, either by conventional grouting or by concrete placed into lined holes excavated by core drills, was constructed to depths required as predetermined by the cores from NX size diamond-drill holes, water and dye tests, and grouting. This excavation varied in depth from 20 to 100 ft. With this cutoff in place, the entire foundation could then be consolidated as follows (see Fig. 15(*b*)).

After completing the 18-in. drilling and concreting, diamond-drill holes were driven upstream from the new cutoff on 10-ft centers and the upstream openings were grouted by cement or asphalt to perfect the seal. These were followed wherever necessary by similar treatment at closer spacing. Later 13-in. holes were drilled through the dam, 6 ft to 10 ft on centers tapping the cavities, and these were filled with concrete. Diamond-drill holes were then drilled through the dam midway between the 13-in. holes for final cement grouting. All these holes through the dam, both 13 in. and 3 in., demonstrate the effectiveness of the cutoff. The diamond-drill holes upstream from the lined cutoff were also dye tested before asphalt grouting and these indicated a marked decrease in dye intensity and an increased travel time which, in turn, indicated the reduction of leakage, to the magnitude of a seepage, by the construction of the cutoff wall. Some asphalt grouting through the dam in particularly troublesome areas was required. In general such grouting was required for localized seepage, and it was always followed by concrete or cement grout for effective consolidation.

Since the linear feet of cutoff wall represent an undetermined number of holes, it was desirable to drill holes of as large diameter as possible. However, since access into the hole to remove cores was impossible because of the underwater nature of the work, the diameter of the holes was restricted to a size that would permit breaking and removing cores by gravel-grouting the core into the core barrel. Eighteen-inch holes at depths prevailing on this job appeared to be the probable upper limit, as recommended by the drill manufacturers, and this size was adopted. The selection of this size seems to have been well justified since no insurmountable obstacles were encountered in pulling cores although the bottom pulls in good rock were usually difficult, thus assuring contact of the cutoff trench with good foundation rock, and confirming geologists' predictions. It is believed that 20-in. or even 24-in. holes probably could have been used down to the level of good rock; but material scarcity caused by the national emergency precluded changing tools and casings to try the larger diameter.

The selection of the correct drill for such highly specialized excavation was very important. Preliminary experimental drilling was done with a 35-hp gasoline-driven 36-in. shot core drill. The results of this test indicated the desirability of having a heavier and more rugged machine, and 48-in. machines were specified for the work. These were built from standard parts to TVA specifications for a machine particularly adapted to the Hales Bar work but also one that could be used elsewhere. Nine of these drilling units were used, and were equally adaptable for the 18-in. and 13-in. drilling which was done.

Water for feeding shot to the drill bit and washing up the sludge was supplied from two 60 gal per min, 250-lb electric-driven pumps set up on the trestles at opposite ends of the drilling operations. The pumps were connected by a pipe line running along the downstream edge of the trestle, and a sufficient number of take-offs were left in this line to make quick hose connections to any drill at any time.

Air for operating the air-driven hoists, grouting, cleaning out holes, and testing was furnished from two 315 cu ft per min portable compressors permanently placed on the left bank of the river upstream from the power house. These were replaced later by one electric-driven 1,500 cu ft per min stationary compressor. Air was piped from the bank along the downstream edge of the trestle with sufficient take-offs to permit hose connections wherever desired.

Electric power was brought to the trestle from a bank of three 250-kw 44,000/2,300-v transformers in a substation on the left bank of the river, downstream from the power house. A 2,300-v bus line was suspended on cross arms over the downstream side of the trestle, to two sets of three each, 112.5-kw 2,300/440/220 v and one set of three 150-kw 2,300/440/220-v transformers; whence power was delivered to the drills in conduit to steel outlet boxes near the upstream side of the trestle and conveniently arranged so that all drills could be fed within a minimum distance. Three-conductor cable with three-pronged plugs for plugging in at these boxes made quick connections possible whenever the drills were moved.

Where there was 50 to 70 ft of water on the surface, the casing had to be at least 60 ft long and sufficiently rigid to insure that the boring itself was absolutely plumb. For this purpose 0.5-in. wall, 20-in. steel pipe (outside diameter) with cast-steel flanged couplings was selected. These three-ton casings were rotated into place, which is a most effective procedure at slow speeds. Drilling in old asphalt also slowed up the speed of rotation where horsepower was required. When the workers were drilling through cavernous areas with only one side of the bit riding on rock, high speeds and slow feeds were required but momentary horsepower was also high.

For continuous and satisfactory drilling, it was desirable, therefore, that the driving motors on the drills have multi-speed control and constant horsepower. Four-speed electric motors, of 40 hp, were specified. The efficacy of using this much horsepower has been proved in drilling holes where velocities are high. For lifting tools one 3,500-lb line-pull electric hoist and one 2,000-lb line-pull air hoist were specified. The drill derrick was designed to move back for available hook work over the hole with outside live boom equipment. The manufacturers devised a unique eccentric arrangement for this purpose and also built the five-head block sheaves and two-lead sheaves into the crown block of the derrick, resulting in a maximum available headroom and flexibility for reeving lines to the two hoists. Hoists were arranged for individual mounting, one on each side of the drill, and the operator worked up in front where he had a clear unobstructed view of operations (see Figs. 16 and 17).

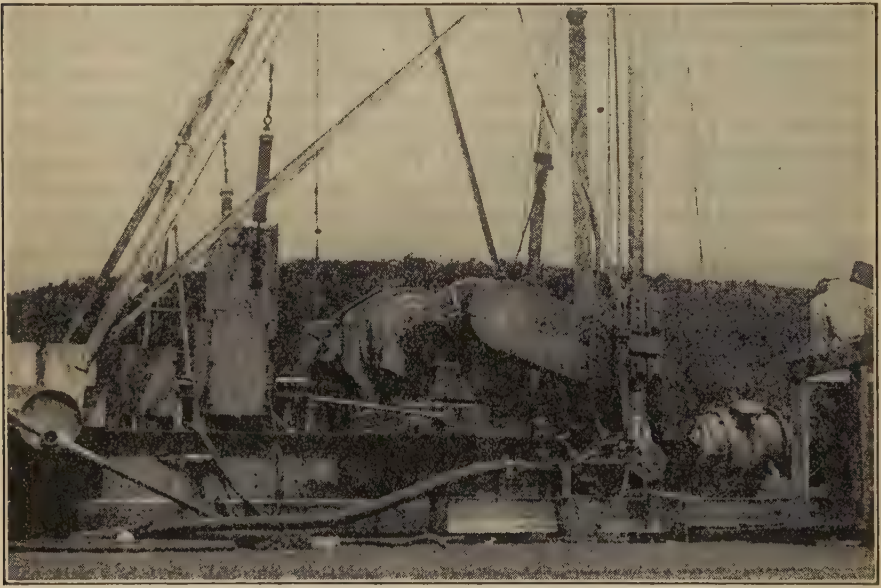

Fig. 16.—View of 48-In. Core Drill

Drill rods were of the 4-in. box and pin type since it would have been impossible to recover broken nuts or bolts of flanged type rods from a completely submerged hole. Oil-well type wrenches were used to break joints, the rods being supported on elevators and forks on the 20-in. casing. The cavernous condition of the foundation produced much pounding through the rods and the powerful 40-hp motors made these rods up very tight. Wrenches capable of 56,000 ft-lb of torque broke consistently, and it was necessary to specify casing tongs capable of more than 100,000 ft-lb of torque to overcome this difficulty (see Fig. 18). These tongs were activated from cables reeved through snatch blocks to air hoists, one of which was located centrally on each barge, and each hoist served several drilling units when pulling core.

For vertical holes, the drill tool was longer than 20 ft (see Fig. 19). It consisted of an open end piece on top to catch cutting sludge, a male plug designed to receive a pin type coupling from the drill rods, a core barrel, a renewable coupling between the core barrel and bit, the point of maximum wear, and the bit. This assembly proved to be very effective and, except for the bit, was built from standard 18-in. pipe with a $\frac{1}{2}$-in. wall. The bit was intended to

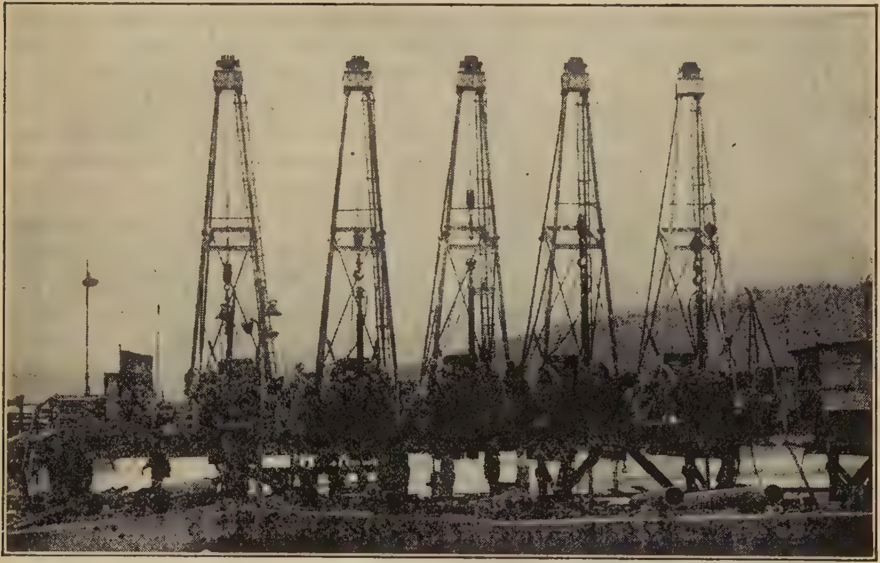

Fig. 17.—Battery of 48-In. Core Drills in Operation

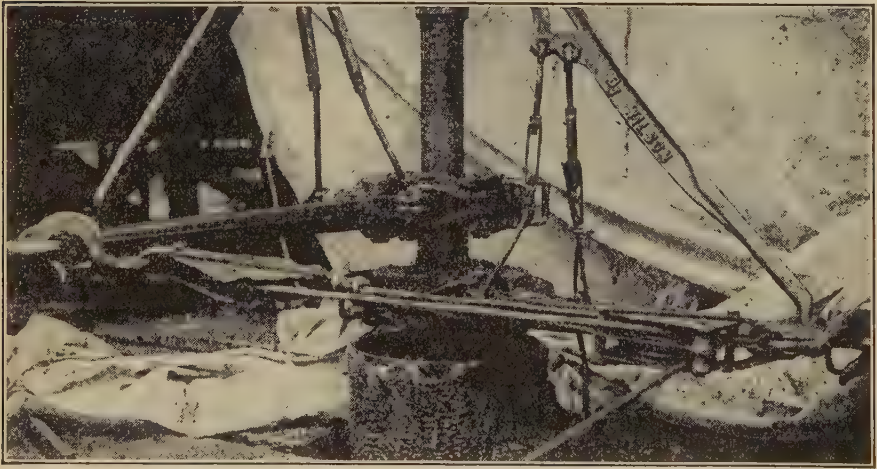

Fig. 18.—Breaking Out a 4.5-In. Tool Joint with Casing Tongs

be made from standard 18-in. pipe of $1\frac{1}{8}$-in. wall thickness but it was impossible to secure this type, and cast-steel bits and later even laminated bits from thinner wall pipe were used satisfactorily, although the latter did not wear as well as the solid section bits.

Since the overburden varied in thickness from 5 to 35 ft it was very desirable to remove as much of this as possible before drilling in any one area. Silt and mud accumulated in the reservoir at the heel of the dam and much trash from the original construction was also still in place. Old crib cofferdams, piles of rock excavation, old-style steel sheet piling, pipe, wrenches, concrete buckets, logs, and sundry items which are found, would be an impediment to drilling if not removed first. Therefore, a $1\frac{1}{2}$-yd clamshell digging bucket with the floating steam whirley crane was used to clean out an area 10 ft to 15 ft upstream from the upstream face of the dam before the drill operations were begun.

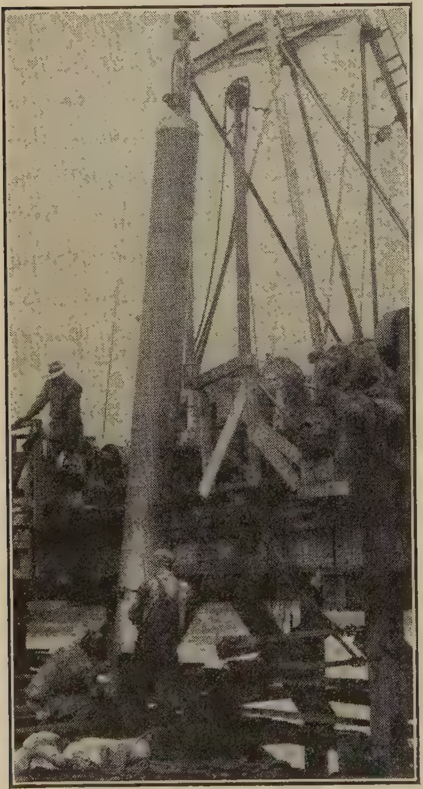

Fig. 19.—18-In. Drill Tool Assembly

Among the many other items that needed to be removed were four old closure gates that had never been salvaged. These 19-ton gates were supposedly standing in an upright position in front of the closure blocks but it remained for an 18-in. drill penetrating one corner of one of them to reveal that they had fallen forward and were now resting flatwise in the river bed at angles from 0° to 45°. Divers were dispatched to the bottom to determine their position and location more accurately. They hooked the gates to the crane which removed them from the river bottom where they had been for almost thirty years (see Fig. 20). The steel was cleaned and found to be in surprisingly good condition, and, because of the steel shortage, these gates were disassembled and all the structural shapes and plates were reused.

Holes were alined by the template shown in Fig. 21 which was fabricated from structural steel, and suspended at the line of overburden on cables from the deck of the trestle on the dam. This template had $20\frac{1}{2}$-in. holes 24 in. on centers, with guide skirts for entering the casing. After a template had been lowered and leveled, a 20-in. flush-joint casing 60 ft long was set into one end hole by a floating whirley crane. At the opposite end of the template a flush-joint casing was set similarly into the second hole from the end. Flush-joint casing was made up with $\frac{1}{4}$-in. square threads. A 1-in. plate, machined to take a pin type coupling, was bolted to a flange screwed to the top of the casing, and the drill rotated each of these end casings about 2 ft to 3 ft into good rock. These casings then served to hold the template in place for all intermediate drilling, and acted as guides for spacing the intersecting holes and setting adjacent templates. The steps in the use of the template were as follows:

First Template Setting, Position 1 (*Fig. 21*(*a*)).—The template was set with openings 1A and 2A facing upstream. The flush-joint casing was set in the template openings 1 and 2 and the casings were rotated 2 ft to 3 ft in rock. All the intermediate holes were drilled in the order shown, using flanged casings. The template was finally removed, leaving the flush-joint casings in place.

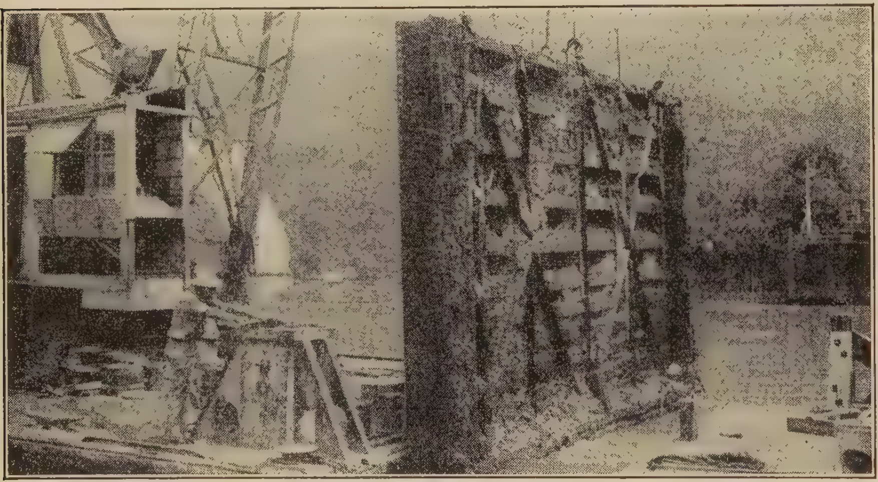

Fig. 20.—Recovery of an Old Closure Gate from the Reservoir at the Heel of the Dam

First Template Setting, Position 2 (*Fig. 21*(*b*)).—The template was then reversed by turning it end for end so that openings 1A and 2A (Fig. 21(*a*)) were placed over the flush-joint casing left in holes 2 and 1, respectively. The secondary holes were drilled in the order shown and the template was removed again, leaving all flush-joint casings in place (Fig. 21(*c*)).

Second Template Setting, Position 1 (*Figs. 21*(*g*) *and 21*(*h*)).—The template was moved to the left or to the right to extend the line of drill holes. As in the first setting, the template was placed with openings 1A and 2A facing upstream, the end opening being over the flush-joint casing in hole 1 when the template was moved to the left and over hole 2 if moved to the right. Flush-joint casing was set in template opening 20 and that primary hole was drilled. The intermediate primary holes were then drilled in the order shown.

Second Template Setting, Position 2 (*Figs. 21*(*i*) *and 21*(*j*)).—This procedure was essentially the same as Fig. 21(*b*), template opening 1A being placed over the casing in hole 1 when the move was to the left and over the casing in hole 20 when to the right. Openings 2A were placed over the flush-joint casings in holes 20 and 2 left and right, respectively. Flush-joint casings were placed in template openings 30 and 31 and these secondary holes were drilled leaving the flush-joint casings in place temporarily. Next the flush-joint casing in holes 1 and 2 was removed. With flush-joint casings in holes 20,

31, and 30, all other secondary holes were drilled, using flanged joint casing. After the drilling of secondary holes in the order shown was completed all casings except that in holes 20 were removed and the templates again were moved forward into primary position.

The flanged casings were 60 ft long and were placed by the crane in a manner similar to the flush-joint. The flanged casings were rotated to a depth of about 6 in. in solid rock. The bottom 20 ft of all casings, with which the drill tool was in contact when starting a hole, was always plumbed. For this work

Plumbing the 20-In. Drill Casing

plumb bob was suspended. Above the plumb bob a contactor was fastened to the ¼-in. rod, and this contactor was set at the same level as four copper contacts arranged in a circle and fastened to the inside of the 6-in. pipe. The contacts connected each to one wire of a four-conductor cable which led to the water surface where they were connected with four 6-v to 8-v lamps. The piano wire completed the circuit. A bell ringing transformer was used so that the system could be plugged into any 110-v light circuit.

The device had a set of three wheels on the outside, one of which was spring mounted both at the top and bottom. The two stationary wheels of each set were placed 120° apart on an arc of exactly 19 in., the inside diameter of the casing. The plumb-bob center was set with relation to these two wheels. The spring-mounted wheel insured that the two fixed wheels would always be in contact with the casing. It was also set at 120° with each of the other two.

This entire assembly was lowered to the bottom of the casing without pumping out. Movement of the plumb bob toward any contactor lighted the corresponding light at the surface and, by means of a jack at the center of the casing and two diagonal rods and turnbuckles, the casing could be moved in any desired direction until all lights were out, at which time the casing was plumb. These rods and jack were left in place to hold the casing during drilling, lining, and concreting. The lights were then checked by short circuiting to be sure that none had burned out. The clearance between the contacts and the contactor was $\frac{3}{64}$ in. all around.

Until a hole was 20 ft deep, a ¼-in. by 2-in. removable band in two pieces at the top of the sludge receiver was used on the cutting tool to obtain perfect vertical alinement by reducing the clearance between the drill tool and the guide casing. This band was made of two sets of two semicircular pieces of steel, the inner one projecting into the sludge collector. The inner band had four stud bolts which fastened to the sludge receiver. Therefore, the unit could be put on or taken off from any tool with a minimum of effort. Two pieces were required to form wash-out slots between the band sections.

A view of the template is shown in Fig. 23.

Studies on the drilling tool revealed that there was a point of maximum wear just above the bit; and in order to save on the other parts of the tool a renewable female coupling, 18 in. long, was placed between the bit and the core barrel. This concentrated wear on one short section of the tool, and this section was turned end for end when wear became noticeable but before the threads were worn down too far to be effective at the other end. Such a coupling was good for approximately 125 ft of drilling in this foundation. The 1⅛-in. wall bits have 15 in. of wearing surface and after 35,000 ft of drilling it appeared that bit life was about 115 lin ft of drilling. The solid section bits averaged closer to 150 ft of life but the over-all average was less due to enforced use of laminated bits because of material shortages. Because they were protected at the bottom by the coupling, core barrels averaged 420 ft of drilling, and usually could be cut off and rethreaded once.

Above the core barrel a male plug was used which had a useful life of approximately 900 lin ft of drilling. When this plug was placed into the drill tool, the expensive connection between the 18-in. tool and the drill rods was reduced materially since this connection was used with various replacements of other parts of the tools; whereas, if it had been a part of the tool, the connection would have been lost each time that part wore out. Experience at Hales Bar indicated that the drill rod connecting to the male plug crystallized after approximately 1,500 ft of drilling and invariably broke just above the pin type coupling. These rods were changed after 1,000 and 1,500 ft of drilling, eliminating considerable breakage at depths requiring costly "fishing" operations.

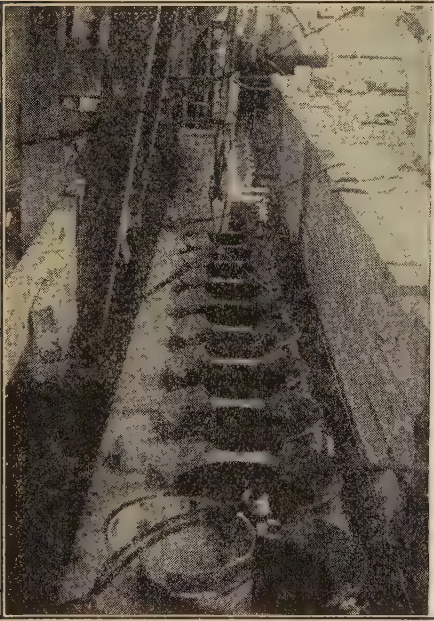

FIG. 23.—VIEW OF TEMPLATE PLACED IN SECONDARY POSITION

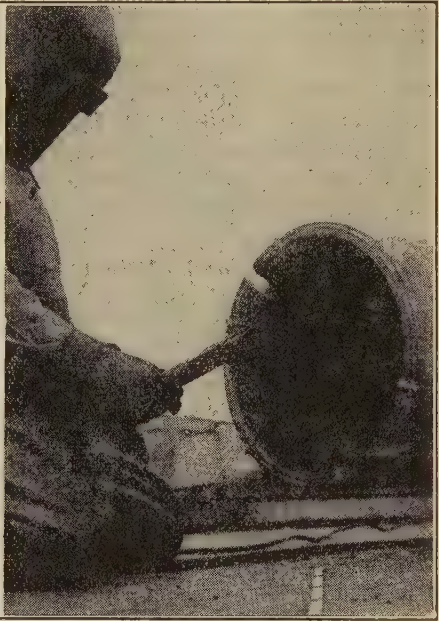

FIG. 24.—WELDER APPLYING ELECTRIC TUBE TUNGSTEN CARBIDE

The sludge collector above the plug was made with a left-hand thread fastening to the plug. The wear on this unit was light and its life was approximately 500 lin ft. These sections were generally reclaimed from worn core barrels, which diminished somewhat the period of their useful life.

All drilling was done from a trestle 11 ft above flashboard level. Three barges lined up in front of the trestle over a distance of 330 ft were used for laying out drill tools, rods, bits; removing core; and in general providing a platform and working space forward of the machines.

Where cavities were encountered which cause shot to be lost under the bits six tungsten carbide knobs were welded to the cutting face of the bit at equally spaced intervals (see Fig. 24). This material has a Brinell hardness of 700 and generally cuts to a point at which shot can again be held under the bit after one or several applications. If a full shot ring is cut, shot can be fed under the bit about as soon as the tungsten carbide is worn smooth without removing the tools, with the advantage that the same bits may be used for either shot or this diamond substitute drilling. Tungsten carbide is made in various screen sizes for acetylene or electric application. Experiments with various available screen sizes of the tube type rods revealed that the 20-mesh to 30-mesh particles were applied easiest and cut better footage than the coarser particles in the Hales Bar foundation rock.

Since drilling at Hales Bar offered no opportunity for differentiating between work done with shot and the tungsten carbide faced bits, it is necessary to state the amount of each being used as a joint figure. Approximately 11 lb of shot and 0.12 lb of tungsten carbide were used currently per foot of 18-in. drilled hole. This value seems high but it must be remembered that shot loss in cavities was high; also, shot and the diamond substitute were used for drilling in casing, which did not contribute any 18-in. footage drilled. Comparisons between 3-in., 13-in., and 18-in. drilling indicate the use of ⅔ lb of shot per inch of diameter of bit at Hales Bar.

Where large cavities occurred, the drills pounded very hard if given a slack line feed. This militated against plumb drilling and also caused repairs on the drills to run high. For such places, a turnbuckle was clamped into the hoist line, the bit was faced with extra tungsten carbide, and the drill was rotated at high speed and the drill tool fed very slowly with the turnbuckle. Although the speed of cutting was probably slower, the advantages gained by eliminating the tendency of the tool to deflect in the direction of the cavity, and by obtaining smoother operation, outweighed the disadvantage of decreased footage.

Drilling speeds varied from day to day, depending on the type of material encountered and on its state of solidity. Over-all rates for more than 35,000 ft of 18-in drilling which involved nine machines and twenty-seven different operators were: 5 in. per gross operating hour; and 6 in. per net operating hour. Thirteen-inch drilling was somewhat better, being about 9 in. and 11 in., respectively, per gross and net operating hours. The former included time for moving drills, drilling in casing, repairs, and other unavoidable delays except layoffs on account of high water—in other words, all workable shift hours. The latter is only net drilling time but includes pulling core. Monthly average rates per gross operating hour for 18-in drilling for the number of machines indicated have been as high as 7.50 in. per hr. Drilling the intersecting holes, however, reduced this rate, since the drilling was slower and more difficult. With nine drills running, 70 ft were drilled in one 8-hr shift, 199 ft in 24 consecutive shift hours, and 2,900 ft in one month of twenty-six working days.

A brief summary of the operating cost per foot for drilling 18-in. holes is as follows:

Description	Cost per foot
Labor	
Direct operations	$4.61
Repairs	0.39
Other expense	2.13
	$7.13
Drilling Tools	
Sludge collector	0.05
Plugs	0.10
Corebarrels	0.14
Couplings	0.19
Drill rods	0.14
Bits	1.07
Wrenches	0.11
	$1.80
Materials	
Lubricants	$0.16
Electricity	0.21
Air and water	0.38
Repair parts	0.28
Shot	0.42
Tungsten carbide	0.31
Sand and gravel	0.02
	$1.78
Other Costs	
Supervision	0.50
Drill depreciation	1.40
Miscellaneous	0.77
	$2.67
Totals	$13.38

It should be understood that these values do not include such job construction plant items as are customarily required in large construction work. Nor do they include such items as the trestle, templates, 20-in. casing, and other charges peculiar only to the Hales Bar project. The costs given are representative for 18-in. shot core drilling in foundation rock similar to that at Hales Bar, and, if used advisedly with due allowance for other locations and requirements, can furnish a satisfactory index of probable unit costs. It also is a satisfactory check-list of materials, equipment, and services involved in this type of operation. Application of these costs also must take into account the fact that nine drills were being used at Hales Bar, a fact which would alter labor, supervisory, and many of the other costs if less or more units are involved.

After the 18-in. hole had been drilled, in each case to a depth of 3 ft below the lowest known cavity, a $1\frac{1}{2}$-in. pipe was lowered into the hole to check the depth, thus determining if all core had been pulled. The grout pump was then hooked to this pipe and cement grout was pumped to the bottom of the hole to seal the liner. Asbestos-cement pipe, made up into one long piece from 13-ft sections, was then lowered into the hole on a 6-in. pipe screwed into a left-hand coupling which was concreted to a plug at the bottom of the asbestos-cement pipe. Sections of asbestos-cement pipe (inside diameter, 16 in.; wall thickness, $\frac{7}{8}$ in.; and lengths, 13 ft) were connected and lowered into the hole, and were supported by the 6-in. pipe on the 20-in. casing, using a fork and elevator. All these asbestos-cement pipe joints were fastened together progressively with No. 16 gage steel sheets 30 in. by 54 in., rolled to 16-in. diameter. The metal was fastened to one end of the pipe sections by six $\frac{1}{4}$-in. flat-head machine screws and nuts in the storage yard. The pipe was assembled over the hole in a vertical position, the end of the succeeding pipe being slipped over the protruding 15 in. of metal and fastened to the metal with two rows of four each, flat-head self-tapping sheet-metal screws (see Fig. 25). Across cavernous regions, a 3-in. mesh expanded metal was placed inside the asbestos-cement pipe for reinforcing, and a 1¾-in. round bar was placed inside the 6-in. pipe to hold it in a central position so that it would not interfere with drilling the intersecting hole. When sufficient liner and reinforcement had been assembled to line the hole completely, a cover was placed over the top of the asbestos-cement pipe, as shown in Fig. 26. This cover had outstanding angle legs tapped for stud bolts which fastened to the outside of the 6-in. pipe. On the underside, the cover was equipped with four rollers spaced to fit the inside diameter of the liner. These permitted the 6-in. pipe to turn without disturbing the liner. This cover, therefore, held the 6-in. pipe centered and also prevented any of the asbestos-cement pipe from breaking joints. Such breaks might occur in lowering sections to the bottom due to caving rock, tightening of the hole in previously placed asphalt areas, or friction developed by the differential head against the liner. In some instances, velocities of more than 6 ft per sec, measured by lowering a current meter into the open hole, were recorded. In some cases this differential head was sufficiently high to impede the rotation of the drill tool seriously, and, in lining these holes, the liners had to be forced down, obviously necessitating the use of the cover plate.

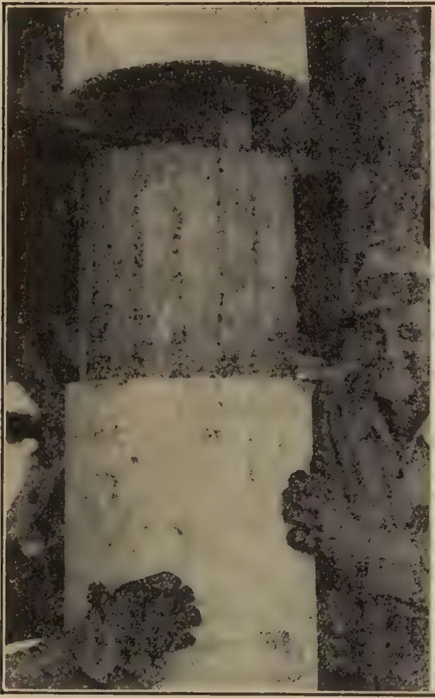

Fig. 25.—Making an Asbestos-Cement Pipe Joint

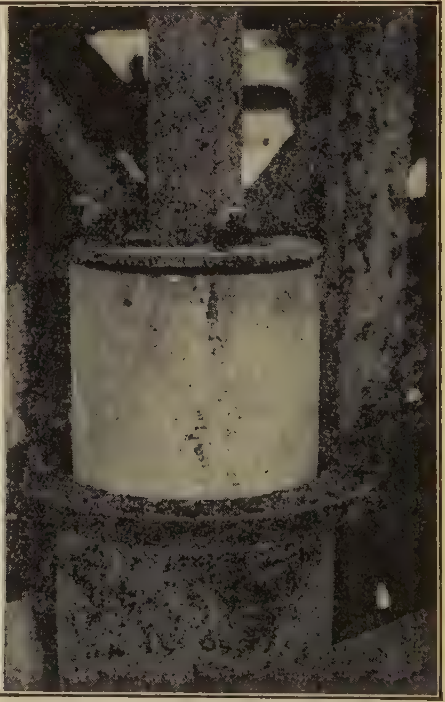

Fig. 26.—Cover or Hold-Down Plate at the Top of the Asbestos-Cement Pipe Assembly

Additional 6-in. pipe was added, permitting the assembled liner to reach bottom where it sank into the previously poured grout. The 6-in. pipe was then filled with heavy neat cement grout, and the left-hand thread at the bottom plug was unscrewed from the top. The grout dropped in the 6-in. pipe and filled the bottom of the asbestos-cement pipe until it found its level in both. Sufficient concrete to fill the liner was added through the 6-in. pipe which then acted as a tremie. The liner was overfilled by computed volume to effect a seal at the top of rock. It was important to gage this overfilling so as to be sufficient for the seal, but not so great to concrete in adjacent 20-in. casings in which other drills might still be operating. The remaining 6-in. pipe was then removed, and the 20-in. casing was pulled out and taken to the checking station where it was inspected for straightness. Small deflections were adjusted by shimming between flanges. The bottom of the casing was then prepared with a few tungsten carbide knobs and two water slots. If the casing was worn thin at the bottom it was cut off to a point where full wall thickness was available before applying the tungsten carbide. The casing was measured and marked and set aside for placement in the next projected drill hole. One casing was always placed in front of each drill, ready for drilling. Fig. 27 shows the method of lining and concreting, and details of the joints and bottom plug. To summarize the procedure:

(1) Fill the 6-in. pipe with neat cement grout through a 1.5-in. pipe to the bottom of the hole, by means of a grout pump, using a water-cement ratio of 0.4, and remove 1½-in. pipe;

(2) Unscrew the 6-in. pipe from the left-hand cap (see Fig. 27(*k*)); the grout rises inside the asbestos-cement pipe and drops in the 6-in. pipe to the point of head equalization for grout, establishing tremie action;

(3) Fill the 6-in. pipe with 1 : 2½ : 3 concrete using quick-setting cement;

(4) Lift the 6-in. pipe and add concrete, maintaining the tremie action until the hole is full;

(5) Remove the 6-in. pipe; and

(6) Lift the 20-in. casing and thread it into the new template opening, after checking.

The 20-in. casing was handled in one piece by a floating steam whirley crane mounted on a barge. The crane had a lifting capacity of 5½ tons on a flat boom and 20 tons on a close boom. The boom was 75 ft long. The barge was equipped with one 56-ft and one 70-ft spud to reach bottom in the 50-ft to 60-ft depth of water upstream.

A small temporary plant consisting of a 10-sack concrete mixer on a barge also loaded with aggregate and cement was replaced by one of the TVA 2-yd floating concrete mixing plants, originally used during the construction of Wheeler Dam. Quick-setting cement, or standard cement with 2% calcium chloride added, was used for concrete since it was desirable to have the primary holes set up as quickly as possible so that secondary holes could be drilled. Except in a few exigencies, concrete in the primary holes was always 30 days old before secondary holes were drilled. All concrete materials except those in the mixer plant bins were normally stocked at the dock.

RETING DETAILS

A 22-ft by 100-ft steel work barge, on which 20-in. casing and 6-in. pipe were stored, asbestos-cement pipe was assembled, and reinforcing mesh and rods were placed, and the TVA towboat completed the marine equipment required for this work.

Concrete was proportioned from Tennessee River gravel and sand, the nominal mix being 1 : $2\frac{1}{2}$: 3 with a water-cement ratio of 0.5. This concrete tested consistently at 4,000 lb per sq in. in 28 days and the cement factor was 1.87 bbl per yard of concrete. This is high but was believed necessary due to the underwater nature of the work.

Twenty-four hours after concrete placement, the hole was sounded to determine the effectiveness of the concrete and if it was not as high as the anticipated level, it was brought up by placing cement grout or tremie concrete, after which it was sounded again after sufficient time had elapsed to permit hardening.

On October 15, the cutoff trench had been completed; the 13-in. drilling of 7,500 ft and concrete foundation consolidation were 90% complete; diamond drilling at 49,000 ft was 90% complete; cement and asphalt grouting were approximately 90% complete. Of the fourteen original boils showing downstream from the dam, all but two have been eliminated, and these two show marked improvement as a result of the impact of the work. Most of the remaining percentage of uncompleted work as of October 15 is in contact with these, and the completed work should show the same result here as has been effected on areas completed. Fig. 13 shows the boils which have been eliminated and those on which work is still being done. Circles representing these boils indicate by their diameter the relative sizes of the visible leakage as found at the time this work was begun.

All holes were logged and plotted in order that a complete record of the entire cutoff would be available at all times. A projection of the trend of the overlap in any series of holes indicated that the failure to secure perfect overlap should not be considered an impediment to securing satisfactory results since in cases where intersections were lost the drift of the holes was not sufficient to cause any serious harm and the later upstream asphalt placement was used to correct these minor defects. This was found to be correct in principle. After the cutoff was completely in place in the worst leakage area which connected with boils G, E, and F, Fig. 15, these boils had been reduced from bubbling as much as 18 in. above tailwater surface, to flat but still visible flows, indicating an estimated 75% effectiveness. Strategically placed asphalt holes upstream from this cutoff trench eliminated the visible balance of flow. Tremie concreting under the dam through the 13-in. holes, and cement and asphalt grouting through 3-in. holes, complete the operations. Job experience also indicates that, without the cutoff trench, the asphalt seal could not have been relied upon to secure the desired results because the flows were too large. The combination use of these methods, judiciously applied, is considered effective in cutting off flows of the magnitude encountered at Hales Bar.

During the period of high water in January, 1943, just after heavy general rains over the Tennessee Valley, some interesting phenomena occurred which had not been noticed during any previous high-water periods prior to completion of some parts of the cutoff walls.

At approximately Station 12+00 and about 150 ft upstream, where suctions had previously been indicated, and at Station 16+50 just upstream from the dam, boils appeared in the swollen headwater. Some of these carried mud and others were clear, but violent upheavals were in evidence more or less at 10-sec intervals.

At Station 19+50 and approximately 225 ft upstream, air bubbles in very large quantity effervesced continuously for three or four days during high water.

In the former instance an explanation is believed to be that the channels to higher ground water, as a result of the general rains, were open, but, since the cutoff obstructed easy passage to the downstream side of the dam, the differential head produced this boiling effect in the headwater. In the latter case it seems probable that large quantities of air became trapped in openings accessible to atmosphere during the long period of dry weather and that heavy rains running off into these subterranean channels entrapped this air and, due to hydrostatic pressure, shoved it through the openings to come up in the reservoir, the normal channel under the dam having been closed off.

A repetition of high water soon after the former high flows again brought out the water boils but not the air bubbles, which lends some weight to the assumptions.

Frequent checks of concrete in the adjacent holes have indicated that it remained well in the liner. Diamond-drill holes were drilled into this concrete to ascertain its condition, and soundings were made frequently through the intersecting holes as they were being drilled.

Many improvements over the originally conceived construction methods were made in the field. Notable among these were developments of the required core drill characteristics, which were used to specify requirements in acquiring this equipment. The drill tool used was modified from the originally proposed tool to take advantage of experiences gained on the wear of this part. The substitution of ½-in. wall casing for previously tried lighter sections, and the substitution of cast-steel instead of cast-iron flanges both on the 20-in. casing and on the 6-in. tremie pipe were important advances not originally foreseen. The development of the template and the underwater electric plumb bob stands out, perhaps, as the two most important improvements toward attaining the desired goal. The use of the tungsten carbide was essential. Not nearly enough importance can be attached to the wrenches and tongs which were acquired heavy enough to accomplish desired results after trial-and-error experiments with lighter tools. In the field of lining the holes, much work was done before the liner joints were satisfactory, and such handy adjuncts as the hold-down plate at the top of this liner were invaluable.

The original conception of a liner was that of a flexible fabric and rubber bag. In its trial stages this was found wanting. This type of liner was desirable because it filled the drilled hole completely. The very satisfactory handling of the rigid asbestos-cement liner, and the inability to secure the fabric and rubber products due to the war, precluded further experimentation with the flexible liner.

Summary

In retrospect, two improvements not evident without the experience gained on this work could have been made, and should be made if this plan is used elsewhere again:

1. After dredging upstream from the dam, a concrete block, tremied into the place of the removed overburden would have provided two advantages—
   (*a*) All casings could have been the same length; and
   (*b*) The templates could have been set directly on this block for drilling to begin.

Although it was thought that some overburden would be desirable for holding the casings in place, this was not found necessary.

2. Much importance was originally attached to overlapping of holes to secure a continuous cutoff. The amount of this overlap was determined to allow for some deflections in drilling to minimize the lack of it at lower levels. This overlapping has a definite theoretical advantage, but results at the job indicate that this is probably outweighed by practical consideration, such as:
   (*a*) Too deep overlaps cause caving of the concrete remaining in the primary holes, resulting in the necessity of drilling additional holes upstream from the secondary holes to correct this condition where it occurs. It is true that this condition obtains in only about 1% of the holes but it can be eliminated by decreasing the overlap.
   (*b*) The secondary hole does not drill as fast as the primary hole because of the overlap and consequent shot loss, particularly in holes lined with the rigid liner.
   (*c*) The time element, waiting for concrete to harden in holes adjacent to proposed intersecting holes, can be eliminated.

Therefore, to overcome these defects in application, it is felt that primary holes could have been spaced about the same, but that secondary holes should have been drilled farther upstream so that the periphery of the holes just touch instead of overlap. The disadvantage of this arrangement is that there would be slightly greater impairment of coverage of the leakage areas, but the record of overlap indicates the need for some asphalt grouting to perfect the seal anyhow, and therefore this disadvantage is outweighed by the aforementioned advantages.

Acknowledgment

The work was done by the Tennessee Valley Authority, for whom T. B. Parker, M. Am. Soc. C. E., later succeeded by C. E. Blee, M. Am. Soc. C. E., was chief engineer, and A. L. Pauls, M. Am. Soc. C. E., chief construction engineer. At the project, H. D. Towers was assistant superintendent in charge of the construction forces. He was assisted by B. W. Crowe, R. M. Winston, and L. E. Tidwell, shift foremen. A. H. Weber was in charge of engineering and inspection for the project. The writer also wishes to acknowledge the cooperation and assistance of Frank Miller and manufacturers supplying equipment and materials to the project for their part in the development of methods and specialized items required to do the work.

DISCUSSION

Berlen C. Moneymaker,[4] Assoc. M. Am. Soc. C. E.—An interesting and valuable record of how a serious and difficult foundation problem was solved successfully is presented in Mr. Hays' paper in this Symposium. Solution channels create foundation problems at nearly all limestone dam sites, but the large channel at Kentucky Dam presented a problem of unusual magnitude, involving both bearing strength and watertightness. So far as is known, this channel is the largest solution cavity ever to be encountered and treated in any part of a dam site. It lies entirely below the water table and is from 70 ft to 100 ft wide at the top (El. 289), decreasing in width with depth to El. 70±, where it disappears. The linear extent of the channel is unknown, but it is more than 1,000 ft long, and there is good evidence that it is more than 2,000 ft long. The channel extends across the lock and dam in the direction of N 02° W, but its trend changes to N 07° W a short distance downstream.

Immediately downstream from the lower lock gate, where the cutoff was effected by a subterranean arch dam 195 ft high, built from the top downward, the channel is 70 ft wide at the top. It extends downward without any appreciable decrease in width to El. 217, where it bifurcates, and from here the two prongs taper to extinction at about El. 70. The channel was nearly completely filled with residual chert and clay, sand, and blocks of limestone. In the upper region of the channel the limestone blocks are flat-lying and appear to be but little out of place. Although the channel was formed by the solution of the rock, it was never a large open cavity. Solution progressed along numerous closely spaced parallel joints, producing a series of vertical channels which subsequently were filled by material which slumped from the sides and from above. Solution, followed by cavity filling, progressed until nearly all of the rock in place was dissolved.

The deep solution channel was not found in the early stages of exploration; in fact, it was discovered little in advance of the actual excavation of the rock in the area involved. Although the Geologic Division of the TVA did not conduct the exploration activities at Kentucky Dam, it is appreciated that it was not practicable, however desirable it might have been, to drill closely spaced holes to within 100 ft of sea level over the entire dam site. As the dam alone is about 8,700 ft long, the total area under exploration was more than 10,000 ft long and several hundred feet wide, and ranged in elevation from 300 ft to nearly 450 ft. With the exception of two small outcrops, bedrock was covered by an overburden of alluvial and residual materials which varied in thickness from 20 ft to 110 ft. In view of the thickness and continuity of the overburden, the necessity of locating the exploration holes on fairly wide centers, the relatively narrow and linear character of the channel, and the presence of large and little disturbed blocks of limestone in the cavity filling down to El. 230, it is not surprising that the channel was not discovered in the course of the preliminary exploration.

---

[4] Chf. Geologist, Geologic Div., TVA, Knoxville, Tenn.

The exploratory drilling revealed that, in places, the rock in the lock area was extensively dissolved, that the solution cavities were predominantly vertical channels, and that some of the cavities extended to great depths. Prior to January, 1939, only two holes, both relatively shallow, had been drilled into the channel. Both holes encountered numerous filled solution cavities alternating with layers (blocks) of undissolved limestone. As the same condition prevailed in narrow vertical solution channels, the vertical drill holes afforded no clue as to whether the solution channel was 1 ft wide or 100 ft wide. However, as additional holes subsequently were drilled, it became evident that rock was intensely and deeply dissolved in certain areas. Deep holes drilled into one of these areas at various angles disclosed that the deep and intense solution was confined mainly to a well-defined zone. Intensive drilling soon revealed the linear character of the zone, its width and its depth, and the extent of solution within the zone; but the details of geology as shown in the geologic section (Fig. 9) were not fully appreciated until excavation for the cutoff was undertaken.

Precisely how the cutoff of this large channel was effected is very clearly and concisely reported in Mr. Hays' paper. He is to be congratulated upon contributing to the engineering profession such an excellent record of the problem and its solution.

Mr. Schmidt deals with another unique cutoff problem. The excessive leakage at Hales Bar Dam has been referred to so frequently in engineering and geological publications that it has been accepted as the classic example of a dam built with insufficient foundation investigation, preparation, and remedial treatment.

When Hales Bar Dam was built (1905–1913), the science of engineering geology had not been developed. At that time, large masonry dams were few in number, were widely separated geographically, and were built with little or no geologic investigation. Even until 1933 most large masonry dams in the United States were built without more geologic investigation than a few cursory examinations by one or more consulting geologists. Until 1930 American geologists were almost unanimously of the opinion that solution cavities could not develop in limestones lying below the water table. It is not surprising, therefore, that Hales Bar Dam was built without an adequate geological investigation. Moreover, it is extremely doubtful whether a mere geologic investigation of the type current from 1905 to 1913, without extensive exploration with core drills, would have revealed in advance the serious foundation defects which caused trouble and delays during construction and appreciable leakage after completion of the project.

Hales Bar Dam is located on the Bangor (unrestricted) limestone of Mississippian age. The formation consists mainly of limestones with which are interstratified shaly layers of various thicknesses. The limestones, in the main, are quite pure, containing as much as 99% calcium carbonate. Structurally, the rock is almost horizontal and is cut by numerous joints and a few minor faults.

As stated by Mr. Schmidt, much of the rock under Hales Bar Dam is cavernous. The solution cavities, which are quite numerous in certain areas have developed mainly along joints, faults, and bedding planes. Some of them are large and open, and they are present down to El. 480, or more than 100 ft below the original river channel.

In effecting a cutoff under the dam, intersecting 18-in. holes had to be drilled and concreted to depths as great as 100 ft. The cavernous character of the rock rendered the task difficult at best, but the difficulties were enhanced appreciably by large volumes of water under considerable head, moving through the cavities at high velocities.

Mr. Schmidt's paper is timely and is of considerable interest to both engineers and geologists. In view of the widespread interest in the leakage problem at Hales Bar Dam, the paper is a valuable report on an entirely new method of cutting off excessive leakage.

In both papers of this Symposium, the value of detailed geologic work in the solution of the problems at hand is obvious although perhaps not sufficiently emphasized. At the Kentucky project the geologic work was done, successively, by Roger F. Rhoades, Portland P. Fox, Assoc. M. Am. Soc. C. E., and Leland F. Grant. The geologic studies involving the deep solution channel, discussed by Mr. Hays, were made first by Mr. Rhoades and later by Mr. Fox. At Hales Bar Dam the work was done first by Cecil B. McGavock, Jr., and later by John W. Frink, Juniors, Am. Soc. C. E. The geologic exhibits used in the two papers were adapted from drawings prepared by these men.

PORTLAND P. FOX,[5] ASSOC. M. AM. SOC. C. E.—Because it offers remedies for serious defects in dam foundations, this well-prepared paper by Mr. Hays should be of considerable interest to other engineers and geologists. The writer succeeded Roger F. Rhoades as geologist on the Kentucky project in April, 1941, and logged approximately the lower 50 ft of the deep channel. Although most of the exploration was done while Mr. Rhoades was geologist at the project, the writer had the opportunity to study the excavation at close hand.

The selection and exploration for the Kentucky dam site involved many unusual geologic problems and conditions.[6] Kentucky Dam is located at the northeastern edge of the Mississippi embayment and there are no exposures of bedrock on the left bank of the river for many miles either upstream or downstream. Bedrock outcrops near the right bank in the vicinity of the dam and consists of a few small, scattered, flat-lying limestone beds. It was impossible, therefore, to make any accurate detailed predictions of the bedrock conditions to be expected below the river bed from what could be seen on the surface. The territory surrounding Kentucky Dam is of very low relief; the highest hills, located from 1 to 6 miles away from the river, reach a maximum height of only 200 ft. Both abutments and most of the surrounding region are capped by from 10 to 100 ft of Cretaceous sand, clay, and gravel, which largely concealed most of the bedrock. Before and after the deposition of the sand, clay, and gravel, the limestone bedrock had been subjected to a long period of intense and deep weathering.[7] During the late Pleistocene period[8] the river cut its bedrock channel 70 ft below the present river bed and later filled the channel with more recent gravel.

---

[5] Geologist, TVA, Fontana Dam, N. C.

[6] "Subriver Solution Cavities in The Tennessee Valley," by B. C. Moneymaker, *Journal of Geology*, Vol. XLIX, No. 1, January-February, 1941.

Between 1935 and 1937 seven dam sites on the lower Tennessee River, two on the Cumberland River, and four on the Ohio River were intensely investigated by numerous core drill holes. Most of the sites were found to be entirely unsatisfactory because of the absence of rock to depths of 200 to 300 ft below river bed or because of cavernous conditions below the top of rock.

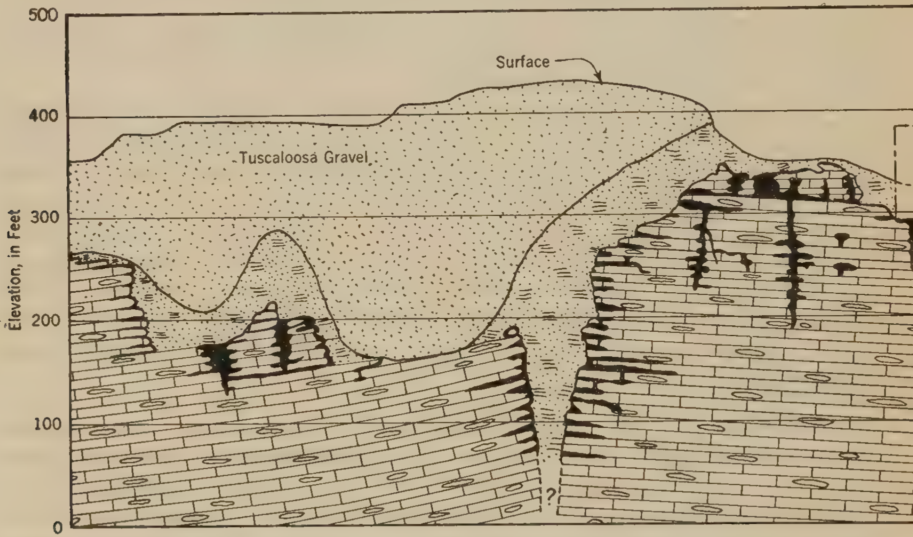

Fig. 28.—Geologic Section Diagonally Acros

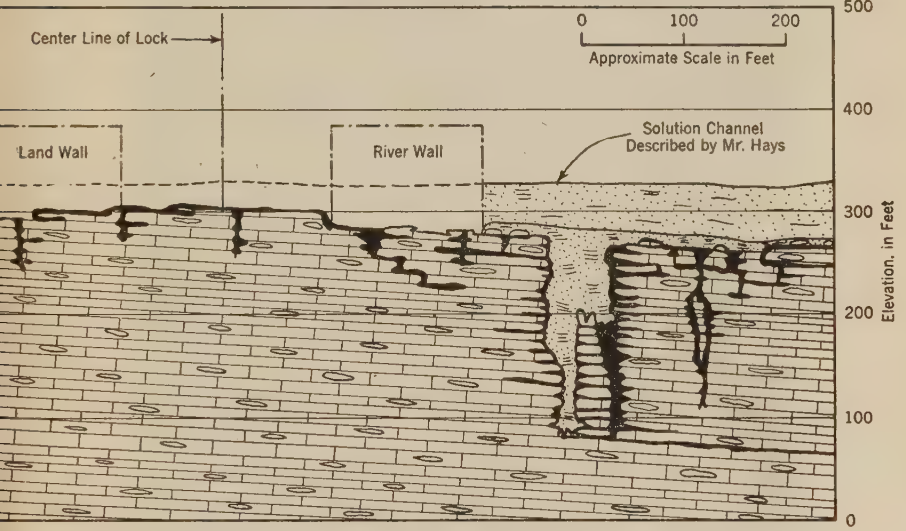
During the exploration for the many dam sites, holes were drilled only 30 to 40 ft into bedrock regardless of the conditions encountered, because the first objective was to find a site where the top of the rock was high, and the second was to reduce the cost of drilling in case the site had to be abandoned. Two of these shallow core holes encountered a part of the large solution channel, but nothing unusual was thought of this condition as numerous other channels had looked much worse on the core record. The vertical holes did not indicate the width of the channels. This fact was realized early and many of the exploration holes were drilled on a 45° angle to discover the width of the channels. Of the 8,500-ft axis, 90% was covered with holes at 45°; but the large channel occurred near the right abutment not far from the only rock outcrops at the site, and in an area not penetrated by angle holes. The angled core drill holes revealed a slightly smaller but similar solution channel between Station 38+00 and Station 40+00, or about in the middle of the first bottom, and under the west earth embankment. Because there was a thick cover of nearly 100 ft of overburden, this area was treated by closely spaced grout holes.

---

[7] "Relation of the Tuscaloosa Formation of Western Kentucky to a Pre-Existing Weathered Terrain," by R. F. Rhoades, *Bulletin*, Geological Soc. of America, Vol. LI, No. 12, Pt. 2, December 1, 1940, p. 1940.

[8] "Geologic Profile of the Lower Tennessee River," by Portland P. Fox, *Journal*, Tennessee Academy of Science, April, 1944.

Core holes drilled during the early exploration also disclosed a large escarpment in the bedrock which greatly influenced the location and design of the structure immediately upstream from the lock walls. This escarpment in the bedrock is approximately 100 ft high and has a north-south trend approximately parallel to the solution channel described by Mr. Hays. Recent exploration for grouting in the right abutment indicates that the escarpment is but one side of a larger solution channel that has formed in the crest of a breached anticline which is the dominant structure of the region (see Fig. 28).



ock and Right Abutment, Facing Upstream

This channel has been explored down to El. 130, or 301 ft below the surface, where it is approximately 40 ft wide.

The bedrock underlying the lower 60 miles of the lower Tennessee River is known as the Fort Payne formation of Lower Mississippian age. Although it is essentially flat lying, broad gentle folds having maximum dips of 10° are common but not obvious. Deep drill holes at the site have proved the formation to be 545 ft thick and to have a remarkably uniform lithology throughout this entire thickness. To make the geologic problem more complicated, the lower part of the overlying Warsaw and St. Louis formations in the vicinity have lithologic characteristics similar to the Fort Payne formation. The Fort Payne formation consists of alternating thick beds of dense, dark gray, relatively pure limestone and of thinner layers, lenses, and nodules of dense, glassy black chert (see Fig. 29).

The chert comprises about one third of the formation and is entirely insoluble, but, due to its brittle nature and numerous joints, it readily breaks up into small angular blocks when weathered. Some of the layers of chert are more than 1 ft thick and such layers frequently project nearly 1 ft from the receding soluble limestone beds. The limestone beds contain some impurities in the form of finely divided silt, but normally they are more than 70% soluble.

Because of the roughness of the cavity walls formed by the overhanging layers of chert, the residual clays never completely fill the spaces immediately under the chert. Thus, the limestone walls are exposed to constant solution and as the chert layers break off the face slowly recedes.

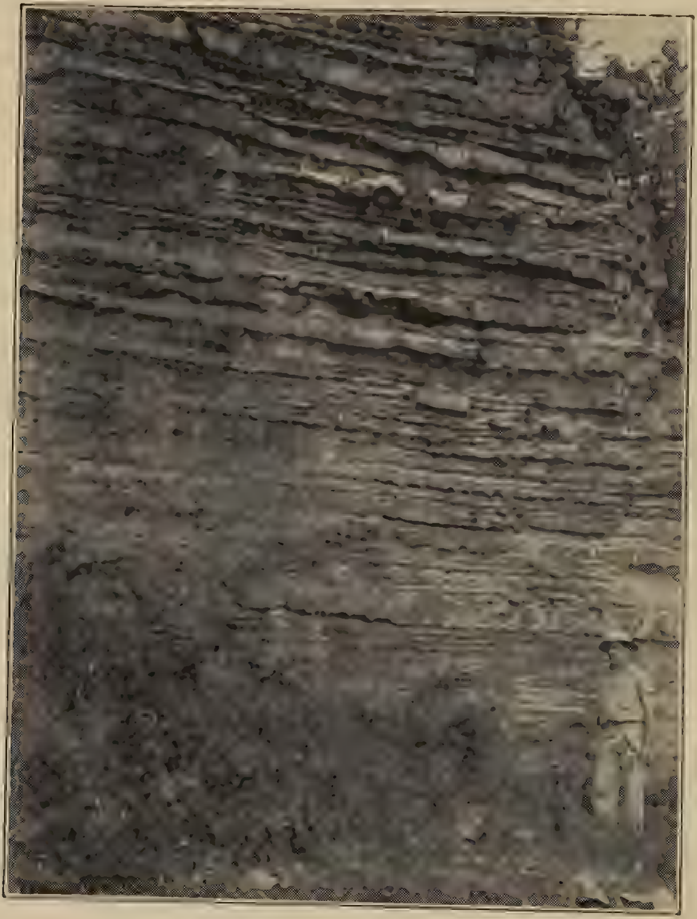


Fig. 29.—Typical Fort Payne Limestone and Chert

The larger solution channel described by Mr. Hays has formed along several large parallel strike joints. Because of the brittle character of the bedrock and a slight change in the dip of the strata, the rock had been literally torn apart to resemble a fault breccia at several places. The large tension joints and fractures disappear completely at the bottom of the solution zone on one of the more prominent bedding planes. If the joints had continued to a greater depth, so would have the solution. Thus, with a slight change in the dip of a uniform, brittle, cherty limestone, closely spaced joints can produce a major solution zone which perhaps is just as serious as a major fault.

During early exploration work considerable emphasis was placed on the superior value of angled core drill holes as compared with vertical holes, since the angle holes intercepted more of the vertical solution channels and they gave the width of the channels as well. These advantages are obvious and not too many angle holes were drilled, but, if more deep vertical holes had been completed first, several large continuous bedding plane seams would not have been overlooked. Even after the deviation of the angle holes had been measured by suspending hydrofluoric acid bottles in the holes and by measuring the angle with a transit sighted on a lowered flashlight in the hole, the deep holes curved so that both methods were inaccurate. As a result, the holes were never plotted correctly. Thus, the nearly horizontal seams were never recognizable from the staggered holes and they were not understood until construction was well under way. More deep vertical holes would have disclosed the bedding plane seams. The large solution channel described by Mr. Hays could have been recognized as easily from vertical holes since the high dips in the cores indicated tilted blocks, but a few angle holes would have given more information on the width of the channel.

In addition to the method described by Mr. Hays, this solution zone could have been treated by at least one other procedure. If the top of rock between the lock walls downstream from the lower gates had been cleaned off and a slab of concrete placed over the dissolved area, the solution channel could have been grouted extensively with clay where the cutoff was constructed. The concrete slab would have served to prevent too many grout leaks, and it would have prevented the washing out of the clay filling in the channel. With these precautions, and with the rather wide, deep cover of overburden upstream from the cutoff, the risk of possible leakage does not appear great.

Kentucky Dam[9] demonstrates the difficulties often encountered in limestone foundations that have long been exposed to intense weathering. A few closely spaced joints can make a tremendous difference. Even the most thorough exploration programs often leave much to be desired in cavernous limestones.

Mr. Schmidt's detailed account of the methods and equipment used to cut off the flow under Hales Bar Dam is a worthy contribution to engineering literature, but a more complete discussion of geologic conditions causing the cavitation would have been a welcome addition for a better understanding of the problems, since former literature on the foundation was similarly incomplete. The large amount of recent drilling should have afforded a much better picture of the geologic conditions than had been possible previously.

The "washing out of the shales in horizontal bedding planes, causing horizontal openings" is somewhat unusual and needs additional explanation. Shales are generally impervious and it is difficult to understand how the shales could wash out unless they were badly weathered or exposed in a cavity.

The photograph, Fig. 12(*a*), shows a considerable amount of cavitation following the bedding planes, but in Fig. 13 only a small amount of cavitation appears along the bedding of the limestone. This seems to be unusual and worthy of additional explanation. At Kentucky Dam nearly horizontal bedding plane seams, of from 0.1 ft to 0.5 ft thick, have been recognized for 4,000 ft down the slight dip.

---

[9] "Foundation Exploration at Kentucky Dam Site," by A. V. Lynn and R. F. Rhoades, *Engineering News-Record*, Vol. 125, 1940, pp. 70–73.

In Fig. 13 both cavernous areas indicate a dip to the right approximately parallel to the reverse faults shown. Both cavernous zones seem to have developed in this pattern as a result of more general minor faulting and fracturing than is shown in Fig. 13. A probable minor fault could be assumed in Fig. 13 from Station 22+10, at the top of rock, to Station 19+85, at El. 485, where it becomes tight or dies out into bedding planes. Cavities do not need to exist everywhere along a fault, as the solid areas of rocks between the cavities represent pillars and there may be cavities only a few feet away behind these pillars. Once water has gained access to the limestone and a cavity has started to develop, solution of the limestone should take place in some part of the cavity away from the original fracture faster than along the opening.

If the cavernous areas are not the result of faulting and fracturing, why has not the entire river bed been affected uniformly since the limestone is essentially the same? Solution normally could not work its way below beds of impervious flat-lying shales unless they were broken. Small faults of only a few inches in limestones may afford just as good an opening to start solution as would a large fault. As shown in Fig. 13, curved fault planes are apt to produce additional small faults and fractures, which would aid solution. Indirectly, defect 3 (faulting) listed by Mr. Schmidt appears to have been the cause of both large cavernous areas which comprise at least 90% of the problem.

Geologic cross sections, such as those in Fig. 13, form an invaluable record, and, if a cross section had been prepared before construction of the dam, the seriousness of the problem would perhaps have been apparent. The problems of limestone foundations are not so difficult to treat when they are fully understood. Several errors seem to have been made at Hales Bar before the large leakage was finally cut off under Mr. Schmidt's direction. The first error was in misunderstanding the foundation problems or in not acknowledging their seriousness. The second error was in not having thoroughly grouted the rock for a considerable depth below the cofferdams before attempting to unwater.

Asphalt seems to have been used successfully with neat-cement grout, but the suitability of asphalt as a permanent material seems questionable. Mr. Schmidt noted that cavities frequently occurred above or around the former asphalt filling. He concluded that sand and clay had since been washed out to leave open cavities around the asphalt. Although this may be true in part, there are two other logical possibilities: (1) Gradual deformation and flow of the asphalt under the reservoir pressure, or slumping under its own weight if the cavities are not completely filled for some distance up and downstream, and (2) solution of the limestone since the asphalt was injected.

A perfect sphere of asphalt or pitch will flatten noticeably in one day under its own weight. In the course of several days the spheroidal shape of the asphalt is no longer noticeable. Columbus is supposed to have patched the leaks in his boats from the large asphalt lakes on the southwest corner of Trinidad; and vast quantities of the asphalt have been removed since Columbus visited the island, but the level of the asphalt remains approximately the same.

Asphalt is a semi-solid and its satisfactory behavior in cavities over a long period is doubtful. It is granted that a complete cutoff may be obtained in a large cavity without filling the cavity laterally for any great distance from the cutoff line. However, if the unfilled cavity has a slight downstream slope, there seems to be no reason why the asphalt seal will not be broken by slumping or slow flowing as a result of its own weight or the reservoir pressure.

If the asphalt is backed up with neat-cement grout as was done at Hales Bar Dam, this could be prevented. For the foregoing reason, up to 1940 the gradual increase in the leakage following asphalt grouting may have been due in part to a slow deformation of the asphalt.

During the construction of Watts Bar cofferdam, a large navigation dike made of limestone boulders was removed from the river channel. The dike had been constructed in 1912 by the Corps of Engineers, U. S. Army, and was removed in 1940, 28 years later. Most of the limestone boulders had been continuously under water and freely washed by the waters of the Tennessee River. After 28 years of exposure to solution the layers of limestone had receded by solution from one half to three fourths of an inch, and impure and cherty layers protruded the same distance. This example gives a very good idea of the normal rate of solution of a limestone in a free-flowing channel. This particular limestone was more dense and much tougher than the type occurring at Hales Bar Dam. Exposed to such rapid flow currents as existed under Hales Bar Dam, each wall of the solution channels might recede as fast as 1 in. in 25 years, or a narrow fissure only 1 in. wide might increase to 3 in. in width in this time. This factor may have contributed a noticeable amount to solution in the areas of broken rock and along the joints. For this reason a perfect cutoff is necessary in a limestone foundation.

The difficulties experienced with this and other dams constructed on limestone may cause many engineers to be dubious of a dam site on limestone. Regardless of this bad publicity, limestone foundations can be among the best if proper care is used in the selection of the site. Limestones have many good features not found in other rocks. They are usually soft and easy to drill, blast, and crush. Most limestones which have been subjected to great stresses have yielded by gliding within the calcite crystals; and fractures, shear planes, and joints are healed with cementation of calcite so that less difficulty is experienced than with many other rocks.

J. K. Black,[10] M. Am. Soc. C. E.—Complete and interesting descriptions of the cutoff programs at Kentucky and Hales Bar dams and records of procedures and results are contained in the papers of this Symposium. Both the problems and their solutions are exceptional even in a limestone formation where unusual conditions are expected. It is fortunate that the two papers were grouped as they were because the conditions which were corrected by Mr. Schmidt at Hales Bar Dam are a good illustration of what could have happened at Kentucky Dam if a cutoff by grouting alone had been considered acceptable.

---

[10] Project Mgr., TVA, Fort Loudoun Dam, Lenoir City, Tenn.

Both papers illustrate the erratic changes that can occur in limestone formations, and emphasize the necessity for a great amount of exploratory drilling to secure complete information. They also demonstrate the need for, and the aid furnished by, the geologist in interpreting data, preparing drawings, and otherwise collaborating with the engineer on conditions and possible treatment of various formations.

A positive cutoff, in a badly weathered formation, at great depths below the water table, where rapid movement of large volumes of water occurs, is difficult to construct and requires the utmost study, skill, and perseverance. In addition to the difficulties encountered in handling the water, the engineer is confronted with the decision as to how far to go, especially in depth, in treating badly weathered formations under such extremely bad conditions. That decision is often very difficult to make.

At both Kentucky Dam and Hales Bar Dam, conditions were investigated thoroughly and completely and the objectionable features were treated and corrected in the same thorough and complete manner. There appears to be no doubt that the treatment was effective at both places. The methods adopted, the procedures followed, and the equipment selected evidence the thought and consideration that assured efficient execution and successful completion. The programs at both projects are to be commended.

L. C. Glenn,[11] Esq.—The emphasis in each of the papers in this Symposium is twofold: (1) Geological conditions, which, in general, were formerly considered as unusual, are described; and (2) the ingenious methods devised to cope with the problems are detailed. The extensive explorations, by the TVA, of dam sites in limestones have thoroughly discredited the old idea that circulation and consequent solution quickly cease below ground-water level. Solution under favorable circumstances may extend several hundred feet below ground-water level. Fortunately, solution does have a tendency to decrease in depth, so that solution channels may be expected to close up gradually if followed down with the necessary persistence. At Kentucky Dam the ordinary solutional activity below ground water has undoubtedly been considerably augmented by a depression of the water table in this region of some 200 ft or more in early Pleistocene time. The Ohio River gorge, only about 25 miles away, has been cut down to near sea level and has since filled with sand and gravel. In one of the very deep 48-in. holes at Kentucky Dam, pieces of chert were found near the bottom encrusted with limonite. The surfaces of the pieces of chert were covered with fine limonitic stalactites about an inch in length. These could have been formed only when the chert was above ground-water level. Since then, there has been a regional subsidence of some 200 to 300 ft at least. During the higher stand of the land there was a deeper-reaching solution.

Rocks at Kentucky Dam have been subjected to two periods of stress, each of which produced jointing or fracturing. The earlier fractures were later healed by deposition of coarsely crystalline calcite. The later fractures were not healed subsequently but have become the paths for the solution that has given trouble. Incidentally, the same two periods of fracturing also characterize the rocks of the Ozarks, the earlier fractures being healed by calcite, dolomite, and occasionally sphalerite, as is shown by core drilling for dams in that region. The regional structural history has been similar.

---

[11] Cons. Geologist, Nashville, Tenn. (formerly Head, Dept. of Geology, Vanderbilt Univ., Nashville, Tenn.).

Fig. 9 shows the marked tendency of grout to follow the contact between limestone and residual clay and how difficult it is to obtain any worth-while penetration of the grout into the clay. Mining the clay out, as was done at Kentucky Dam, is really the only effective method of treatment.

It is hoped that Mr. Schmidt has written finis to the long-standing leakage troubles at Hales Bar. Water flowing in strong currents through honeycombed limestone beneath the dam was constantly enlarging its passageways. Also, the water velocity added much to the difficulty of successfully placing concrete to stop the flow and to consolidate the foundation. One is sometimes inclined to wonder how the dam has stood up at all, especially in recent years. Mr. Schmidt describes well the intricate details of the plan adopted for closure and the modifications necessary to meet conditions that developed during the work. He has shown himself highly ingenious and resourceful in handling a very difficult problem and in solving it in an original and effective way. Although some leakage may develop in the future, the troubles at Hales Bar seem essentially to belong to the past.

E. H. Burroughs,[12] M. Am. Soc. C. E.—The reader will be impressed by the bold scope and thorough execution of the deep cutoff construction on the Kentucky Dam, described in the interesting paper by Mr. Hays. The method used to provide an effective upstream water seal probably has salvaged an important dam site where the foundation materials would otherwise have precluded successful development of the relatively high-head structure to be supported.

The engineering and construction features of this structure should be emphasized, rather than the geology. A subterranean cutoff wall built by methods substantially the same as those used by the author will make valuable but defective reservoir sites suitable for development almost regardless of the geological conditions. Few changes are required to adapt this method to almost any type of difficult foundation, as practical experience has shown. The applicability of this method is not limited to cutoff walls built deeply into river beds where flowing ground water may be encountered, since the method is safe, rapid, and economical for almost any deep trench work, and the size of the working chamber can be reduced to an area in which the water inflow can be handled and sloughing controlled. The excavation principle is somewhat similar to the methods of middle-western contractors in the 1910's when they invaded the deep foundation field in New York, N. Y., with their so-called "Chicago method." With open caissons and heavy pumping equipment, plank-sheeted circular pits with steel-ring walers could be driven to great depths, for column footings, faster and cheaper in all soils than by the conventional methods of the pneumatic-caisson contractors.

---

[12] Pres., Ambursen Eng. Corp., and Vice-Pres., Ambursen Dam Co., Inc., New York, N. Y.

As a last resort, where a water-logged material becomes too costly, slow, or dangerous to excavate, compressed air can be applied to the shaft until the difficult area has been traversed; but in no instance has it been needed.

In the case of the Hales Bar Dam, a cellular cutoff, built from the top downward, would have avoided heavy water losses and the eventual costly repair work described in Mr. Schmidt's paper. The writer can give similar instances, such as hydroelectric plants built under his direction on the porous limestone of the Shenandoah River in Virginia (one directly above the Luray Caverns) where solution channels swallowed enormous quantities of wasted grout.

It is difficult to conceive a cutoff wall or core-wall problem that will not be solved adequately by this type of construction. One of its greatest advantages, not mentioned by Mr. Hays, is that the men work without fear or restraint in the free air, as compared to conditions under the costly, laborious, and slow pneumatic-caisson method. Relatively little heavy equipment is needed. Safety for workmen against sudden inrushes of water or mud is assured by shafts of ample dimensions, where the undercut face of the excavation is only a few feet at most beyond shaft limits, as shown in Fig. 30. This strengthens the writer's view that the geological deficiencies of the foundation at Kentucky Dam are less important to the engineering profession than the designing and construction methods which repaired those deficiencies.

Once the initial drilling has determined the rock elevations at a dam site and has demonstrated suitability for the methods outlined, little is gained by further expenditure for an elaborate pattern of drilling, as any changes in the conditions are adequately met as the work progresses below ground.

Since 1928 the writer has applied the cellular cutoff wall design to four different projects, two actually having been built by that method. Each foundation material was entirely different from the others, and yet the advantages of the method applied with equal force to all four projects.

Designs were prepared under the writer's direction in 1930 for a high dam on the Kootenay River in British Columbia, Canada (later abandoned for financial reasons). The river bed was ledge rock but both sides consisted of rapidly rising, high banks of porous sand, gravel, and boulders, upon which large embankments were to be built as wings or abutments for the spillway. Core walls approximately 100 ft deep were required, but the cost of a sheet steel-pile core wall was prohibitive and driving it impossible. Comparable data for the cellular wedge type of core wall, built from the ground surface downward, showed a cost 46% of that of a concrete core wall of conventional type, constructed in a sheeted and shored open trench. This design reduced the top width of the excavation considerably and left adjoining material practically undisturbed. Any underground slumping of materials would be replaced by grouting as the core-wall construction progressed downward. Freezing was contemplated where necessary for controlling any water-bearing sand in the lower depths of the core wall, since the small confined area under each shaft was admirably suited to this method. Modern chemical soil consolidation would be equally helpful. The difficulty and danger of maintaining a deep sheeted and shored trench would have justified the method described even at an equal cost.

The writer believes the first example of the design and construction of a concrete cutoff wall built from the ground surface downward, making use of working shafts through the completed sections, was the Rodriguez Dam in Lower California, Mexico,[13] begun in 1928. This wall was constructed (without reaching bedrock at the bottom) to a final depth of about 300 ft below the working level in the stream bed to provide the proper creep ratio for the head of 240 ft above river bed created by a full pond. The total distance or head from pond level to bottom of cutoff wall was 475 ft. This work was done at low cost by a small force without accident or serious injury to any workman,

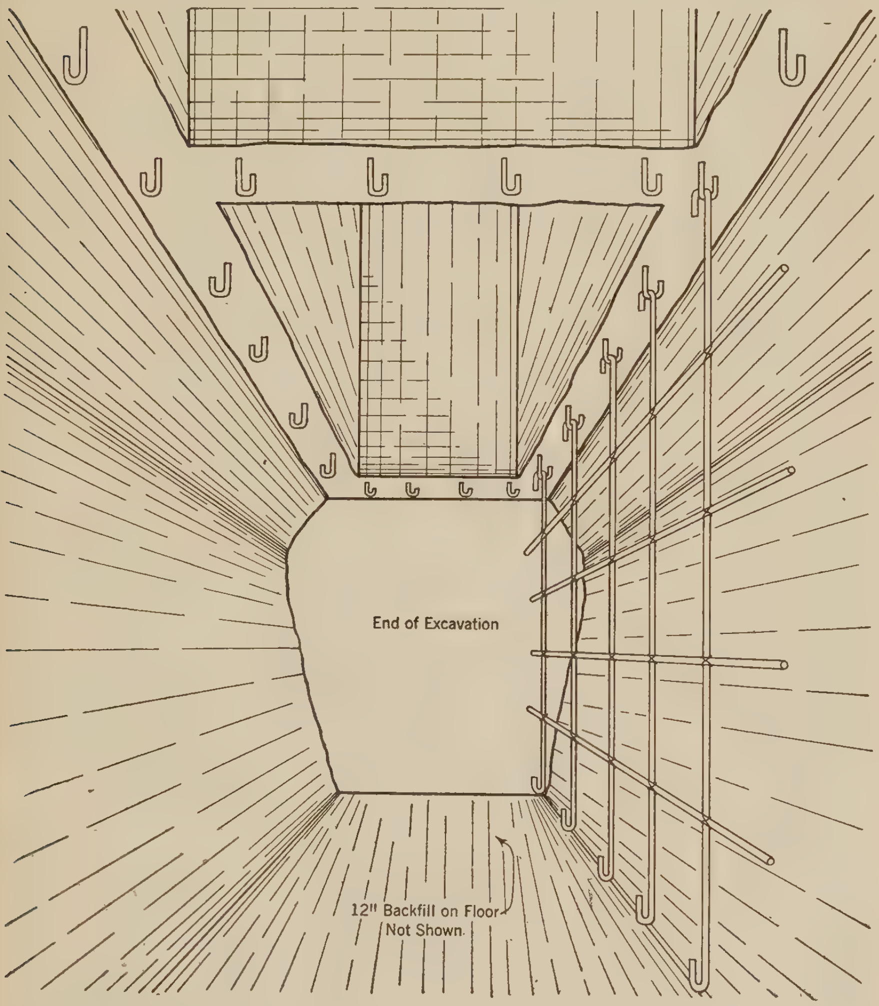

FIG. 30.—TYPICAL EXCAVATION FOR CELLULAR CUTOFF WALL BLOCK

against the full head of the Tijuana River. The structure was built through soft clay gouge, fugitive blocks of granite and rhyolite, areas of crushed foundation rock, and lenses or continuous beds of sand of varying texture, including quicksand.

---

[13] "Foundation Treatment at Rodriguez Dam," by Charles P. Williams, *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 295.

Mr. Hays is fortunate indeed to have had the opportunity of sketching the actual geology of the Kentucky Dam cutoff wall as the work progressed. His data afford an admirable check on the accuracy of the conclusions drawn from the wide network of borings. At the time the Rodriguez Dam site was selected for development in 1927, the Mexican Government was engaged in a very extensive irrigation program elsewhere in the republic and little money was available for a boring program. However, even had this government been able to make an advance subsurface survey as extensive as that made for the Kentucky Dam cutoff (which the writer understands cost about $500,000), the problem would not have been simplified. The site was the only one available, and the Mexican Government was committed to the development of this project for international and economic reasons. The writer cannot see how even the most elaborate pattern of borings would have affected, measurably, the ultimate design and construction of the cutoff wall and other foundation structures.

Only nine borings and fifty-two shallow test pits (which represented a cost of about $7,500) had been made by the National Irrigation Commission when the writer's company took over the design and construction of this project. Of the borings, five indicated satisfactory rock at depths not exceeding 50 ft, but no cores could be obtained from four, two of which indicated badly disintegrated materials. A main fault about 30 ft wide and a secondary fault about 10 ft wide existed, filled principally with clay gouge, but also with many pockets or layers of water-bearing sand. The area between the two faults was filled with crushed foundation rocks of varying sizes, bedded in clay and sand. The hanging wall of the main fault had been shattered for a considerable distance beyond the edge of the fault, necessitating special treatment, and similar conditions existed on the opposite side of the filled-in river channel. The main fault was assumed by the Mexican Government's consulting geologist, Frederic L. Ransome, to extend downward for a thousand or more feet.

Excavation for the Rodriguez Dam cutoff wall was begun in an open trench, curved in plan to secure the added strength of a subterranean arch without interfering with the connection at the top to the straight upstream deck of the 240-ft Ambursen type dam being built above it. Considerable sloughing occurred in the wet, broken formation resulting in the change to a wedge shape about 25 ft wide at the top and 15 ft wide at the bottom. Vertical shafts, mostly 5 ft wide and 10 ft long, were formed in this excavation and the entire trench plug was then concreted. The wedge shape was expected to aid in supporting the block against settlement, which would halt itself by consolidating the material on each side, but no measurable settlement ever occurred.

When the shaft excavation was well under way, construction began on the main dam itself, so that work on the dam was not delayed pending completion of the cutoff.

The vertical cutoff arch was projected into the fractured hanging wall by a system of grouting from the surface and from adits (as shown in Fig. 31), after other adits, forming a continuous vertical wall, had been cut into the hanging wall from the adjoining shaft to the distance considered economical by that method, as compared to the cost by drilling and grouting. FIG. 31.—RODRIGUEZ DAM: PLAN, AXIAL SECTIONS, AND VERTICAL SECTIONS, SHOWING PROCEDURE

Fig. 31 shows the novel method used for constructing these adits. The wedge-shaped adit at the highest elevation was first excavated and concreted. Then the adit next below was similarly excavated, using the bottom of the concrete next above as a roof, which made for very rapid and safe excavation. Much grout was taken by the drill holes in the hanging wall, which supports the right wing abutment of the main dam.

The writer doubts whether, on a project where the utmost economy might have to prevail, the cost of the author's method of redrilling 36-in. and 48-in. holes through the finished concrete blocks—to enable the cutoff wall to be deepened progressively below and concreted by the use of these very restricted openings as working shafts—would be justified. It has been the writer's experience that, by forming large rectangular shafts, plenty of room was obtained for the rapid evacuation of excavated material and for pipes, conduits, telephone cables, etc. More important still, where water-bearing sand and porous crushed rock under great pressure invited slumps and blowouts, the generous cross-sectional area of the working shaft (about 5 ft by 10 ft) enabled the men to work with greater confidence, and hence more effectively, than if the exit from the working chamber had been a circular shaft of small diameter. Wide steel rungs were set as a continuous ladder in every shaft from the top to the bottom —an emergency exit for the workmen.

The lengths of 6 ft along the axis, used for the Kentucky Dam cutoff wall blocks where the drill hole was 36 in., and 7 ft where it was 48 in. in diameter, called for mining out about 18 in. under the sides of each block—practically the average undercut for the Rodriguez Dam. However, the ultimate cost of the job is controlled more by the actual number of shafts and blocks than by their dimensions; hence, the writer believes that a given length of cutoff wall using long blocks with big shafts, similar to the Rodriguez cutoff, would cost much less than a length of wall with double the number of blocks half as long with their smaller shafts.

Attempts were always made to impart a wedge shape to the excavation for each block before concreting. The writer's preference for this procedure comes from the conviction that wedge-shaped pours are subject to less danger of settlement and that they form a tighter and stronger structure. They also create a longer and rougher path for percolation; but this was not taken into consideration in computing the creep ratio. These individual blocks are actually given support in four ways: (*a*) From a vertical reinforcing system; (*b*) by friction on the sides of the excavation; (*c*) by the horizontal steel reinforcing bonds, and (*d*) by bridging or beam action from the contacts with the adjoining blocks at the same level. The wedge-shaped configuration gives a fifth support. Faster progress was made in excavation by leaving a layer of 10 in. or 12 in. of loose material on the floor of the excavation and by pouring the concrete block on it, since excavation for the next lower block was made easier by starting from this soft loose layer.

The writer's experience was identical with that of Mr. Hays—by driving alternate shafts or blocks first and maintaining these ahead of the intermediate blocks, the width (thickness) of the latter could be considerably reduced and lifts could be extended deeper than for the adjoining blocks and with less pumping. Only two faces had to be maintained, as against four in the shafts which were pushed ahead first.

Straight bars were first used as the vertical reinforcing, and, as at the Kentucky Dam, were driven or drilled into the bottom of the excavation before the concrete was poured. Later, hooked bars were found more convenient. As shown in Fig. 30, the hooks made for better working conditions than a series of long bars projecting down into the area being excavated. The horizontal bars were driven from the open excavation laterally into the intermediate unexcavated area, as was the case at the Kentucky Dam.

At the beginning there was no certainty that this novel cutoff wall method could be followed to the bottom of all shafts, but, as ample compressor capacity was available, the job was always in readiness to switch to the pneumatic process, which never had to be adopted. Even areas of semifluid quicksand were usually controlled without undue delay by pushing adjoining shafts down past them. Drainage through the walls of these intermediate blocks soon eliminated the difficulties in the bad pockets.

It is not clear to the writer whether the 36-in. and 48-in. drill holes at the Kentucky Dam through which the excavation and concreting were conducted were eventually filled with concrete or spoil, or whether they were left open and merely capped at the top. Likewise, the details of the connection of the steel sheet-pile core wall of the dam to the cellular concrete core wall would be of considerable interest. Upon completion of the Rodriguez cutoff wall, all but two of the shafts were backfilled with concrete. However, it was considered that it might be desirable at some future time to extend the cutoff wall deeper, should seepage beneath the cutoff occur in dangerous quantities. Therefore, in shafts 8 and 9 a cylindrical form 48 in. in diameter was installed, the remainder of the shaft being filled with concrete. These two circular shafts were then plugged with concrete at the bottom, backfilled with sand and gravel, and topped with a specially designed watertight cover. In the future if it is considered advisable to deepen this cutoff, steel cylinders will be attached to the two circular shafts and excavation and concreting operations will be conducted through them from a point above the lake level.

It would be interesting to know how much grout the vertical joints between the Kentucky Dam cutoff blocks took and whether any attempt was made to grout the horizontal joints between the blocks. At Rodriguez Dam grout pipes were built into all contacts between concrete blocks and into the outside foundation material adjoining the cutoff wall. Practically no grout could be forced into any of the joints, indicating no subsidence of the blocks, probably due to their wedge-shaped formation and reinforcement. The pipes to the exterior of the blocks were capped on the inside when installed but were left open to the outside ground. When excavation began below, the caps were replaced by canvas hose, which led the outside drainage freely into the sump. This drained off much outside water that otherwise would have caused difficulties. To avoid building up pressure, the pipes were left open until several sections of the concrete had been placed below them, when grout was forced out into the foundation material on both sides of the wall, usually under a pressure of 100 lb per sq in. Every precaution was taken to reduce the head that could build up against any part of the excavation. Many slumps inevitably occurred behind the blocks as excavation progressed, but always were stopped by quick plank shoring. For many blocks, some sheeting and bracing were also necessary to restrict the amount of excavation. The sheeting and bracing were of the most rudimentary nature possible, usually merely a few short planks braced as might be most convenient. Most sheeting was left in place and, it is assumed, became subsequently embedded in the grout.

Contrary to Mr. Hays' experience on Kentucky Dam, where the water leakage increased as the work deepened, the Rodriguez Dam inflow at 200 ft to 300 ft below river level was no greater than at 50 ft, and as far as could be determined had no relation to the depth of the shaft. Rather, it depended on the texture of the material through which the wall was passing. The drainage program did much to ease the water control, and, by keeping as many drains open as possible above the working chamber, little or no trouble was experienced in maintaining satisfactory pumping from the sumps. Relay pumping stations were installed whenever needed, the water usually being pumped into a small tank with a high-head electric pump over it. The tank and pump were both placed in one side of the shaft where they would not disturb the hoisting of muck. Pipe lines, 4 in. in diameter, were originally installed in each shaft through which the water was pumped to the surface, but, as confidence was gained in the method being pursued, adjoining shafts were interconnected, which expedited the work materially and considerably reduced the pumping installations.

The over-all cost per cubic yard of work in the shafts was less than that for the adits cut into the hanging wall of the fault, and, as the hanging wall was departing from shaft 10 when the cutoff wall was about halfway down, shaft 11 was opened under one of the adits, which shortened all the remaining adits. Shaft 11 was interconnected with shaft 10 and was worked entirely from the latter shaft.

To maintain a continuous record under full reservoir conditions of the pressures at the bottom of the cutoff wall and under the dam itself, instruments including pressure gages and pipes for soundings were installed in the dam foundations and in the sides and bottom of the shafts before concreting. Frequent observations have indicated that such leakage as can be detected in the river bed below the dam does not come from beneath the cutoff wall, but through seams in the earthquake-shattered banks of the river which carry the side wings of the dam, below the limits of the grouting done in the bottom of the conventional relatively shallow cutoff wall where the dam rests on rock. No lateral or longitudinal flow can be detected along the base of the dam, and there is no evidence of any water passing under the cutoff wall at its bottom. At one point along the bottom of the cutoff wall the hydrostatic pressure is greater immediately downstream from the wall than immediately upstream.

The National Irrigation Commission felt that, by applying one of the conventional creep-ratio theories to the material in the fault, it would be safe to stop the cutoff wall at some depth between 200 ft and 250 ft. The decision to extend it to 300 ft was influenced by the low cost and relative ease of the cellular cutoff wall method.

The cellular cutoff wall method (including the features of building the cutoff wall from the top surface downward through shafts instead of from the bottom up) and also the adit construction method used in the firmer rock areas (of building a top adit first in wedge shape to form a safe and convenient working chamber below it for each succeeding wedge-shaped adit, thus constructing downward a continuous concrete curtain or cutoff) were developed by Spencer W. Stewart, M. Am. Soc. C. E. To the best of the writer's knowledge the Rodriguez Dam was the first project on which these principles were ever used.

A third project using designs and construction methods similar to those described in Mr. Hays' paper (except as to the drilled shafts) was the Bristol Dam on the Pemigewasset River in New Hampshire. This work was incidental to adding 30 ft to the height of the dam in 1931, to increase the head on the power plant from 50 ft to 80 ft—for which program the Ambursen type dam had been adopted ten years earlier. Deep core walls were constructed adjacent to the abutments on each side of the river, the maximum depth being 113 ft, without lowering the pond level or shutting down the power plant. By the method adopted the core walls were constructed with no difficulties, although they were extended 77 ft below the pond level.

Fig. 32.—Bristol Dam: Plan, Axial Sections, and Vertical Sections, Showing Procedure

In constructing the Bristol core wall, an open trench 14 ft wide and 16 ft deep was first excavated (see Fig. 32). The sides were roughly sloped, so that the cellular masonry section would be partly supported by wedge action when material was excavated below it.

Because of experience gained on the Rodriguez Dam and in view of more favorable materials at the Bristol site, the shorter core wall in the right bank was built as a single block for its entire length, but contained three vertical shafts. The longer core wall behind the left abutment was built in three sections, two with three working shafts apiece and the other containing one. When the cellular concrete core wall was completed, a concrete bottom slab was poured in all shafts, and all were backfilled with spoil from the excavation.

Practically no grout was taken between the vertical and horizontal concrete surfaces of the blocks and very little was taken in the areas outside the walls.

Although no attempt was made to speed up the construction or to set a record of any kind, both core walls were built in 95 days, a demonstration of the advantages of this construction method.

Steel sheet piling could not have been driven to the necessary depth in the Bristol material. Estimates for conventional open-trench methods, including sheeting and pumping, indicated a total over-all cost for the excavation of $10 per cu yd, whereas the final cost on a comparable basis for the method followed was $4.15 per cu yd. One reason for the low cost was the freedom with which the men worked as compared with the caution necessary when working under adverse conditions in a deep heavily braced and shored trench.

The core wall for the Quabbin Dike Dam in Massachusetts, for which twenty-five bids were received based on the pneumatic-caisson method in 1933, affords persuasive comparative data as between the cellular core-wall free-air method (built from the ground surface downward) and the pneumatic-caisson method. Earth excavation through the caissons was estimated at 33,000 cu yd, and the depth averaged about 80 ft. The three lowest bids averaged $7.50 per cu yd; and all twenty-five bids, $12.67. Moreover, the heavy pumping and grouting costs were paid for under other items, and vastly more grouting was involved than with the cellular type of core wall. Rock excavation cost must always be higher because of the necessary use of expensive sand hogs instead of common labor, and concrete costs would also be somewhat higher under the pneumatic method.

The useful field for the method of cellular construction from the surface downward as described in Mr. Hays' paper is not limited to foundation materials of a soft or porous nature such as those at the Kentucky, Kootenay, Rodriguez, or Bristol dams. This method is likewise entirely suitable and surprisingly economical where shattered and seamy rock is to be penetrated, such as is the case at many California and other western sites. Naturally, it cannot be applied where the rock is well bedded or where conventional grouting will tighten the fractured material and restore sound bedding.

In 1930 when construction of the gravity section masonry dam for San Gabriel Site No. 3 was abandoned by the Los Angeles County Flood Control District because excavation showed the rock to be incapable of carrying a dam of that type safely, preliminary designs and estimates were prepared by the writer for an Ambursen type spillway dam, which, because of its relatively low base pressures, was entirely suited to the foundations. However, the problem of supporting and tightening the high rock banks on each side of the river was difficult to solve. The high rock banks were bad in their natural condition, and heavy blasting had further impaired their stability. An abutment was designed for each side of the spillway and three parallel cellular core walls were laid out for each, extending at right angles to the abutment. The upstream and downstream walls were to be sunk only enough in depth and in length to confine and support the shattered and seamy rock as found necessary, and the center core wall on each bank was to be constructed 200 ft down to cut off percolation through the banks. The cost by the method under discussion, starting at the top and working downward to the desired elevations, was found to be very much less than for core walls built in an open trench, which method probably could not have been used at all. As the subsequent choice of the district was for a different site, the cellular design was not projected to the construction stage, but its speed and low cost in poor rock formation were thoroughly established.

Mr. Hays' paper is a very instructive recital of the methods followed in solving a difficult engineering problem. It serves to emphasize that the cellular type of construction for cutoff walls and core walls has proved a practicable and efficient method of solving the problems incidental to providing an adequate water seal for poor foundations. The writer's experience with the aforementioned four projects shows also that this method can be used at low cost. Not only because of this economy, but because of the safety of the method itself, the cellular cutoff wall type of construction, from the ground surface downward, makes available for rapid and economical development many dam sites previously rejected as unsafe or uneconomical because of foundation difficulties. Mr. Hays has also added much knowledge to the scant information available to the engineering profession on the subject of compacting yielding material by grouting. The paper is a fine contribution to a relatively new and little understood field.

James B. Hays,[14] M. Am. Soc. C. E.—As stated by Messrs. Moneymaker and Fox, the preliminary exploration work on Kentucky Dam was not intended to disclose all the details of the underground conditions, but to select the best site from among those available. It was the practice of the Tennessee Valley Authority (TVA) to work out the details after the Construction Department took over from the Planning Division.

Mr. Fox gives an excellent description of the formations and explains how the solution occurred. The deep solution channel or fault shown on the left in Fig. 28 was grouted, but there is no certainty as to how thoroughly this was done. The leakage path through, or along, this channel was very long; hence, it was not considered a serious menace.

When the problem of making a cutoff in the channel at Kentucky Dam arose, the engineers were well aware of the conditions at Hales Bar Dam and realized only too well (as Mr. Black states) that "* * * the conditions * * * at Hales Bar Dam are a good illustration of what could have happened at Kentucky Dam if a cutoff by grouting alone had been considered acceptable."

Mr. Glenn has added more information on the general geology of Kentucky Dam and the surrounding territory. Mr. Burroughs' discussion is a welcome addition since it presents other methods for solving similar problems. It was part of the writer's purpose in presenting the paper to show the results obtained by grouting in the type of materials generally found in badly weathered zones of rock, particularly in limestone. In reply to Mr. Burroughs' question, the 36-in. and 48-in. core holes were all finally filled with concrete.

---

[14] New York, N. Y.; formerly Project Mgr., South Holston and Watauga Projects, TVA, Bristol, Tenn.

Fig. 2 shows, in plan, the location of the steel sheet-pile cutoff wall. From about Station 10+00 to the powerhouse wall, it was driven through deep overburden to rock with grout pumped in along the base of the piles to further reduce the leakage. However, across the area between the lock (block R-17) and Station 10+00 (where all overburden had been removed), a concrete trench was built on the rock surface or concrete slab. The trench was filled with an asphaltic material. After the rolled earth fill had been placed to a depth of about 10 ft, steel sheet piling was driven through it into the asphaltic compound.

Mr. Burroughs' point about redrilling the shaft through each block of concrete is well taken and would be reconsidered if the job were to be undertaken again. In concrete that has not set too hard, shot drills penetrate rapidly. If the concrete is too green, the small aggregate is likely to ravel and interfere with the drilling. Previous experience at Chickamauga Dam (TVA) near Chattanooga, Tenn., had indicated the necessity of pregrouting an area similar to the one described herein, before attempting to drill large holes or to sink shafts in which men were expected to work.

When the writer was construction engineer at Chickamauga Dam, a thorough study of the construction methods followed at Hales Bar Dam was made, although at that time TVA did not own Hales Bar Dam. The general conditions were quite well known, and every effort was made to avoid a repetition of the earlier mistakes in building the much larger Chickamauga Dam. The writer has naturally followed Mr. Schmidt's work in repairing the foundation of Hales Bar Dam and offers his congratulations on the novel yet proper solution. The problem at Hales Bar Dam was one of stopping large flows of water with considerable velocity, whereas the problem at Kentucky Dam was one of stopping small flows and negligible velocities.

The writer and his staff at Kentucky Dam benefited greatly by the excellent practical advice of Roger F. Rhoades and Portland P. Fox, Assoc. M. Am. Soc. C. E., and their assistants who constituted the Geological Section on this project.

L. A. SCHMIDT, JR.,[15] M. AM. SOC. C. E.—The solution of a very difficult cutoff problem in the foundation of a dam under construction has been described by Mr. Hays. This solution reveals the ingenuity used to acquire the desired result, and sets this work apart as unique, effective, and unquestionably economical. Compared with the only other practicable method of attack—namely, open excavation and concrete backfill—the treatment accorded the foundation area under Kentucky Dam described by Mr. Hays is so logical that it is difficult to understand how any one could possibly criticize it. The successful use of large-diameter core drills for excavating purposes on this project appears to justify this type of equipment. In any case, the work done at

---

[15] Engr., Chattanooga, Tenn.; formerly, Acting Constr. Engr., TVA, Hales Bar Dam, Chattanooga Tenn.

Kentucky Dam has prevented the development of a foundation problem similar to the one that existed at Hales Bar Dam, as aptly stated by Mr. Black.

Certainly Mr. Hays' application of core drills to excavation would have been the logical and surest method of securing the desired results at Hales Bar Dam had that project also been in the construction stage, or had it been possible or desirable to drain the reservoir. The Hales Bar Dam has been in operation since 1913. However, if these procedures had been used on the project they would have been inimical to the best interests of power production during the critical period before Pearl Harbor, and some other method capable of being executed without draining the reservoir was required at Hales Bar Dam. After considerable study the method described in the paper was evolved.

The writer is particularly grateful to Mr. Fox for his presentation of the geological characteristics inherent in the Hales Bar foundation. The part played by faulting in the development of the zones of weakness against leakage in the foundation was probably insufficiently emphasized. Unquestionably, the conditions that either permitted clays and shales from horizontal strata to be washed out by exposure to the differential water pressure, or permitted flows caused by solution of the limestone, were given their initial impetus by faulting as shown in Fig. 13.

The writer subscribes to Mr. Fox's contentions about asphalt, with some reservations. To some extent, Mr. Fox overlooks the effect of temperature on asphalt, and temperature is the relative medium by which the characteristics of asphalt may be judged. In a cavity from 60 to 160 ft below water surface, temperatures of about 56° F are prevalent in the Tennessee River. Thus, when asphalt is placed in the irregular labyrinths (which the channels form) at this low temperature, under sufficient pressure to compensate for shrinkage, it should be capable of long life. Supporting evidence was obtained in the form of asphalt cores removed in drilling, which indicated that asphalt placed twenty years previously had remained in place.

The 1923 placement of asphalt at Hales Bar Dam could have been the final "coup de grâce" to leakage. However, rather too much was expected of asphalt fill at that time since its possibilities had not been exploited to a maximum degree. In addition, an insufficient amount was placed in the widely spaced holes. Had closer spacing been used and had adequate cement grout under pressure been placed for consolidation, it is conceivable that the gains would have been stable.

That asphalt is not as desirable as cement is conceded, but, where cement cannot be placed, asphalt is far more desirable than nothing. Certainly backing up the asphalt with cement is correct and has no definable upper limit.

Mr. Moneymaker principally discusses the part the geologist can play in foundation problems, and the writer agrees with him that the geologist can contribute much in enabling constructors to avoid foundation errors. However, it should be emphasized that the geologist needs cores and data for analytical purposes, and without them his work cannot be effective. The writer wishes to acknowledge the accuracy of the predictions of geologic characteristics made by J. W. Frink, Jun. Am. Soc. C. E., who was stationed at Hales Bar Dam. The location of holes to supplement treatment was determined in many instances from data supplied by Mr. Frink. This type of service, although passive and secondary to the main objective, is often overlooked and Mr. Moneymaker rightly calls attention to its importance.

Final quantities at Hales Bar Dam were:

Description	Quantity
Drilling, in Linear Feet—	
18-in. diameter	34,221
13-in. diameter	7,448
3-in. diameter	55,264
Asbestos-cement liners, in linear feet	30,986
Concrete, in cubic yards	8,653
Reinforcement, in tons	70
Cement grout, in cubic feet	364,361
Asphalt, in cubic feet	135,017

The writer shares the hope expressed by Mr. Glenn that the work done at Hales Bar Dam this time may be more effective and permanent than was the previous work. The visible results at the completion of the job were gratifying. The placement of the final quantities certainly reduced any future potential leakage, and it is doubtful that leakage could again develop to such an extent as it had by 1940. The problem has been of such long standing, however, and the many attempts at its correction have been frustrated so often that the unequivocal assumption that additional maintenance in the future will be unnecessary seems too optimistic. Given careful, orderly inspection and maintenance if and when required, the problem should eventually become history.

DESIGN CONSTANTS FOR BEAMS WITH NONSYMMETRICAL STRAIGHT HAUNCHES

BY AUGUST L. AHLF,[1] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. ROBERT O. JAMESON, JOHN SHERMAN, DALE H. REA, I. B. HOSIG, AND AUGUST L. AHLF.

SYNOPSIS

Tables are presented in this paper, with outlines of the procedure to be followed in their use, to assist the structural designer in determining the stiffness, carry-over factors, and fixed-end moments for various loadings of beams having straight haunches placed nonsymmetrically with respect to the center of the span. Although this work was performed to determine these factors for nonsymmetrically haunched beams, it is also applicable to beams having straight haunches at only one end and to symmetrical cases as well.

THE METHOD

Hardy Cross,[2] M. Am. Soc. C. E., and others[3] have shown that the column analogy method may be used to obtain the stiffness and carry-over factors and also the fixed-end moments for structural members having either constant or variable cross sections throughout their length.

The properties that must be obtained for the analogous column are the area, the location of the centroidal axis, and the second moment of the area about the centroidal axis. When these have been determined, the stiffness and carry-over factors may be obtained.

To determine the fixed-end moments, it is also necessary to obtain the area under the $\frac{M}{E\,I}$-curve corresponding to the loading and the dimensions of the beam as well as the location of the centroidal axis of the $\frac{M}{E\,I}$-diagram.

When the beam under consideration has haunches at the ends, which haunches are not symmetrical with respect to the center of the span, the

computations required to obtain the properties of the analogous column and its loading diagram may become laborious and time consuming, particularly if accurate results are desired.

The tabular values herein presented have been prepared to facilitate the computations. By their use, the properties of the analogous column and the $\frac{M}{E\,I}$-diagram may be obtained by simple arithmetical combinations.

Notation.—The letter symbols adopted for use in this paper are defined where they first appear, either in the text or by diagrams, and are assembled in an Appendix for convenience of reference.

The Analogous Column

A beam, having straight haunches placed nonsymmetrically with respect to the center of the span, and the corresponding analogous column are shown in Fig. 1. The properties of the analogous column were obtained by integrating the $\frac{1}{E\,I}$-diagram, which was divided into the four parts shown in Fig. 2. The properties of each segment were determined separately and then combined to obtain the desired properties at each end. The total area of the analogous column was found to be

(*b*) ANAGOLOUS COLUMN

Fig. 1.

$$A = \frac{L}{E\,I_o}(C_1 + C_2) \quad \text{.......................(1)}$$

in which I_o is the moment of inertia of the central section of a beam. The dimensionless constants, C_1 and C_2, for this case, are the coefficients pertaining to ends 1 and 2, respectively. These constants (see Table 1(*a*)) are expressed by

$$C = \left(\frac{d+1}{2\,d^2} - 1\right) a + \frac{1}{2} \quad \text{.....................(2)}$$

Eq. 2 is made applicable to either end 1 or 2 by inserting the appropriate subscript on each symbol. This is true also of subsequent equations for C. Table 1(*a*) was prepared to yield values of C for various values of a and d, applying the appropriate subscript.

The total statical moment of the area of the analogous column about the center of the span was found to be

$$Q_I = \frac{L^2}{E\,I_o}(-C_1 + C_2) \quad \text{.....................(3)}$$

in which the factor C (with appropriate subscript) is expressed by:

$$C = \frac{1}{24} + \left[\left(\frac{1}{d-1} \right)^3 \left(\log_e d + \frac{2}{d} - \frac{1}{2\,d^2} - \frac{3}{2} \right) + \left(\frac{d-1}{2\,d^2} - \frac{1}{3} \right) \right] a^3 + \left(\frac{1}{2} - \frac{1}{2\,d} \right) a^2 + \left(\frac{d+1}{8\,d^2} - \frac{1}{4} \right) a \qquad (6)$$

Table 1(*c*) was prepared to yield values of C for various values of a and d in Eq. 6.

The location of the centroidal axis of the total area of the analogous column from the center of the span may be obtained by the relation,

$$e_a = \frac{Q_{\mathrm{I}}}{A} \qquad (7)$$

The eccentric distance e_a will be positive if the centroidal axis is toward end 2 from the center of the span and negative if it is toward end 1. The longer distance from the centroidal axis to the end of a beam (end 1, Fig. 2) is expressed by:

$$L_1 = -\frac{L}{2} - e_a \qquad (8a)$$

Similarly the remaining distance from the centroidal axis to the end of a beam (see end 2, Fig. 2) is

$$L_2 = \frac{L}{2} - e_a \qquad (8b)$$

If values of L_1 are always considered to be negative and values of L_2 are always considered to be positive, the signs in the column formula will follow automatically.

The total second moment Q_a of the area of the analogous column, taken about the centroidal axis, is

$$Q_a = Q_{\mathrm{II}} - e_a\,Q_{\mathrm{I}} \qquad (9)$$

STIFFNESS FACTORS

The "absolute stiffness factor" is defined herein as that bending moment required to rotate the hinged end of a beam through an angle of one radian while the opposite end remains fixed. It may be shown that the absolute stiffness factor for a member having a uniform cross section throughout its length is equal to $\frac{4\,E\,I}{L}$. However, if the member is not prismatic, but has a variable moment of inertia along its length, the coefficient of the absolute stiffness will be something other than 4. This factor will be different for the two ends unless the haunches at the two ends have the same dimensions.

When the modulus of elasticity, E, of the several members of the frame is the same and each of the members is a prismatic one, the quantity $4\,E$ will be constant and, therefore, can be eliminated from the computations. For this reason it has become common practice to regard the stiffness of a member as being equal to I/L. Herein this factor is called the relative stiffness factor. The relative stiffness factor may be obtained by dividing the absolute stiffness factor by $4\,E$.

When using the analogous column, the rotation of the structural member must be represented as a reaction or load and the bending moments are represented as fiber stresses. The stiffness factor at either end may be found by applying a unit load at that end and computing the extreme fiber stress at the corresponding end by the column formula,

$$f = \frac{P}{A} \pm \frac{P\,e\,C}{Q_a} \quad \text{(10)}$$

The load applied in this instance represents the unit load, P, of one radian; the fiber stress, f, represents the absolute stiffness factor; and the distance, C, is the distance from the center of gravity of the analogous column to the end of the beam where the stiffness factor is desired. The absolute stiffness at end 1 is, then:

$$K_1 = \frac{1}{A} + \frac{L^2_1}{Q_a} \quad \text{(11a)}$$

The relative stiffness at end 1 is

$$k_1 = \frac{K_1}{4\,E} \quad \text{(11b)}$$

Similarly, the absolute stiffness at end 2 is

$$K_2 = \frac{1}{A} + \frac{L^2_2}{Q_a} \quad \text{(12a)}$$

and the relative stiffness at end 2 is

$$k_2 = \frac{K_2}{4\,E} \quad \text{(12b)}$$

CARRY-OVER FACTORS

If the end of a member, which is upon unyielding supports at both ends, is rotated while the other end is held fixed, a moment will be induced into the fixed end. The induced moment is defined as the "carry-over moment," and that proportion of the applied moment which is carried over is defined as the "carry-over factor."

The "carry-over moment" induced at the far end of the member may also be computed by the column formula:

$$N = \frac{1}{A} + \frac{L_1 L_2}{Q_a} \quad \text{(13)}$$

The carry-over factor at end 1 may be obtained from:

$$r_1 = \frac{N}{K_1} \quad \text{(14a)}$$

and the carry-over factor at end 2 may be obtained from:

$$r_2 = \frac{N}{K_2} \quad \text{(14b)}$$

FIXED-END MOMENTS

The magnitude and point of application of the load placed on the analogous column to determine the fixed-end moment were obtained by integrating the $\frac{M}{E\,I}$-diagram shown in Fig. 3. The diagram was divided into the four parts shown. The load and statical moment about the center of the span were obtained for each part separately, and then combined to obtain the load and statical moment of the two ends. The load representing the total $\frac{M}{E\,I}$-diagram was found to be

$$P = \frac{W\,L^2}{E\,I_o}(C_1 + C_2) \quad \text{(15)}$$

The equations representing the values of these constants for the various types of loading are given subsequently under the discussion of the particular type of loading. Tables 1(*d*), 1(*f*), and 1(*h*) contain values of C for various values of a and d, and for several of the more common loadings, in the application of Eq. 15.

The following was found to represent the statical moment of the total $\frac{M}{E\,I}$-diagram about the center of the span:

$$Q_f = \frac{W\,L^3}{E\,I_o}(-\,C_1 + C_2) \quad \text{(16)}$$

The equations representing the values of these constants for the various types of loading are given subsequently under the discussion of the particular type of loading.

Values of C in Eq. 16, for various values of a and d for several of the more common types of loading, are given in Tables 1(*e*), 1(*g*), and 1(*i*).

Fig. 3.

of the span may be obtained by

$$e_f = \frac{Q_f}{P} \qquad \text{(17)}$$

The value of e_f will be positive if the centroidal axis is toward end 2 from the center of the span and negative if it is toward end 1.

The fixed-end moment at end 1 may be computed from the column formula:

$$\text{FEM} = \frac{P}{A} + \frac{(e_f - e_a)\,P\,L_1}{Q_a} \qquad \text{(18}a\text{)}$$

Similarly, the fixed-end moment at end 2 may be computed by:

$$\text{FEM} = \frac{P}{A} + \frac{(e_f - e_a)\,P\,L_2}{Q_a} \qquad \text{(18}b\text{)}$$

Fixed-End Moment with Uniform Load

The value of the constant C necessary for determining the area of the $\frac{M}{E\,I}$-diagram for the case of a uniform load (Table 1(d)) was found to be

$$C = \frac{1}{24} + \left[\frac{\frac{d}{2} - 1 + \frac{1}{2\,d}}{2\,(1-d)^2} - \frac{1}{4}\right] a^2 + \left[\frac{1}{6} - \frac{2\,d - \frac{d^2}{2} - \frac{3}{2} - \log_e d}{2\,(1-d)^3}\right] a^3 \quad \text{(19)}$$

with subscripts 1 and 2, for symbols C, d, and a, to denote the appropriate end of the span. Similarly (see Table 1(e)), to find the statical moment of the $\frac{M}{E\,I}$-diagram for uniform load:

$$C = -\frac{1}{128} + \left[\frac{1}{8} - \frac{\frac{d}{2} - 1 + \frac{1}{2\,d}}{4\,(1-d)^2}\right] a^2 + \left[-\frac{1}{4} + \frac{-\frac{3\,d^2}{2} + 6\,d - \frac{9}{2} - 3\log_e d}{4\,(1-d)^3}\right] a^3 + \left[\frac{1}{8} - \frac{1 + \frac{3\,d}{2} - 3\,d^2 + \frac{d^3}{2} + 3\,d\log_e d}{2\,(1-d)^4}\right] a^4 \quad \text{(20)}$$

Fixed-End Moments for Triangular Loads

The constants C were found to have different values when the small end of the triangular load was at the end farthest from the centroidal axis (see end 1, Fig. 1) than when the larger end was so placed. When the small end of the triangular load was at end 1, the constants were found to be as follows:

For the area of the $\frac{M}{EI}$-diagram (see Table 1(f))—

$$\begin{aligned} C_1 = {} & \left[\frac{1}{3\,(1-d)^2} \left(0.5\,d - 1 + \frac{0.5}{d} \right) - \frac{1}{6} \right] a^2 - \left[\frac{1}{3\,(1-d)^4} (1 + 3\,d \log_e d \right. \\ & \left. + 1.5\,d - 3\,d^2 + 0.5\,d^3) - \frac{1}{12} \right] a^4 + \frac{7}{192} \qquad \text{(21}a\text{)} \end{aligned}$$

and (see Table 1(h))—

$$\begin{aligned} C_2 = {} & \left[\frac{2}{3\,(1-d)^2} \left(0.5\,d - 1 + \frac{0.5}{d} \right) - \frac{1}{3} \right] a^2 \\ & + \left[\frac{1}{(1-d)^3} (0.5\,d^2 - 2\,d + 1.5 + \log_e d) + \frac{1}{3} \right] a^3 \\ & + \left[\frac{1}{3\,(1-d)^4} (1 + 3\,d \log_e d + 1.5\,d \right. \\ & \left. - 3\,d^2 + 0.5\,d^3) - \frac{1}{12} \right] a^4 + \frac{3}{64} \qquad \text{(21}b\text{)} \end{aligned}$$

For the statical moment of the $\frac{M}{EI}$-diagram (see Table 1(g))—

$$\begin{aligned} C_1 = {} & \left[\frac{1}{6\,(1-d)^2} \left(0.5\,d - 1 + \frac{0.5}{d} \right) - \frac{1}{12} \right] a^2 \\ & + \left[\frac{1}{3\,(1-d)^3} (0.5\,d^2 - 2\,d + 1.5 + \log_e d) + \frac{1}{9} \right] a^3 \\ & - \left[\frac{1}{6\,(1-d)^4} (1 + 3\,d \log_e d + 1.5\,d - 3\,d^2 + 0.5\,d^3) - \frac{1}{24} \right] a^4 \\ & + \left[\frac{1}{3\,(1-d)^5} (0.5 - 4\,d + 4\,d^3 - 0.5\,d^4 \right. \\ & \left. - 6\,d^2 \log_e d) - \frac{1}{15} \right] a^5 + \frac{37}{5{,}760} \qquad \text{(22}a\text{)} \end{aligned}$$

and (see Table 1(i))—

$$\begin{aligned} C_2 = {} & \left[\frac{1}{3\,(1-d)^2} \left(0.5\,d - 1 + \frac{0.5}{d} \right) - \frac{1}{6} \right] a^2 \\ & + \left[\frac{7}{6\,(1-d)^3} (0.5\,d - 2\,d + 1.5 + \log_e d) + \frac{7}{18} \right] a^3 \\ & + \left[\frac{7}{6\,(1-d)^4} (1 + 3\,d \log_e d + 1.5\,d - 3\,d^2 + 0.5\,d^3) - \frac{7}{24} \right] a^4 \\ & - \left[\frac{1}{3\,(1-d)^5} (0.5 - 4\,d + 4\,d^3 - 0.5\,d^4 \right. \\ & \left. - 6\,d^2 \log_e d) - \frac{1}{15} \right] a^5 + \frac{53}{5{,}760} \qquad \text{(22}b\text{)} \end{aligned}$$

Symbols a and d carry the subscript 1 in Eqs. 21*a* and 22*a* and the subscript 2 in Eqs. 21*b* and 22*b*. These subscripts are omitted from Eqs. 21 and 22 to simplify the typography. Eqs. 21 and 22 can be adapted for the case when the large end of the triangular load is at end 1 by reversing the subscripts. Constants C_1 and C_2, then, for the area of the $\frac{M}{E\,I}$-diagram are read from Tables 1(*h*) and 1(*f*), respectively; and for the statical moment of the $\frac{M}{E\,I}$-diagram from Tables 1(*g*) and 1(*i*), respectively.

EXAMPLE 1

Find the stiffness and carry-over factors for the beam shown in Fig. 4.

Given: $L = 25.00$ ft; $a_1 L = 5.00$ ft; $a_2 L = 2.50$ ft; $h = 1.50$ ft; $d_1 h = 3.30$ ft; and $d_2 h = 3.00$ ft.

Calculate: $a_1 = \frac{5.00}{25.00} = 0.20$; $a_2 = \frac{2.50}{25.00} = 0.10$; $d_1 = \frac{3.30}{1.50} = 2.20$; and $d_2 = \frac{3.00}{1.50} = 2.0$.

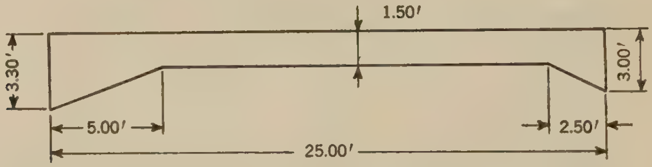

FIG. 4.

Area of Analogous Column.—From Table 1(*a*), using a_1 and d_1 to find C_1, and a_2 and d_2 to find C_2—$C_1 + C_2 = 0.3661 + 0.4375 = 0.8036$. Substituting this value in Eq. 1,

$$A = 0.8036 \frac{L}{E\,I_o} \qquad (23)$$

Centroid of Analogous Column.—From Table 1(*b*), using a_1 and d_1 to find C_1, and a_2 and d_2 to find C_2—$-C_1 + C_2 = -0.0690 + 0.0962 = 0.0272$. Substituting this value in Eq. 3,

$$Q_{\mathrm{I}} = 0.0272 \frac{L^2}{E\,I_o} \qquad (24)$$

By Eq. 7,

$$e_a = \frac{0.0272\,L^2}{E\,I_o} \div \frac{0.8036\,L}{E\,I_o} = 0.0338\,L \qquad (25a)$$

$$L_1 = -\frac{L}{2} - e_a = -0.5338\,L \qquad (25b)$$

and

$$L_2 = \frac{L}{2} - e_a = 0.4662\,L \qquad (25c)$$

Second Moment of Analogous Column.—From Table 1(*c*), using a_1 and d to find C_1, and a_2 and d_2 to find C_2—$C_1 + C_2 = 0.0179 + 0.0285 = 0.0464$. Substituting this value in Eq. 5,

$$Q_{II} = 0.0464 \frac{L^3}{E I_o} \qquad (26a)$$

and (Eq. 9)

$$Q_a = (0.0464 - 0.0009) \frac{L^3}{E I_o} = 0.0455 \frac{L^3}{E I_o} \qquad (26b)$$

Absolute Stiffness of End 1.—Substituting appropriate values in Eq. 11*a*,

$$K_1 = \frac{1.2444\, E\, I_o}{L} + \frac{6.2625\, E\, I_o}{L} = \frac{7.5069\, E\, I_o}{L} \qquad (27)$$

Relative Stiffness of End 1.—By Eq. 11*b*,

$$k_1 = \frac{7.5069\, E\, I_o}{L \times 4\, E} = \frac{1.8767\, I_o}{L} \qquad (28a)$$

Absolute Stiffness of End 2.—Substituting appropriate values in Eq. 12*a*,

$$K_2 = \frac{1.2444\, E\, I_o}{L} + \frac{4.7768\, E\, I_o}{L} = \frac{6.0212\, E\, I_o}{L} \qquad (28b)$$

Relative Stiffness of End 2.—Substituting appropriate quantities in Eq. 12*b*,

$$k_2 = \frac{6.0212\, E\, I_o}{L \times 4\, E} = \frac{1.5053\, I_o}{L} \qquad (28c)$$

Absolute Carry-Over Moment.—By Eq. 13,

$$N = \frac{1.2444\, E\, I_o}{L} + \frac{-5.4694\, E\, I_o}{L} = \frac{-4.2250\, E\, I_o}{L} \qquad (29)$$

Carry-Over Factors.—The carry-over factor away from end 1, by Eq. 14*a*, is $\frac{-4.2250\, E\, I_o}{L} \div \frac{7.5069\, E\, I_o}{L} = -0.563$; and, from end 2 (see Eq. 14*b*), is $\frac{-4.2250\, E\, I_o}{L} \div \frac{6.0212\, E\, I_o}{L} = -0.702$.

Example 2

Find the fixed-end moments for a uniform load totaling W pounds for the beam shown in Fig. 4. (Values for A, e_a, L_1, L_2, and Q_a are as taken from Example 1.)

Load on the Analogous Column.—From Table 1(*d*), using a_1 and d_1 to find C_1, and a_2 and d_2 to find C_2—$C_1 + C_2 = 0.0368 + 0.0405 = 0.0773$. Substituting this value in Eq. 15,

$$P = 0.0773 \frac{W L^2}{E I_o} \qquad (30)$$

Statical Moment of Load.—From Table 1(e), using a_1 and d_1 to find C_1, and a_2 and d_2 to find C_2—$-C_1 + C_2 = -0.0060 + 0.0073 = 0.0013$. Substituting this quantity in Eq. 16,

$$Q_f = \frac{0.0013\,W\,L^3}{E\,I_o} \tag{31}$$

Then Eq. 17 yields

$$e_f = \frac{0.0013\,W\,L^3}{E\,I_o} \div \frac{0.0773\,W\,L^2}{E\,I_o} = 0.0168\,L \tag{32a}$$

Finally,

$$e_f - e_a = (0.0168 - 0.0338)\,L = -0.0170\,L \tag{32b}$$

Fixed-End Moments.—Applying Eq. 18a to determine the fixed-end moment at end 1,

$$\begin{aligned} \text{FEM} &= \frac{0.0773\,W\,L^2}{E\,I_o} \div \frac{0.8036\,L}{E\,I_o} \\ &\quad + \frac{0.0773 \times -0.0170}{0.0455}(-0.5338)\,W\,L = 0.1116\,W\,L \end{aligned} \tag{33a}$$

Similarly, applying Eq. 18b to determine the fixed-end moment at end 2,

$$\text{FEM} = 0.0963\,W\,L + \frac{0.0773 \times -0.0170}{0.0455}\,0.4662\,W\,L = 0.0828\,W\,L. \tag{33b}$$

EXAMPLE 3a

Find the fixed-end moment for a triangular load totaling W pounds, having the small end of the load at end 1, for the beam shown in Fig. 4. (Values of A, e_a, L_1, L_2, and Q_a are as taken from Example 1.)

Load on the Analogous Column.—From Table 1(f), using a_1 and d_1 to find C_1; and from Table 1(h), using a_2 and d_2 to find C_2—$C_1 + C_2 = 0.0329 + 0.0454 = 0.0783$. With these factors known, Eq. 15 becomes

$$P = \frac{0.0783\,W\,L^2}{E\,I_o} \tag{34}$$

Statical Moment of Load.—From Table 1(g), using a_1 and d_1 to find C_1; and from Table 1(i), using a_2 and d_2 to find C_2—$-C_1 + C_2 = -0.0047 + 0.0085 = 0.0038$. With these factors known, Eq. 16 becomes

$$Q_f = \frac{0.0038\,W\,L^3}{E\,I_o} \tag{35}$$

Then, by Eq. 17,

$$e_f = \frac{0.0038\,W\,L^3}{E\,I_o} \div \frac{0.0783\,W\,L^2}{E\,I_o} = 0.0485\,L \tag{36a}$$

and

$$e_f - e_a = (0.0485 - 0.0338)\,L = 0.0147\,L \tag{36b}$$

Fixed-End Moments.—Applying Eq. 18a to determine the fixed-end moment at end 1,

$$\text{FEM} = \frac{0.0783\, W\, L^2}{E\, I_o} \div \frac{0.8036\, L}{E\, I_o}$$

$$+ \left(\frac{0.0783 \times 0.0147}{0.0455}\right)(-\,0.5338)\, W\, L = 0.0839\, W\, L \ldots\ldots (37a)$$

Similarly, applying Eq. 18b to determine the fixed-end moment at end 2,

$$\text{FEM} = 0.0974\, W\, L + \frac{0.0783 \times 0.0147}{0.0455}\, 0.4662\, W\, L = 0.1092\, W\, L \,..\, (37b)$$

EXAMPLE 3b

Find the fixed-end moment for a triangular load totaling W pounds, having the large end of the load at end 1, for the beam shown in Fig. 4. (Values of A, e_a, L_1, L_2, and Q_a are as taken from Example 1.)

Load on the Analogous Column.—From Table 1(h), using a_1 and d_1 to find C_1; and from Table 1(f), using a_2 and d_2 to find C_2—$C_1 + C_2 = 0.0407 + 0.0356 = 0.0763$. Eq. 15 then yields:

$$P = \frac{0.0763\, W\, L^2}{E\, I_o} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (38)$$

Statical Moment of Load.—From Table 1(i), using a_1 and d_1 to find C_1; and from Table 1(g), using a_2 and d_2 to find C_2—$-\,C_1 + C_2 = -\,0.0067 + 0.0060 = -\,0.0007$. With these factors known, Eq. 16 becomes

$$Q_f = \frac{-\,0.0007\, W\, L^3}{E\, I_o} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (39)$$

Then, as in Example 3a, Eq. 17 yields

$$e_f = \frac{-\,0.0007\, W\, L^3}{E\, I_o} \div \frac{0.0763\, W\, L^2}{E\, I_o} = -\,0.0092\, L \ldots\ldots (40a)$$

and

$$e_f - e_a = (-\,0.0092 - 0.0338)\, L = -\,0.0430\, L \ldots\ldots\ldots (40b)$$

Fixed-End Moments.—Applying Eq. 18a to determine the fixed-end moment at end 1,

$$\text{FEM} = \frac{0.0763\, W\, L^2}{E\, I_o} \div \frac{0.08036\, L}{E\, I_o}$$

$$+ \frac{(0.0763 \times -\,0.0430)}{(0.0455)}(-\,0.05338)\, W\, L = 0.1334\, W\, L \ldots\ldots (41a)$$

Similarly, applying Eq. 18b to determine the fixed-end moment at end 2,

$$\text{FEM} = 0.0949\, W\, L + \frac{0.0763 \times -\,0.0430}{0.0455}$$

$$\times (-\,0.5338)\, W\, L = 0.0613\, W\, L \ldots\ldots\ldots\ldots (41b)$$

SUMMARY

Published literature and texts present charts and tables whereby the design constants may be readily obtainable for structural members which have a haunch at only one end or which have haunches at each end that are symmetrical about the center of the span. Little information is available regarding these constants for beams which are nonsymmetrically haunched.

The usual method of obtaining the design constants for the nonsymmetrical case is laborious and time consuming.

This paper is presented to assist the engineer in obtaining the stiffness and carry-over factors for beams having nonsymmetrical straight haunches, and the fixed-end moments for uniform and triangular loads. The results were obtained by the use of the well-known column analogy. The labor required to compute the area, centroid, and moment of inertia of the analogous column, and the area and centroid of the $\frac{M}{E\,I}$-diagram has here been simplified so that they may be obtained by simple arithmetical combination of the constants presented in the tables. Examples have been included to illustrate the use of the tables and the procedure to be followed in obtaining the design constants.

The tables have not been extended to cover other loading conditions because of the great amount of work involved. The two cases covered are those most commonly encountered and therefore the most important loading conditions to be considered. The tables can be enlarged to cover any desired loading condition and the procedure would be equally adaptable.

ACKNOWLEDGMENT

The primary source from which the material was assembled which deals with the analogous column and the calculation of the stiffness and carry-over factors was an academic thesis by the writer, entitled "Stiffness and Carry-Over Factors for Beams with Nonsymmetrical Straight Haunches," submitted to the University of Colorado, in Boulder, in 1939, in partial fulfilment of the requirements for the Degree of Master of Science in Civil Engineering. The part of the paper pertaining to the fixed-end moments has been prepared since that date.

APPENDIX

NOTATION

The following letter symbols, used in the paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials,[4] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

---

[4] ASA—Z10a—1932.

A = area; total area of an analogous column;

a = ratio of the total span length L (Fig. 1):

$a_1 = a$ for distances $a_1 L$ measured from end 1;

$a_2 = a$ for distances $a_2 L$ measured from end 2;

C = a dimensionless constant selected from Table 1 to suit various conditions of a problem, the subscripts 1 and 2 designating the end of the beam; in Eq. 10 it is the distance from the center of gravity of the column section to the point at which the fiber stress is computed;

d = coefficient of depth h to indicate total depth of haunch:

$d_1 = d$ for depths $d_1 h$ measured at end 1;

$d_2 = d$ for depths $d_2 h$ measured at end 2;

E = modulus of elasticity of the material;

e = eccentricity = distance from the center of the span to the center of elastic weights (in Eq. 10 it is the eccentricity of the applied load P):

$e_a = e$ for an analogous column;

$e_f = e$ for the problem of fixed-end moments;

f = the fiber stress in the column formula, Eq. 10;

h = uniform depth of a beam without haunches and the minimum depth of a beam with haunches;

I = moment of inertia:

I_o = inertia moment of the minimum section of a beam;

I_x = inertia moment at a distance x along a haunch (Figs. 2 and 3);

K = absolute stiffness factor (Eqs. 11*a* and 12*a*) with subscripts 1 and 2 denoting the end of the beam;

k = relative stiffness factor (Eqs. 11*b* and 12*b*) with subscripts denoting the end of the beam;

L = length of a beam:

L_1 = part of a beam to the left (end 1) of the gravity center of elastic weights (Fig. 2);

L_2 = part of a beam to the right (end 2) of the gravity center of elastic weights;

M = bending moment;

N = a carry-over moment induced at the far end of a member;

P = a load applied to an analogous column;

Q = statical moment of an area;

Q_{I} = first moment of the area of the analogous column about the center of the span (Eq. 3);

Q_{II} = second moment of the area of the analogous column about the center of the span (Eq. 5);

Q_a = total second moment of area of analogous column about the gravity axis (Eq. 9);

Q_f = statical moment, about the center of the span, of the load acting on an analogous column used in determining fixed-end moments (Eq. 16);

r = a carry-over factor (Eqs. 14), subscripts 1 and 2 being used to designate the ends;

W = total load on beam (Fig. 3);

x = variable distance from end 1 of a beam to a place on the haunch where the depth is y (Fig. 3);

y = depth of the haunch at any distance x from the left end of a beam (Fig. 3).

DISCUSSION

ROBERT O. JAMESON,[5] M. AM. SOC. C. E.—Evidently, considerable labor was involved in the preparation of this paper, and the author is to be congratulated for devising an ingenious method of solving a troublesome problem. A valuable addition to this paper would be the inclusion of data for calculating fixed-end moments due to a concentrated load at any point on a span; however, this would be a huge task. Such data could be presented on several charts showing influence lines for various combinations of haunch lengths. Comprehensive charts have been published,[6] showing properties of beams with parabolic haunches whose lengths are equal to one half of the span and with various ratios of end depths. With this exception, few data have been published on the subject of structural members with haunches of unequal dimensions. Although, in designing, the writer has seldom used the column analogy, due to its abstract qualities, this method has some advantages in the preparation of tables involving unsymmetrical haunch coefficients. Eqs. 1 to 14*b*, inclusive, have been verified. Values of stiffness and carry-over factors, as shown in Example 1, were checked by use of the fixed-point method and identical answers were obtained.

It is hoped that the following discussion, concerning beams having haunches of infinite moment of inertia, will add to the usefulness of this valuable paper.

In the design of rigid frames, including flat slab bridge and building frames, it is frequently necessary to calculate shape and load coefficients to satisfy the assumptions that (*a*) the haunches at each end of a member have unequal lengths, and (*b*) the value of the moment of inertia is infinite at the haunches. The effect of the latter assumption is to make the $\frac{M}{E\,I}$-value equal to zero for the length of the haunch. Based on the foregoing assumptions, shape coefficients, similar to those in Table 2, may be used in the design of members with symmetrical or unsymmetrical haunches or in the design of members that are haunched at one end only. This condensed table is offered as an illustration. In actual practice, of course, the table may be made as large as necessary.

Referring to Figs. 5(*a*), 5(*b*), and 5(*c*), the coefficients in Table 2 are defined as follows: p is the area of the $\frac{M}{E\,I}$-diagram for a unit moment at the left support of a unit span, with E and I equal to one; u is the distance of the centroid of p from the left support; q is the area corresponding to the definition of p, for a unit moment at the right support; v is the distance of the centroid of q from the right support; S_1 and S_2 are stiffness factors when a moment is applied at end 1 and end 2, respectively, while the opposite end of the member is fixed; and r_{12} and r_{21} are the percentages of moment transferred, respectively,

from end 1 to end 2 and from end 2 to end 1 when the far end of the member is fixed. Values of the foregoing coefficients are obtained from the following formulas:

$$p\,u = q\,v = \frac{(1-a_2)^2-(a_1)^2}{2} - \frac{(1-a_2)^3-(a_1)^3}{3} \tag{42}$$

$$p = \frac{(1-a_1)^2-(a_2)^2}{2} \tag{43a}$$

$$q = \frac{(1-a_2)^2-(a_1)^2}{2} \tag{43b}$$

$$u = \frac{p\,u}{p} \tag{44a}$$

$$v = \frac{p\,u}{q} \tag{44b}$$

$$r_{12} = \frac{v}{1-v} \tag{45a}$$

$$r_{21} = \frac{u}{1-u} \tag{45b}$$

$$k_1 = S_1\frac{I}{L} \tag{46a}$$

$$k_2 = S_2\frac{I}{L} \tag{46b}$$

In Eqs. 46, k_1 and k_2 are relative stiffnesses, as defined by the author, and values of S_1 and S_2 are:

$$S_1 = \frac{1-v}{4\,p\,(1-u-v)} \tag{47a}$$

$$S_2 = \frac{1-u}{4\,q\,(1-u-v)} \tag{47b}$$

FIG. 5

Load coefficients for obtaining fixed-end moments and fixed-point ordinates are presented herein for: (*a*) Uniform loading across the span; and (*b*) a concentrated load placed at any point on the span.

Referring to Fig. 5(*d*), the symbols are defined as follows: A_o is the area of the $\frac{M}{E\,I}$-diagram for an external vertical loading of unity on a unit span when the values of E and I are equal to one; X_o is the distance from the left support to the centroid of A_o; and $1 - X_o$ is the distance from the right support to the centroid of A_o. Referring to Fig. 5(*e*), s and t are fixed-point ordinates or ordinates to the closing lines of the fixed-end moments for a conjugate beam. For any type of external vertical loading, the values of s and t are obtained from:

$$s = \frac{A_o\,(1-X_o)}{p} \tag{48a}$$

$$t = \frac{A_o\,X_o}{q} \tag{48b}$$

For a uniformly distributed load of unity on a unit span:

$$A_o\, X_o = \tfrac{1}{2}\left[\frac{(1-a_2)^3-(a_1)^3}{3}-\frac{(1-a_2)^4-(a_1)^4}{4}\right]\ldots\ldots(49a)$$

$$A_o\,(1-X_o) = \tfrac{1}{2}\left[\frac{(1-a_1)^3-(a_2)^3}{3}-\frac{(1-a_1)^4-(a_2)^4}{4}\right]\ldots(49b)$$

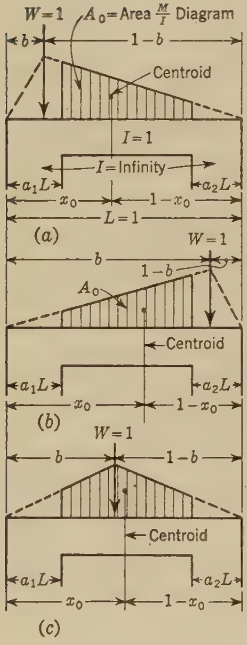

Fig. 6

Fixed-end moments for a total uniform loading, W, and span length, L, are:

$$\text{FEM}_1 = \left[s+\left(\frac{s-t}{1-u-v}\right)u\right]W\,L\,.(50a)$$

$$\text{FEM}_2 = \left[t-\left(\frac{s-t}{1-u-v}\right)v\right]W\,L\,.(50b)$$

Values of s and t, for uniform loading, may be determined by Eqs. 48 or by use of a chart[7] devised by Ulrik T. Berg, Assoc. M. Am. Soc. C. E. For a unit concentrated load on a unit span, the load coefficients are as follows:

For a load over the left haunch (Fig. 6(*a*))—

$$A_o\, X_o = b\left[\frac{(1-a_2)^2-(a_1)^2}{2}-\frac{(1-a_2)^3-(a_1)^3}{3}\right]$$
$$= b\,p\,u\ldots\ldots\ldots\ldots\ldots(51a)$$

$$A_o\,(1-X_o) = b$$
$$\left[(a_1)^2-(a_2)^2-a_1+a_2+\frac{(1-a_2)^3-(a_1)^3}{3}\right]$$
$$= b\,p\,(1-u)\ldots\ldots\ldots\ldots(51b)$$

For a load over the right haunch (Fig. 6(*b*))—

$$A_o\, X_o = (1-b)\left[\frac{(1-a_2)^3-(a_1)^3}{3}\right] = (1-b)\,(1-v)\,q\ldots(52a)$$

$$A_o\,(1-X_o) = (1-b)\left[\frac{(1-a_2)^2-(a_1)^2}{2}-\frac{(1-a_2)^3-(a_1)^3}{3}\right]$$
$$= (1-b)\,(p\,u)\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(52b)$$

For a load not over a haunch (Fig. 6(*c*))—

$$A_o\, X_o = (1-b)\left[\frac{b^3-(a_1)^3}{3}\right]+b\left[\frac{(1-a_2)^2-b^2}{2}-\frac{(1-a_2)^3-b^3}{3}\right].(53a)$$

$$A_o\,(1-X_o) = (1-b)\left[\frac{b^2-(a_1)^2}{2}-\frac{b^3-(a_1)^3}{3}\right]$$
$$+\,b\left|\,(a_2)\,(1-a_2)+b^2-b+\frac{(1-a_2)^3-b^3}{3}\right]\ldots\ldots\ldots(53b)$$

---

[7] "Structural Bending Moments Simplified," by Ulrik T. Berg, Polygraphic Co. of America, Inc., New York, N. Y., 1938, p. 95.

Values of s and t for the solution of Eqs. 51 to 53 are obtained by Eqs. 48, whereas fixed-end moments are determined by Eqs. 50, using W for total concentrated load.

A diagram showing influence lines for obtaining fixed-end moments, due to a concentrated load on a beam with symmetrical haunches of infinite moment of inertia, has been published elsewhere.[8]

JOHN SHERMAN,[9] ESQ.—Contrary to the author's opinion (see heading, "Summary"), considerable information is available regarding constants for the analysis of haunched beams. As applied to the properties of haunched beams, the tables prepared by Walter Ruppel,[10] Assoc. M. Am. Soc. C. E., from the earlier tables by A. Strassner,[11] contain all the information needed for the analysis of haunched beams (haunched at one end or both ends), not only by the method of conjugate points but by the moment area, slope deflection, three moment equation, column analogy, and moment distribution methods.

The Ruppel tables, being adapted from the Strassner tables (which made it possible to determine (*a*) the end rotation angles due to a unit couple applied at each end of a haunched beam, and (*b*) the end rotation angles due to a lateral load applied to the haunched beam), may be used to determine these end rotations. According to the principle of superposition, the end rotation angles of a haunched beam should be considered as composed of two parts: (1) The rotation angle due to a beam of uniform moment of inertia, and (2) the rotation angle due to the haunch. As stated, the properties of beams, haunched at one end, are given in the Ruppel tables; and with these values known it is possible, by the principle of superposition, to find (*a*) the properties of a beam symmetrically haunched, and (*b*) the properties of a nonsymmetrically haunched beam.

Mr. Ahlf also states (see heading, "Summary") that "The labor required to compute the area, centroid, and moment of inertia of the analogous column, and the area and centroid of the $\frac{M}{E\,I}$-diagram has * * * been simplified * * * in the tables." This statement is true for the cases presented in the paper; but, for the analysis of continuous bridges, the properties mentioned by Mr. Ahlf are used only by those who choose to ignore the properties of influence lines. It is possible to consider the various $\frac{M}{E\,I}$-diagrams as superfluous and to construct one influence line for each reaction by loading the conjugate beam with the $\frac{M}{E\,I}$-diagram due to this reaction—the $\frac{M}{E\,I}$-diagram being considered as equivalent to a system of closely spaced loads.

The Ruppel tables accomplish so much more than do the tables prepared by Mr. Ahlf that the latter may be considered of interest only in the very narrow range of the moment distribution and column analogy methods as applied to a fixed beam; and even in this specific case the use of the Ruppel tables is more simple and direct. In one sense, the entire subject of haunched beams is primarily a matter of academic interest as the use of haunched beams is the exception rather than the rule.

Dale H. Rea,[12] Esq.—The problem of straight haunched beams has practically been removed entirely from the realm of tedious and laborious indeterminate analysis by this paper. To prove this conclusion the writer has undertaken to check the paper. The formulas are true expressions of column analogy. The formulas for C and the tables computed from them were not checked because of the enormous work involved. However, the column analogy solution presented herein will enable one to predict probable variations of C.

The following rules may prove helpful in analyzing haunched beams: (*a*) The greater the haunch, the larger will be the stiffness factor, but the smaller the carry-over factor; (*b*) the product of the carry-over factor away from the end and the stiffness factor at the end is constant for a given beam; and (*c*) increasing the size of a haunch increases the fixed-end moment at that end.

Table 3 presents the data necessary for a solution of Examples 1, 2, and 3. In computing this table, the beam is divided into sections 1 ft long, and all variables refer to the midpoint of the sections.

---

[12] Engr., U. S. Bureau of Reclamation, Denver, Colo.

In addition to the notation of the paper, the letter symbols in Table 3 are defined as follows: x_0 is the variable distance from the midspan of the beam to any given section; x_1 and x_2 are the distances from end 1 and end 2, respectively, of the beam to any given section; and M_s is the simple bending moment at any section.

Values in Table 3, when substituted in Eqs. 23 to 41, yield results that are quite comparable. Thus, for Example 1: $A\,E\,I_o = 0.801\,L$; $Q_I\,E\,I_o = 0.027\,L^2$; $e_a = 0.034\,L$; $L_1 = -0.534\,L$; $L_2 = 0.466\,L$; $Q_{II}\,E\,I_o = 0.046\,L^3$; $Q_a\,E\,I_o = 0.045\,L^3$; $K_1\,L = 7.58\,E\,I_o$; $k_1\,L = 1.89\,I_o$; $K_2\,L = 6.08\,E\,I_o$; $k_2\,L = 1.52\,I_o$; $N\,L = -4.28\,E\,I_o$; $r_1 = -0.564$; and $r_2 = -0.704$.

Similar results for Examples 2 and 3 are given in Table 4. A comparison of the author's values with the foregoing shows close agreement. The maximum difference is about 2%. Other haunched beams analyzed by the writer in the past have been recomputed by the author's method and show even closer agreement. The difference of 2% is well within limits of design when one considers the many variables involved in rigid frame analysis.

If the two triangular loads in Example 3 are placed upon the beam at the same time, the result is a uniform load of 2 W, which is twice as great as the uniform load W in Example 2. It follows that all other functions bear this same relation regardless of the type of beam used. This relation exists in Table 3 within the limits of slide-rule accuracy.

Adapting this same reasoning to Table 1, it is found that the sum of values in Tables 1(f) and 1(h) equals two times the corresponding values in Table 1(d), and that the three values will be of different magnitude. Therefore, Eqs. 30, 34, and 38 should never be of equal value. The stiffness of all members in a rigid frame, haunched or prismatic, should be expressed as either relative stiffness or as absolute stiffness and not intermixed. In Example 1, N is referred to as the "absolute carry-over moment." The word absolute appears to be extraneous to carry-over moment and should be used only in referring to "stiffness factor."

I. B. Hosig,[13] Esq.—The first reaction to the presentation of data such as those in this paper is the question: "Will engineers use the data in their work?" The writer is sufficiently acquainted with the labor connected with haunched beam problems to appreciate both the immense amount of time applied to the construction of the tables and the objectives sought in presenting the tables. If teaching the elements involved in the calculation of beam performance were as standardized as teaching trigonometry, for instance, the tables presented could, perhaps, be used as safely as are trigonometric tables because similarly fundamental relations based on geometric figures are presented. The tables are the best evidences that the day is approaching when such teaching will be standardized and that facility in the design of haunched and irregular beams will approach present facility in trigonometric calculations. In fact, tables will be necessary to make such facility common, as they are necessary in trigonometry, and these are the best known to the writer. However, he confesses that he would not use the tables except as a check to a problem solved by fundamental relations, but for such a purpose he considers the tables a very valuable addition to his "tool kit."

The second reaction following the general reading of the text accompanying the tables is the complete absence of the words, "curvature," "slope," and "deflection," and the rare use of the words, "rotation" and "reaction." The fact that the author has produced the end products, "stiffness," "carry-over factors," and "fixed-end moments" without the use of these words shows that the words are no longer necessary to him in his progress toward facility, and perhaps is again a preview of the shape of things to come when teaching the elements becomes standardized. The writer believes that such a trend is wrong, however, and that teachers must right it. An indication of the error resulting from the author's viewpoint (which would not result if the entire problem were considered as an interplay of slopes, rotations, etc.) is shown in the second sentence under the heading, "Carry-Over Factors," namely: "The induced moment is defined as the 'carry-over moment,' and that proportion of the applied moment which is carried over is defined as the 'carry-over factor.' "

---

[13] Engr., U. S. Bureau of Reclamation, Denver, Colo.

The fundamental concept of the "carry-over moment" presumes what is equivalent to a cantilever beam, the free end of which is first rotated through an angle of one radian by a couple at that end. Then the beam is restored to its original level by a force applied at the free end to eliminate the deflection that followed the rotation. If the couple alone were acting, there would be along the entire length of the beam a uniform moment with a value equal to that of the couple. The application of the force or reaction induces moments, varying from zero at the free end to the value of force times the span length at the fixed end. The net moment at the fixed end is the difference between the two and may well be called the "induced moment." In all cases investigated by the writer, however, the moment produced by the force is larger than that produced by the couple; hence, the net moment can be no part of the "applied moment." This explains why the carry-over moment is of opposite sign to the applied moment.

The writer has checked scattered values in the tables and found no errors. The computations were made following a procedure in which moments and reactions are applied to the free end of a similarly shaped and loaded cantilever beam to reduce the cantilever beam to a fixed or hinged beam as required. The derivations of the formulas for the constants were not checked by the writer, however, because of the difference between his viewpoint and that of the author, and because available time did not permit the complete analysis of the physical significance of these constants. In the case of a beam uniformly haunched from one end to the other, the method of using the tables is not obvious, and it is suggested that the author clarify the procedure in his closing discussion.

AUGUST L. AHLF,[14] JUN. AM. SOC. C. E.—The discussion by Mr. Jameson, dealing with beams having haunches of infinite depth, is a welcome addition to the paper. This phase of the analysis of haunched beams is somewhat simpler than the case of beams with varying depth of haunch in that one set of variables, d_1 and d_2, are eliminated, leaving only the length of the haunches, a_1 and a_2, to be considered.

The general equations of column analogy as presented in the paper may be made to apply to the case where the beam has haunches of infinite depth. The expressions representing the constants of Eqs. 2, 4, and 6, respectively, will then be as follows: In Eq. 2—

$$C = 0.5 - a \qquad (54a)$$

in Eq. 4—

$$C = 0.5\,(0.5 - a)^2 \qquad (54b)$$

and in Eq. 6—

$$C = 0.333\,(0.5 - a)^3 \qquad (54c)$$

The values of the expressions $(C_1 + C_2)$ in Eq. 15 and $(-C_1 + C_2)$ in Eq. 16 may be obtained by computing the area and locating the center of gravity of the area of the moment diagram which lies between the haunches. As the depth of the beam (and hence the moment of inertia) is constant throughout this reach, these values may be computed from the geometrical properties of the moment diagram without any difficult integration. For the case of a uniform load or a concentrated load, Eqs. 49, 51, and 52 may be used if desired.

---

[14] Engr., U. S. Bureau of Reclamation, Dept. of Interior, Denver, Colo.

The author regrets that the scope of discussion did not permit Mr. Sherman to include a detailed illustration of how the Ruppel tables and the principle of superposition could have been used to simplify the solution of nonsymmetrical haunched beams. A comparison of the relative accuracy and the amount of labor involved would have been of interest.

Mr. Rea has demonstrated ably the procedure to be followed in the column analogy solution of haunched beams by dividing the member into a number of segments. The close agreement between the results obtained by this approximate method and those obtained from tabular values is gratifying. The great number of beam segments chosen and the care with which Mr. Rea made the computations no doubt explain this agreement.

The truth of the statement—"the product of the carry-over factor away from the end and the stiffness factor at the end is constant for a given beam"—may be demonstrated by rearranging Eqs. 14*a* and 14*b* and equating:

$$r_1 K_1 = N = r_2 K_2 \dots\dots\dots\dots (55)$$

The term, "absolute carry-over moment," was used with deliberation. The carry-over factor was determined by dividing the induced or absolute carry-over moment by the applied moment represented by the absolute stiffness factor. It is important that the absolute stiffness factor and not the relative stiffness factor be used. The word, "absolute," was applied to both cases so that the numerator and denominator would agree in terminology.

The energy expended in the preparation of this paper is amply repaid by Mr. Hosig's statement that he "considers the tables a very valuable addition to his 'tool kit'"—even though only as a check for the results obtained by other, more laborious methods. After several hours have been spent in setting up the fundamental equations involving the slopes and deflections of a member, such as in the illustrative example, and in evaluating the resulting integrals, the values in Table 1 should give a convenient, accurate, and useful check of the results.

A discussion of the slopes, deflections, and curvatures of the haunched beam was avoided purposely. The primary objective of the paper was to present a rapid and accurate method by which the structural designer could obtain the stiffness factors, carry-over factors, and fixed-end moments for the nonsymmetrically haunched beam. It was presumed that an academic discussion was not required as a designer qualified to perform this type of analysis must be acquainted with the meaning of these terms.

Mr. Hosig's statement that there is an indication of error resulting from the viewpoint held by the writer is incongruous with his later statement that scattering values were checked by the classical method and that no errors were found.

The writer prefers to consider the phenomena of the induced or carry-over moment as actually existing in a structural frame. In the method of distributing fixed-end moments, each joint of the frame is considered to be held rigidly against rotation while the frame is subjected to loading. As each joint is released successively from restraint, the ends of the members, which comprise the joint, will be rotated because the unbalanced moment has been released. The opposite end of each member, still rigidly held, will have moments induced or carried over to that end because of the rotation which the released end experiences. This procedure seems simpler than the consideration of each member as an isolated cantilever which is permitted to deflect and is then restored to its original position by the application of a force and a couple at the cantilevered end.

The statement that the induced moment can be no part of the applied moment is not consistent with structural theory. There are many charts and tables available whereby the design constants may be obtained for members with a haunch at only one end. The method presented is applicable, although not recommended, for this case. The procedure to be followed is the same as that outlined in Examples 1, 2, and 3. In this case, however, the length of the haunch at the small end should be considered equal to zero and the values of Table 1 under the heading of $a = 0$ must be used.

PRESSURE ON THE LINING OF CIRCULAR TUNNELS IN PLASTIC SOILS

By D. P. Krynine,[1] M. Am. Soc. C. E.

With Discussion by Messrs. M. A. Drucker, John M. Bird, and D. P. Krynine.

Synopsis

No attempt to develop a mathematical theory of pressure on the circular tunnel lining in plastic soils is made in this paper. Available field data are interpreted, using simple statics, arithmetic, and some geometry. The discussion is concerned mostly with the analysis of pressures on the lining of the Lincoln Tunnel, in New York, N. Y.

Introduction

Important observations of pressure on the lining of circular tunnels have been made in the United States since 1930. These observations represent a genuine contribution of American engineers to the world tunnel literature since, to the writer's knowledge, no such observations on full-sized circular tunnels have been made before. In this paper the available data concerning pressure on the lining of a circular tunnel are analyzed mostly as applied to the Lincoln Tunnel, New York City.[2] A comparison is made between pressures on this tunnel and the Central Avenue Pipe Tunnel,[3] in the City of Detroit, Mich. Finally, a few data referring to the Chicago (Ill.) Subway[4] are also cited. For the sake of brevity, these tunnels will be termed hereafter "Lincoln Tunnel," "Detroit Tunnel," and "Chicago Subway," respectively. The general data concerning these tunnels are as follows:

Diameter.—The outside diameter of the lining of the Lincoln Tunnel is 31 ft, that of the Detroit Tunnel about 13 ft, and that of the tubes of the Chicago Subway about 25 ft.

Note.—Published in May, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

Lining.—The lining of both the Lincoln Tunnel and the Chicago Subway tubes consists of the conventional cast-iron segments bolted together. The Detroit Tunnel tube is of reinforced concrete. This is a thick pipe, its inside diameter being 9.5 ft.

Soil Conditions.—The average depth of the Lincoln Tunnel below the bed of the Hudson River is about 46 ft. Silt material (organic clayey silt), in which this tunnel is built, is quite similar to that found in the deltas of many other rivers flowing into the Atlantic. This is a plastic material with high natural moisture content. The silt layer in some parts of the Hudson River gorge is perhaps 400 ft thick.

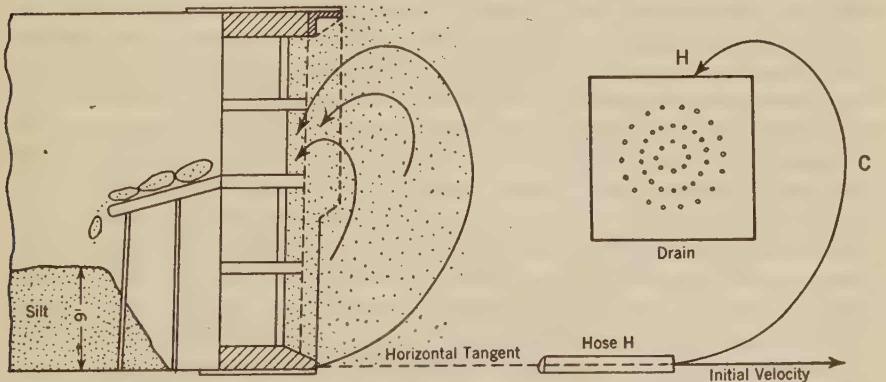
The soil, in which both the Detroit Tunnel and the Chicago Subway are built, is plastic clay. The Detroit Tunnel is located about 60 ft below the ground surface. There are about 12 ft of artificial fill and natural sand covering the soft and medium blue clay deposit, which is about 86 ft thick.

The Chicago soil profile is formed by a layer of silt, sand, and artificial fill, from 10 to 15 ft thick, underlain by a soft blue clay deposit (average thickness 70 ft). Hardpan and rock follow.

Methods of Construction.—Both the Lincoln Tunnel and that part of the Chicago Subway which is referred to in this paper have been constructed by the shield method. The presence of the second tube (in both cases) practically did not influence the results of measurements of the pressure on the lining. The Detroit Tunnel had an open-front face during the construction.

BEHAVIOR OF THE SOIL DURING CONSTRUCTION OF THE LINCOLN TUNNEL

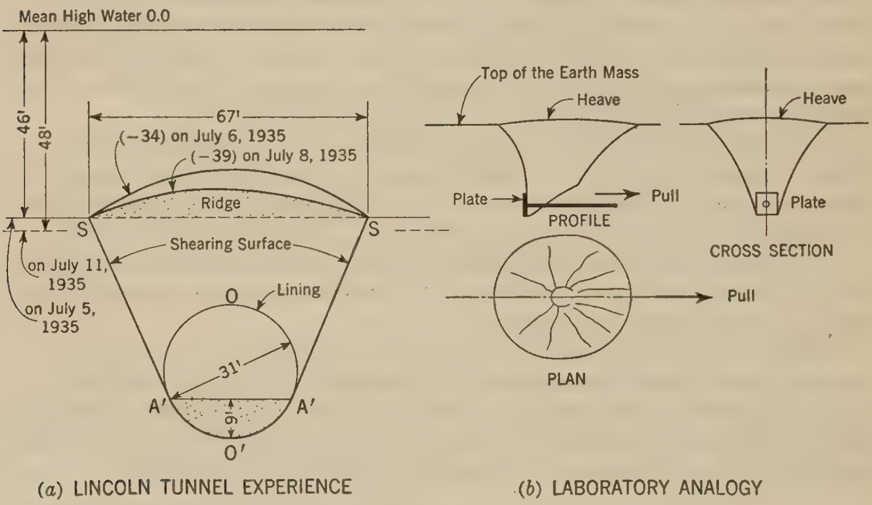
Material Above the Haunches and in Front of the Bulkhead.—There is a tendency for the earth in front of the advancing bulkhead to push forward horizontally; but it cannot move in that direction, because of the passive resistance of the earth mass. It must move somewhere, however, since the shearing strength of the material is overcome, and the bulkhead keeps moving forward. Shearing surfaces are developed in the earth material in front of the bulkhead, both below and above the top of its front face. The particles



(*a*) SECTION OF BULKHEAD (*b*) PLAN OF ANALOGOUS DRAIN

FIG. 1.—BEHAVIOR OF SOIL DURING CONSTRUCTION OF LINCOLN TUNNEL

from the lower part of the mass thus disturbed move upward, follow smooth curvilinear shearing surfaces, and enter the openings in the front face of the bulkhead approximately as shown in Fig. 1(*a*). The particles from the upper part of that disturbed mass push up the earth above them, creating bulges at the boundary of the earth mass similar to the one shown in Fig. 2(*a*). In the Hudson River above the Lincoln Tunnel the advancing shield formed a bulge about 12 ft high. The Chicago Subway is constructed in soft clay, the roof of the tunnel being located beneath a stiff clay crust which separates the soft clay from the superimposed stratum of sand and silt. The heaving of the street was rather slight, because the stiff crust was not broken. The width of this bulge was about twice the diameter of the tunnel. Silt entering through the openings in the bulkhead of the Lincoln Tunnel filled the lower 9 ft of the circular section of the lining which constitutes about 30% of the volume of the displaced silt. Assuming that the remaining 70% formed a parabolic ridge 12 ft high, its width should have been about 67 ft, again practically twice the diameter of the tunnel. Obviously, in each particular case the width of the ridge depends on the depth of the tunnel, other circumstances being equal. The foregoing can be further clarified by analogy: (1) For the movement of particles pushed toward the openings in the bulkhead front face; and (2) for the movement of particles pushed upward and forming the bulge.



(*a*) LINCOLN TUNNEL EXPERIENCE (*b*) LABORATORY ANALOGY

Fig. 2.—Material Displaced by Tunnel Driving

Analogy 1.—In the depressed center of the concrete floor of the writer's laboratory there is a drain for emptying water from a tank, through hose H, Fig. 1(*b*), into a sewer. Water leaving hose H follows a path C, Fig. 1(*b*), and enters the drain from the opposite side (point H). The curve in Fig. 1(*b*) is similar in shape to the curve in Fig. 1(*a*). In describing the shield tunnels of the Chicago Subway,[4] Karl Terzaghi, M. Am. Soc. C. E., states that "when watching the clay coming out of the openings, one got quite decidedly the impression that the clay flowed toward the openings from above." Obviously, the same phenomenon should be expected in the construction of the Lincoln Tunnel.

Analogy 2.—A vertical plate, provided with a horizontal rod and buried in earth, if pulled by the rod, produces both bulging and cracking at the earth surface (Fig. 2(*b*)).

Downward Motion of the Ridge and of the Silt Below It; Friction and Shear.—Formation of the two shearing surfaces A′S, Fig. 2(*a*), divides the silt mass into two individual masses: (*a*) Mass SA′O′A′S bounded by the shearing surfaces and the lining, and (*b*) the remainder of the silt. When the mass SA′OA′S moves up, its movement is resisted first by the shearing strength of the silt, and subsequently, as the latter is overcome, by friction directed downward (that is, against the direction of the movement). As soon as the ridge or bulge reaches its highest position, a downward motion begins due to the consolidation of the silt mass. The friction is now reversed and acts upward. As time passes, the silt along the shearing surfaces creates a healing process which restores the bond between the two masses. The restoration of bond probably is incomplete in the sense that the disturbed silt does not recover its initial shearing strength during the consolidation period. In this period of adjustment friction opposing the downward motion of mass SA′OA′S is gradually replaced by shearing stresses. After all, friction and shearing stress are phenomena of the same order. If two bodies in contact tend to move along the plane of contact with respect to each other, the force opposing the motion is friction; and, if a part of a body or of a mass tends to move with respect to the other part of the same body or mass, the motion is opposed by shearing stress.

For the sake of simplicity, shearing stresses will be assumed acting vertically, and not obliquely, which does not change the reasoning and the results. It is convenient to remember that shearing stresses acting along two mutually perpendicular planes are equal. In other words, existence of a vertical shearing stress, at a point of the mass, implies the existence at the same point of a horizontal shearing stress of the same magnitude.

Consistency of the Remolded Silt Material.—The silt material above the lining and in front of the bulkhead is remolded. As a first approximation, it will be assumed that it acts as a perfect fluid. This is the assumption made by G. M. Rapp and A. H. Baker, Assoc. Members, Am. Soc. C. E., in their report on the Lincoln Tunnel.[2] It implies that at a point of the surface of the lining there is a normal pressure and that both the vertical and horizontal pressures at the same point are numerically equal to that normal pressure. Messrs. Rapp and Baker state[2] that the tangential pressures along the periphery of the lining "were generally less than 2 lbs. per sq. in., and a large portion of them ranged between 0 and 0.5 [lbs. per sq. in.]." In other words, the measured tangential pressures in the silt surrounding the lining were negligible.

Material at the Lower Part of the Lining.—It follows from a simple visual inspection of Fig. 2(*a*) that at the upper part of the lining (above points A′) the moving bulkhead was remolding the silt material and pushing it forward against the passive resistance ("passive pressure") of the silt. In the lower part of the lining (below points A′) the moving bulkhead was making its way through silt which pressed on it from both sides. This is the "active pressure" of the silt on the lining.

It follows furthermore from Fig. 2(*a*) that the moving bulkhead formed a trough in the silt bounded by the line A′O′A′ (Fig. 2(*a*)). The material within this trough was remolded and, as stated, with a certain approximation may be considered as a liquid. This statement concerns a thin cushion of silt along the lower part of the lining A′O′A′. Conventionally and for the sake of brevity, this part A′O′A′ will be termed "bottom of the lining" in this paper.

Recapitulation.—The foregoing statements concerning the behavior of the silt material around the tunnel may be summarized as follows: The bulkhead pushes the silt forward. A part of it travels paths along curved surfaces and enters the openings in the shield. The remainder bulges upward to form a ridge as the shield driving continues. At the same time, the lower part of the lining makes its way through undisturbed silt. During this time a thin cushion of remolded silt is being formed in the trough A′O′A′ as a result of shoving. The lining, disengaged from undisturbed silt, "floats" in the liquid mud of the "trough" A′O′A′ (Fig. 2(*a*)).

External Forces Acting on the Lining and on the Adjacent Silt Mass

Weight of the Overburden.—During the construction of the Lincoln Tunnel the following facts were recorded:[2] Before driving, the elevation of the river bottom next to the test station was − 46, the datum plane being the mean high-water level in the Hudson River (Fig. 2(*a*)). On July 6, 1935, a ridge 12 ft high was produced by the moving bulkhead (elevation of the top of the ridge, − 34). Due to erosion and other circumstances, this ridge was 7 ft high on July 8 (elevation of the top, − 39). On July 11 the bottom of the river was dredged to elevation − 48.

On the basis of this information[2] (assuming the weight of water in the Hudson River at 64 lb per cu ft and the weight of saturated silt at 104 lb per cu ft), the weight of the overburden on July 8 and on July 11 and afterward is given in Figs. 3(*b*) and 3(*c*), in which the unit weight of the overburden, in pounds per square inch of the horizontal projection of the lining, is shown.

Pressure Records and Standard Loading.—A special silt pressure gage and plugs were designed to measure both normal and tangential pressures on the periphery of the Lincoln Tunnel at a special test station. Accuracy of measurements has been reported[2] to be within 1 lb per sq in. or 2 lb per sq in. The tangential pressures were generally less than 2 lb per sq in., and a large proportion of them ranged between 0 and 0.5 lb per sq in. as already stated. In this paper the tangential pressures at the periphery of the lining of the Lincoln Tunnel are neglected altogether. For comparison, the writer decided to reduce all record data to a standard loading as follows:

(*a*) The lining is loaded with the overburden as of July 11, 1935, the only exception being made for the record of July 8, 1935, in order to discount the effect of the ridge (see heading, "Weight of the Overburden");

(*b*) The total weight of the lining is 18 kips and the total weight of the inside silt deposit is 16 kips per running foot of the tunnel;

FIG. 3.—WEIGHT OF OVERBURDEN, LINCOLN TUNNEL

(*c*) There is no compressed air within the lining above the normal atmospheric pressure. If the situation is different from that described, corrections are introduced. First, the corrections for the compressed air will be computed.

Compressed air was in contact with clay through the openings in the shield only. Hence the expanding lining exerted active pressure on the surrounding silt. As a result, the silt exerted a numerically equal passive resistance, which must be deducted from the measured normal pressure (negative correction). In the case of the Detroit Tunnel, the pressure of the compressed air was transmitted through the pore moisture of clay at the front face and around the lining. This neutral stress decreased the measured pressure (positive correction).

Points on the periphery of the lining of the Lincoln Tunnel where pressure records are available are shown in Fig. 3. To identify different vertical sections of the lining, letters A, B, C, D, and O will be used for the upper part of the lining, whereas letters A′, B′, C′, D′, and O′ correspond to the lower part of the lining (Fig. 3(*b*)). Numerical values of pressures, their averages separately for the upper and the lower semicircumference of the lining, and the compressed air pressures are given in Table 1.

[a] "Recorded" values are the original pressures, not corrected for the compressed air pressures; "corrected" values are so corrected. [b] See Fig. 3.

The recorded pressure was corrected by dividing the difference of the average recorded pressures on two given days by the corresponding difference of compressed air pressures. The increase in compressed air pressure from 16 lb per sq in., on July 16, to 28 lb per sq in., on August 8, corresponds to an increase in recorded pressure on the upper part of the lining of $\frac{40.3 - 38.4}{12} = 0.16$ lb per sq in. per pound of compressed air pressure. The corresponding value for the lower part of the lining is $\frac{44.6 - 43.0}{12} = 0.13$ lb per sq in. The reduction in compressed air pressure from 28 lb per sq in., on August 8, to zero, on August 29, is computed as 0.16 lb per sq in. for both parts of the lining.

In view of these considerations all recorded pressures were corrected by deducting from them as an average, 0.15 lb per sq in. per pound of compressed air pressure on that day.

Analogy 3.—Before discussing the play of forces acting on both the lining and the adjacent silt mass, consider the following analogy:

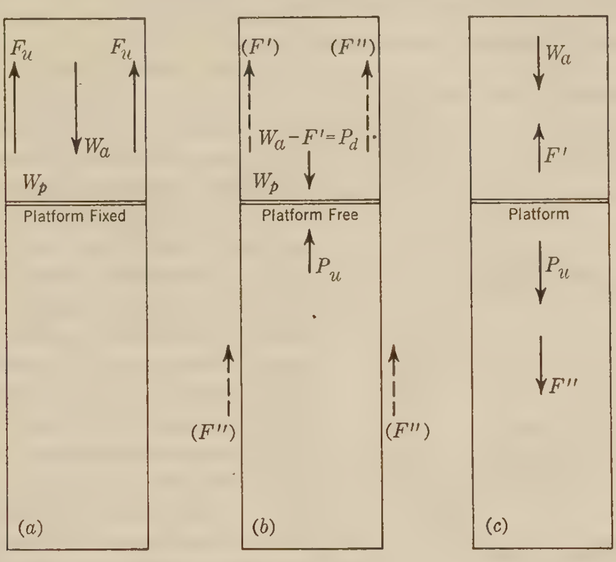

FIG. 4.—ELEVATOR SHAFT ANALOGY

In Fig. 4, a perfectly rigid platform is fixed at a certain position in a hypothetical elevator shaft of unit cross-section area. It supports its own weight W_p and the weight W_a of nonconsolidated silt in the shaft above the platform. Below the platform the shaft is completely filled with a perfectly consolidated silt. As the silt above the platform consolidates, friction forces F_u develop along the walls of the shaft, relieving the load on the platform to that extent. In other words (see Fig. 4(*a*)), the resultant downward force acting on the platform, except its weight, is

$$P_d = W_a - F_u \qquad \qquad (1)$$

and since the platform is wedged in position it reacts upward in the same degree in the silt load. Forces acting upward are distributed throughout the upper silt mass. The resultant of these forces is equal numerically to F_u. Since the platform is fixed (by brakes, say, or wedges), it does not exert any pressure on the silt below it; and since the latter is fully consolidated there is no movement and no friction below the platform.

If the platform is released, a consolidation process begins beneath it, and then the total force or load moving the platform downward is $P_d + W_p$. The platform moves downward following the consolidating silt mass; and this new movement is opposed by some new friction forces F' and F'' on the walls of the shaft and by the reaction of the mass P_u at the bottom of the platform (Fig. 4(*b*)). The weight of the mass below the platform has already caused complete consolidation of the material and need not be considered. Consequently, the mass under the platform should be assumed as being acted upon by a force P_u and vertical forces spread throughout the mass and having F'' for the resultant (Fig. 4(*b*)). The final distribution of the forces acting on the silt mass both above and below the platform is shown in Fig. 4(*c*).

Since the platform and the silt, on which it reposes, move, forces of inertia should be taken into consideration. The possible motion is very slow, however, and the forces of inertia will be disregarded.

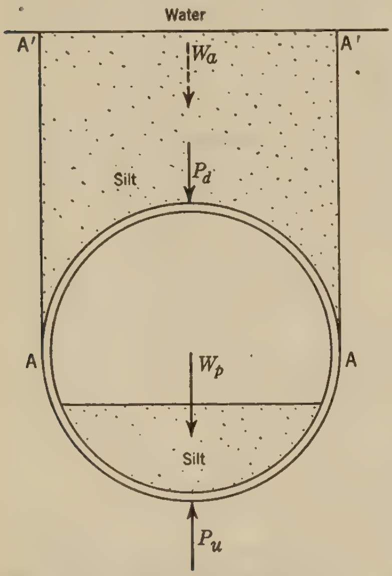

Fig. 5.—Vertical Forces Acting on the Lining

Forces Acting on the Silt Mass Above and Below the Lining.—Analogy 3, as illustrated by Fig. 4, can be applied to the example in Fig. 5, which shows the distribution of forces acting on the lining of the Lincoln Tunnel during its construction. As in Fig. 4, W_a is the weight of the overburden above the lining or "platform" (see Fig. 3); W_p is the total weight of the lining and the inside silt deposit (that is, silt which entered the lining as in Fig. 1(*a*)), P_d and P_u are forces computed from pressures measured during the construction (see Table 1). The total value of the weight W_p is 34 kips per running foot of the tunnel, 18 kips being the weight of the lining itself, and 16 kips being the weight of the inside silt deposit. The distribution of the weight W_p along the surface of contact with the silt mass at the bottom of the lining A′O′A′, in Fig. 2(*a*), is unknown. Two assumptions will be made: (*a*) The lining is perfectly rigid, and the weight W_p is uniformly distributed along the horizontal projection of the lining; and (*b*) the lining is perfectly nonrigid, and the weights of the lining and of the inside silt deposit are distributed along the horizontal projections of the lining proportionately to the respective thicknesses of the lining and of the inside silt deposit in a given vertical section of the tunnel. The results are shown in Fig. 6. The actual situation is between these two assumptions. It is to be noted also that, in the case of the lining (Fig. 5), all "friction forces," as shown in Fig. 4, are "shearing forces."

In Fig. 5 and in all subsequent figures and discussion capital letters designate total forces acting on a slice 1 ft long cut from the lining by two vertical planes perpendicular to its longitudinal axis. These forces are represented by the areas of corresponding diagrams (for instance, areas under curves W_a and P_d in Fig. 7). Unit pressures (or shearing stresses) acting on the lining in vertical planes parallel to its longitudinal axis are ordinates of the corresponding curves. The use of lower case letters for unit pressures was thus avoided except in Table 1.

Difference Between the Analogy (Fig. 4) and the Case of the Actual Lining.—In Fig. 4, the clay mass under the platform is assumed fully consolidated, and as soon as the "platform" is released, a new process of additional consolidation begins under the weight of the platform and the silt deposit above it. In the case of the lining of the Lincoln Tunnel the situation was different: First, in shoving the tunnel a cushion of silt along the bottom of the lining was remolded and became liquid; and, second, the overburden under which the silt along the bottom of the lining was consolidated was not increased, but was relieved as the lining passed through it. This can be disclosed by comparing the weight of the overburden at points O′, D′, C′, B′ (Fig. 3) and the values of $P_d + W_p$ (Table 1 and Fig. 6).

Interpretation of the Curve $W_a - P_d$.—In Fig. 7 the values of the weight of the overburden W_a and of the downward pressure P_d are plotted and their difference $W_a - P_d$ is represented in the form of curves. The difference $W_a - P_d$ is the relieved weight of the overburden at a given vertical section of the lining, as expressed in pounds per square inch on the horizontal projection of the lining. In computing these values, the difference $W_a - P_d$ at the center line of the lining (point O) was assumed to be zero.

Fig. 6.—Average Distribution of the Weight of the Lining, Lincoln Tunnel (Pounds per Square Inch)

Due to symmetry, there can be no horizontal shear and hence no vertical shear at point O (center line of the lining). In other words, there can be no relief in the weight of the overburden at that point. Another feature of the curve $(W_a - P_d)$, and of the curves in Fig. 8, is the horizontal tangent at the center line of the lining, obviously due to symmetry.

Conditions of equilibrium require that at any vertical plane between the center line of the lining and its sides (haunches), the total shearing force, acting upward at that plane, must balance the relieved weight between that center line and the vertical plane in question. For each of the vertical planes B, C, and D (Fig. 7) the relieved weight between that plane and the center line of the lining was computed. This is the "accumulated relieved weight in pounds," in Fig. 7. The area of each of the vertical planes B, C, D, above the lining was taken from Figs. 3(*b*) and 3(*c*). It equals numerically the height of the overburden above the points B, C, D, of the lining. The corresponding figures are to be found at the line "area of action of the shearing stress in square feet"

(Fig. 7). By dividing the accumulated relieved weight at each plane by the area of the latter, the average shearing stresses (in pounds per square foot) were computed. At no place is this shearing stress more than 156 lb per sq ft. The value of the shearing strength of the Hudson River silt may be estimated from comparison with other similar materials of the Atlantic Coast. For instance, the shearing strength of the silt in the Thames River at New London, Conn., which is more wet and hence less resistant than the Hudson River silt, is about 150 lb per sq ft as determined by direct shear test. Apparently the average shearing stress above the lining of the Lincoln Tunnel reached the value close to its shearing strength; but no data exist for judging what was the maximum value of that shearing stress. The ordinates of the curves of the "average upward shearing stress" beyond the sides (haunches) of the lining must decrease and must vanish at a certain distance from the tunnel.

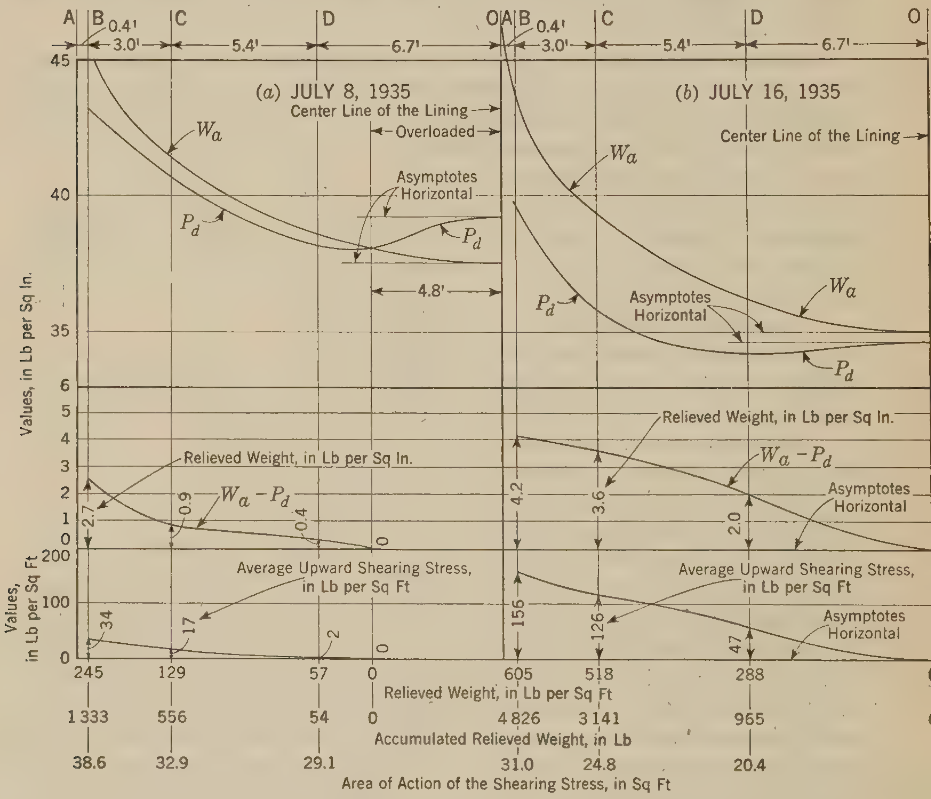

FIG. 7.—EXTENT OF RELIEF FROM TH

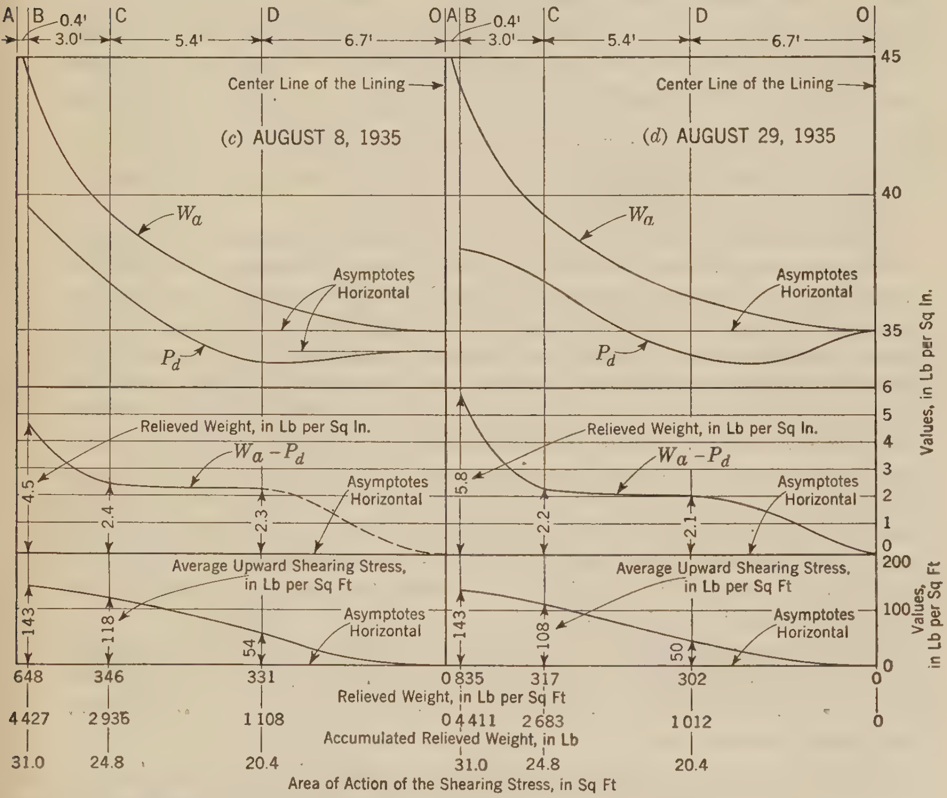
Comparison of the Vertical Upward and Downward Forces Acting on the Lining.—These forces are: The downward pressure P_d; the weight of the lining including the inside silt deposit (W_p in its entirety); and the upward pressure P_u. Their resultant,

$$F_d = P_d + W_p - P_u \ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

is plotted in Fig. 8. The values of W_p are from Fig. 6, for rigid and nonrigid linings, respectively. Since the force $P_d + W_p$ acting downward must be balanced, and the force P_u is not large enough for this purpose, the area bounded by curve F_d, representing the difference of the downward and upward vertical forces acting on the lining shows the force balancing the system in question.

This force may be interpreted as: (*a*) A downward shearing force (such as force F'' in Fig. 4(*c*)); (*b*) a force tending to make the lining settle; or (*c*) items (*a*) and (*b*) combined. There are no data for estimating the value of the downward shearing forces; and some assumption should be made, as, for instance, that the upward and the downward shearing forces at each vertical plane are numerically equal. For comparison purposes, curve F has been plotted in Fig. 8. Under the approximate assumptions made, the difference between areas bounded by curves F_d and F corresponds to the value of the force that tends to make the tunnel settle. On July 8, 1935, this force ($F_d - F$) was considerable (Fig. 8(*a*)), due to the presence of the ridge of freshly remolded silt material. It reduced practically to zero after dredging (July 16, 1935), and afterward gradually increased until August 29, 1935.



WEIGHT OF OVERBURDEN, LINCOLN TUNNEL

Horizontal Pressure on the Lining.—To plot the horizontal pressure on the lining, Table 1 was used again. In Fig. 9 the recorded pressures corrected for compressed air are plotted horizontally at the points of measurement shown in Fig. 3.

Due to the pressure of the surcharge material forming the ridge, the ordinates of curve 1 are about 4 lb per sq in. larger than the ordinates of curves 2, 3, and 4, which are practically the same. The horizontal pressure at the sides (haunches) (point A) on August 29, 1935, was about 40 lb per sq in. Deducting from this value 21.3 lb per sq in. corresponding to the pressure of water on the bottom of the Hudson River, the difference would be $40.0 - 21.3 = 18.7$ lb per sq in. The vertical pressure at the same point and on the same date was $46.3 - 21.3 = 25.0$ lb per sq in. (points A and A′, Fig. 3(*b*)), which corresponds to a ratio of $\frac{18.7}{25} = 0.74$. In a perfect liquid this ratio would be 1. Using the value of 0.74 in the Rankine formula, the corresponding angle of friction of the silt material on August 29, 1935, was about 9°, which is a reasonable value for that kind of material.

The well-known Rankine formula was derived by its author as applying to undisturbed earth mass in which the unit pressure increases from the top downward, following a straight-line law (triangular pressure distribution). Hence, by no means can it be applied after disturbance to the bottom of the lining where the pressure should be practically constant. In this part of the lining the idealized horizontal pressure may be expressed by a vertical line (MN or M′N′ in Fig. 9). In the upper part of the lining (that is, practically above points B′) where the remolded material consolidates, a triangular pressure distribution may be expected, however (lines PN or P′N′, Fig. 9). The slope of the lines PN, P′N′ is too steep due to the fact that the curves, shown in Fig. 9, are constructed considering the remolded silt as a perfect liquid. In reality the pressure at point A may be correct whereas that at point O is exaggerated. Point P″, Fig. 9, is a corrected position of point P′ (for an "angle of friction" of silt equal to 9°).

Change in Average Pressure on the Lining after August 29, 1935.—Detailed data concerning the pressure distribution on the lining after August 29, 1935, are not available. The curve showing the average pressure on the lining[2] reveals the following facts:

(*a*) The average pressure was decreasing until December 24, 1935, when it reached its minimum (36 lb per sq in.). On that day the tie rods were erected. Afterward that pressure was increasing until April 13, 1936, when it was stabilized at a value of 37.6 lb per sq in.

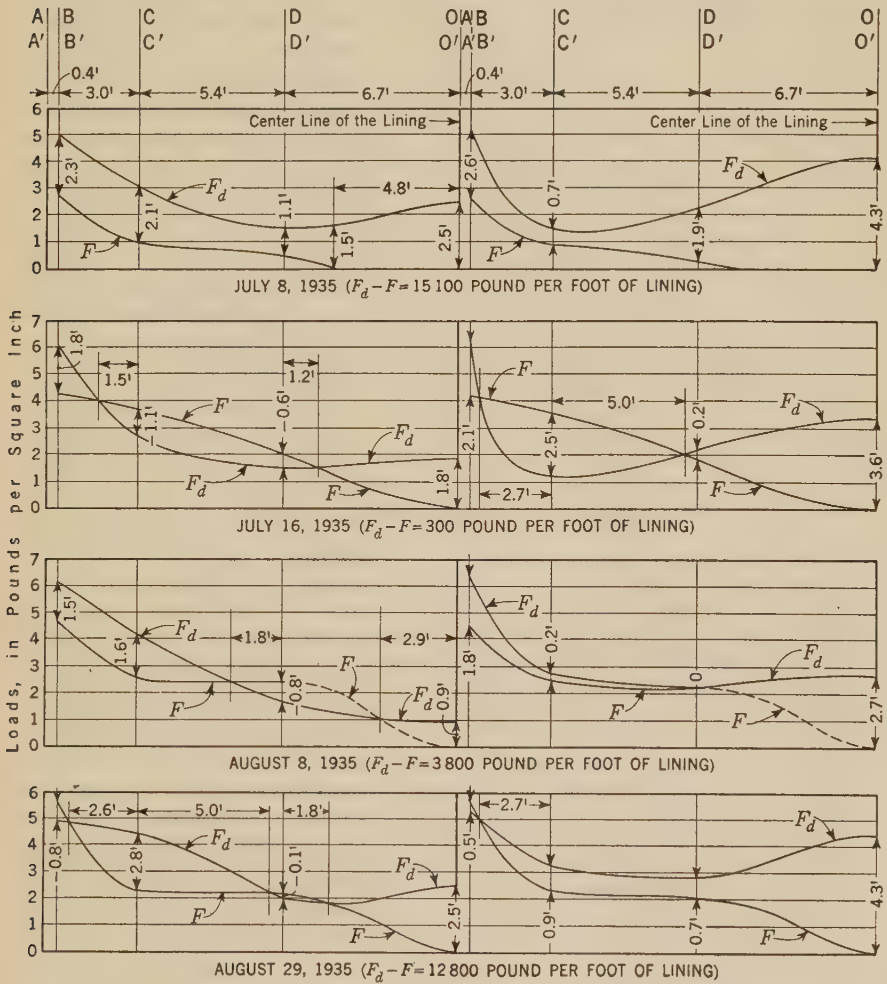
(*b*) On September 30, 1935, the inside silt deposit (weight 16 kips per running foot of the tunnel) was removed.

(*c*) Between December 24, 1935, and April 13, 1936, the roadway was completed, which increased the original weight of the lining (18 kips) to 40 kips per running foot of the tunnel.

A change in load of 1,000 lb inside the lining causes an average change in pressure on the lining equal to $\frac{1{,}000}{2 \times 31 \times 144} = 0.11$ lb per sq in. Corrections due to such changes are:

(1) On December 24, 1935, for the inside silt deposit, 0.11 × 16 = 1.8 lb per sq in., the corrected pressure being equal to 36.0 + 1.8 = 37.8 lb per sq in.

(2) On April 13, 1936, corrections are indicated for both the inside silt deposit and the additional weight of the roadway, these two corrections being of opposite signs. The final pressure, 37.6 lb per sq in., is decreased by 0.11 × (22 − 16) = 0.7 lb per sq in., yielding a value of 36.9 lb per sq in.



JULY 8, 1935 ($F_d - F$ = 15 100 POUND PER FOOT OF LINING)

JULY 16, 1935 ($F_d - F$ = 300 POUND PER FOOT OF LINING)

AUGUST 8, 1935 ($F_d - F$ = 3 800 POUND PER FOOT OF LINING)

AUGUST 29, 1935 ($F_d - F$ = 12 800 POUND PER FOOT OF LINING)

(*a*) RIGID LINING (*b*) NON RIGID LINING

Fig. 8.—Forces That Tend to Drive the Lining Down, Lincoln Tunnel

These results are plotted in Fig. 10, in which the solid line represents the average pressure on the lining as measured in the field, and the dotted line shows that pressure as reduced to the specified standard loading. The reduced pressure decreased systematically until April 13, 1936, when the field records reported a stabilization of the average pressure on the lining.

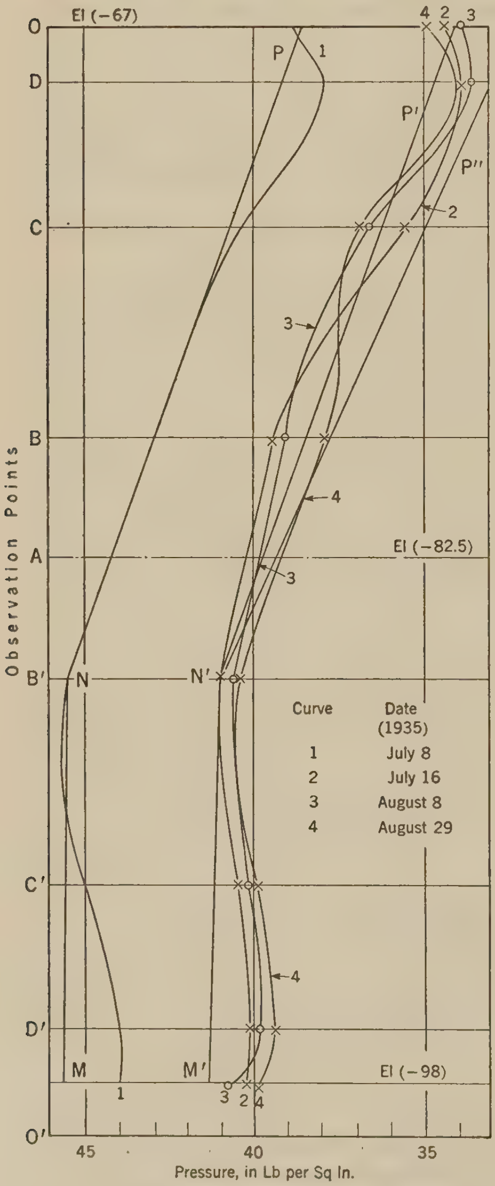


Fig. 9.—Horizontal Pressure on the Lincoln Tunnel Lining

The published material obtained during the construction of the Lincoln Tunnel² is not detailed enough and covers a rather short period (253 days). As an example of a more complete procedure, the Detroit Tunnel³ may be cited. Pressure observations at that tunnel covered the period from December, 1930, to January, 1941—about eleven years. In the ordinary case such a long period of observations may be unnecessary; but it seems advisable to observe pressures on any tunnel during a reasonably long-time interval, which may be estimated, for instance, at three years; this may involve but a small additional expense. It was found at the Detroit Tunnel that the vertical pressure increased and tended to return to its original (preconstruction) value, whereas the horizontal remained more or less constant during the entire period of observations. These facts may be explained by a partial or complete disappearance of shearing stresses, both vertical and horizontal. No definite conclusions as to the disappearance of the shearing stresses can be drawn on the basis of published reports on the Lincoln Tunnel.²

Decrease in the Horizontal Diameter of the Lincoln Tunnel

According to an official statement:²

"Measurements of the horizontal and vertical diameters of the lining showed distortions similar to those that have been observed in other tunnels in Hudson River silt. Immediately after erection the horizontal diameter began to shorten, and the vertical diameter began to lengthen by about the same amount. Nine days after the lining had been erected at the test station, the horizontal diameter had decreased and the vertical diameter had increased, each, by 1½ inches. This was the maximum distortion observed at the test station. From then on, the horizontal diameter increased and the vertical diameter decreased until they returned to their original values six months after the lining was erected [about December 24, 1935; see Fig. 10]."

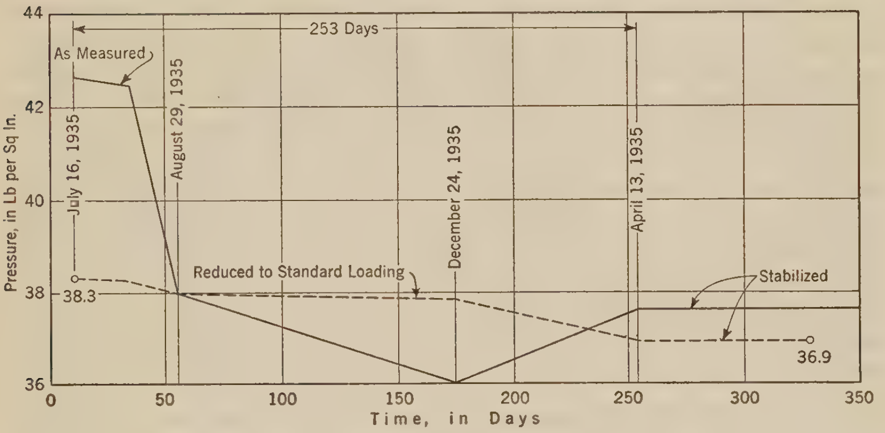

FIG. 10.—AVERAGE PRESSURE ON THE LINING, LINCOLN TUNNEL

A similar phenomenon was observed during the construction of the Chicago Subway. As stated by Professor Terzaghi:[4]

> "Within the first few days after the rings were assembled, the (horizontal) diameter of the rings steadily decreased. The greatest shortening ranged between 1 and 1½ in. * * * After the initial period of shortening the horizontal diameter of the tube increased and after about one year assumed a constant value, which was about 1½ in. in excess of the initial length of the diameter."

Elongation of vertical diameter and shortening of the horizontal diameter seem to be characteristic also of tunneling in North River (New York City) silt where the material is so unstable that the shield can be shoved "blind."

The foregoing examples include tunnels constructed by the shield method in plastic organic silts and plastic clays in which the ratio of the horizontal pressure at a point of the mass to the vertical pressure at the same point is considerable. However, in soils where this ratio is small, such as sandy soils, the horizontal diameter of the lining does not shorten. For instance, John H. Quimby, M. Am. Soc. C. E., in correspondence with the writer, stated:

> "It has been a maxim in constructing all of the East River shield tunnels from the time of the Pennsylvania R. R. tunnels to the present time, that the top iron in the ring should be kept high, i.e. that each ring should be constructed 'out of round' with the vertical diameter longer than the horizontal diameter, since it is practically the universal experience in the soils under the East River, and under the Harlem River as well, that the tunnel rings tend to settle down and elongate on the horizontal diameter."

It follows from this evidence that the shortening of the horizontal diameter of the lining is not characteristic of the shield method generally as is sometimes believed, but that it occurs in plastic soils only, in which the ratio of the horizontal pressure to the vertical is considerable.

It seems undeniable that, to shorten the horizontal diameter, the total horizontal force acting on the lining must be larger than the vertical; yet in the case of the Lincoln Tunnel a careful computation of these forces for all pressure records available since July 6, 1935, did not reveal this to be the case. It must be concluded therefore that the cause of the shortening is to be sought at the very beginning of the shoving. The following explanation may be offered. Before applying force to the shield any point of the bottom of the lining A′O′A′ (Fig. 2) is under the action of a vertical pressure caused by the overburden (silt and water in the river, Fig. 3(*a*)). The bulkhead relieves this vertical pressure (see heading, "Difference between the Analogy (Fig. 4) and the Case of the Actual Lining"); but the lateral pressure that exists in the natural silt mass still persists at the points A′, B′, C′, and D′ and squeezes the lower part of the lining, thus shortening the horizontal diameter. Since the lining is rigid the compressive force at the shield acts not only on the head section of the lining, but also on rear sections through a certain distance. This explains why the decrease in horizontal diameter lasts some days after the lining is set.

So far as its shape is concerned, the graph of lateral pressure distribution at the initial moment of shoving should be similar to line P′N′ in Fig. 9 and its continuation (Rankine or triangular pressure distribution). Due to the remolding of the silt in the bottom of the lining, this pressure is partly replaced by a uniform pressure (distributed approximately as shown by line N′M′ in Fig. 9). There is an opinion that the use of the Rankine formula in the design and analysis of tunnels should be discontinued. Evidence presented in this paper makes it advisable to think twice before doing so.

Action of Compressed Air

The downward vertical pressure P_d, as shown in the first line corresponding to each date in Table 1, may be separated into two parts: (*a*) The active pressure that was exerted by the overburden on the lining as shown in the second line corresponding to each date in Table 1, and (*b*) the pressure exerted by the lining on the overburden due to the action of compressed air during construction. This is the passive pressure of the overburden on the lining, and the pressure-measuring devices recorded the sum of the two. Of course, at no time was the active pressure of the overburden on the lining larger than the weight of the overburden (Fig. 3). Consider, for instance, the action of the compressed air on August 8, 1935. At an air pressure of 28 lb per sq in., the compression stress in the lining at its inside periphery was also 28 lb per sq in. At the outside periphery the average compression stress was only $0.15 \times 28 = 4.2$ lb per sq in., which means that the overburden was loaded approximately with average unit loads of that value acting upward. The resultant of these loads per running foot on half of the lining was $4.2 \times 144 \times 15.5 = 9{,}374$ lb. Upon dividing this value by the area of action of the shearing stress at the sides (haunches) of the lining (34.5 sq ft, see Fig. 3(*c*)), the average value of the downward shearing stress at the haunches caused by the compressed air was $\frac{9,374}{34.5} = 272$ lb per sq in. The shearing stresses in the silt mass caused by the weight of the overburden (Fig. 7) and those due to the action of the compressed air acted in opposite directions. Therefore, the compressed air not only restored the original preconstruction condition in the silt, but even created some excess of safety.

Conclusions

1. During the construction of the Lincoln Tunnel, the weight of the overburden above the tube was relieved by the upward vertical shearing stresses.

2. There were downward vertical shearing stresses below the lining of the Lincoln Tunnel.

3. A diagram of shearing stresses for different points of the periphery, plotted from a horizontal line, has a zero ordinate and a horizontal tangent at the center line of the lining. The ordinates of this diagram increase toward the sides (haunches) of the lining. Such diagrams should be extended beyond the sides (haunches) in order to satisfy conditions of equilibrium; but there are no available data as to the shape of such extensions.

4. The average normal pressure on the lining of the Lincoln Tunnel as reduced to the conditions of a standard loading decreased steadily until it apparently assumed a constant value about eight months after the erection of the lining.

5. The decrease in the average pressure on the lining of the Lincoln Tunnel as cited in conclusion 4 should indicate the gradual change of value in the shearing stresses acting on the mass. No definite conclusions on this subject can be drawn from the information published to date.

6. The decrease in horizontal diameter of the lining of the Lincoln Tunnel is a phenomenon that has been observed in a number of other cases in which the shield method was applied in plastic soils, such as organic silts or plastic clays, but not in sands or similar soils. It is caused apparently by the action of a considerable lateral pressure in the lower part of the lining at the initial stage of shoving, which action is combined with a simultaneous relief in vertical pressure due to the passage of the shield.

7. Diagrams of horizontal pressure on the lining of the Lincoln Tunnel do not sustain the belief that the Rankine formula must be abandoned in the design and analysis of tunnels.

Acknowledgment

The writer extends his thanks to the New York City Tunnel Authority, the Port of New York Authority, and to John H. Quimby, M. Am. Soc. C. E., and G. M. Rapp, Assoc. M. Am. Soc. C. E., for supplying and collating valuable unpublished data used in preparing this paper. James H. Dugan, M. Am. Soc. C. E., was very helpful to the writer in advising him on tunnel terminology.

DISCUSSION

M. A. Drucker,[5] Esq.—As a result of his analysis of the horizontal pressure on the Lincoln Tunnel, the author concludes that the Rankine formula should not be abandoned in the design of tunnels. It is not intended to dispute this statement; but the method indicated for deriving the angle of repose, as well as the angle obtained, seems questionable. In obtaining the angle of repose of the silt, the author considers a uniform horizontal water pressure equal to that at the bottom of the river extending downward through the silt and, in addition, pressure due to a mixture of water and solid particles for the depth of the silt—the total pressure at point A (Fig. 9) being equal to 40 lb per sq in. Two objections may be raised to this method. In the first place, the pressure due to the water is assumed to be divided into two parts, and, secondly, the silt is considered to be a fluid mixture having an angle of repose. That it is not a mixture is evident from the depth of clear water above the top of the silt. It is in fact a sediment having its own angle of repose in water.

Generally for structures in soil below water, the horizontal pressures are calculated on the basis of full water pressure plus the effect of the soil, whose angle of repose is either known or assumed and whose weight is considered to be reduced by the buoyant effect of the water. Applying this method to the case under consideration, it may be seen that the unit water pressure at point A would be $\frac{82.5 \times 64}{144}$ or 36.7 lb per sq in. This result leaves 3.3 lb per sq in., from the measured horizontal pressure of 40 lb, for the effective horizontal soil pressure. For the given weight of silt of 104 lb per cu ft, the effective weight of the solid particles, per cubic foot of silt, would be 40 lb. Using the Rankine formula for active earth pressure, the pressure at point A for a height of silt of 34.5 ft gave the following relationship: $3.3 = \frac{34.5 \times 40}{144} \times \frac{1 - \sin \phi}{1 + \sin \phi} = 9.6 \times \frac{1 - \sin \phi}{1 + \sin \phi}$. From this it was found that $\phi = 29° 20'$—a rather large angle of repose for the material in question. Pressure readings somewhat smaller than the actual pressures could account for this.

The paper contains information from which the angle of repose may be obtained more directly. As stated by Jacob Feld, M. Am. Soc. C. E., the vertical shear planes, discussed by the author, may be considered as approximately equal to the angle of repose of the material.[6]

Assuming that the shearing surfaces start from the horizontal axis of the tunnel and spread out so that they are 67 ft apart at the bottom of the river, which is 46 ft below water level (as given in the paper), the tangent of the angle they make with the vertical is $\frac{0.5\,(67 - 31)}{82.5 - 46} = \frac{18}{36.5} = 0.49$, giving an angle of 26°. A somewhat smaller angle is obtained by considering the bulge of soil over the tunnel. It is stated that, on July 6, this bulge was 12 ft high and 67 ft wide—apparently an unstable condition—and, on July 8, the bulge was down to 7 ft. Assuming the curve of the bulge to be a parabola, as does the author, its maximum slope would be $\frac{7 \times 2}{33.5} = 0.418$ which corresponds to an angle of 22° 40′. This agrees very closely with the assumed upper limit of 20° used in the design of the Holland tunnels in the same Hudson River silt. For such an angle of repose, the pressure due to the solid particles of the silt would be $9.6 \times \frac{1 - \sin 20°}{1 + \sin 20°} = 4.7$ lb. This pressure, added to the 36.7 lb due to the water pressure, would give a total at point A of 41.4 lb which is only 1.4 lb greater than the measured 40 lb and is within the 2-lb limit of accuracy of the pressure measurements as stated in the paper. Incidentally, in accepting the angle of repose of 9° obtained by the author, one would very likely use the general method for finding the horizontal pressure and would obtain a value of $36.7 + 9.6 \times \frac{1 - \sin 9°}{1 + \sin 9°} = 36.7 + 7.0$ or 43.7 lb per sq in. instead of the 40 lb from which the author obtained the 9° angle of repose.

[6] *Proceedings*, Brooklyn Engrs. Club, Vol. 22, No. 2, January, 1924, p. 33.

There is another item in the paper that is of unusual interest. This is the calculated reduction in the measured external pressures due to the internal air pressure which, according to the author, causes the lining to expand. The author finds this correction to be 0.15 lb per sq in. per lb of internal air pressure or 4.2 lb for a maximum air pressure of 28 lb. It is true that after making corrections on this basis the average pressures, p_d and p_u, for the several dates, are brought into close agreement, as shown in Table 1. However, the differences in the measured pressures may be due to entirely different causes or to inaccuracies in the pressure measurements. In support of this view, the writer would like to call attention to the measured horizontal and vertical distortions of the tunnel as given in the paper. It is stated that the increase in diameter in one direction was accompanied by an equal decrease in the diameter at right angles to it. Theoretical calculations show that equal increase and decrease in lengths of diameter at right angles to each are due to external loading.

If the internal air pressure induced passive pressures in the surrounding soil, it would be necessary for the tunnel to expand in all directions. This would cause a greater increase in length of diameter that elongated, due to the outer pressures, and a smaller decrease in the diameter that is shortened due to the same causes. For the case of a corrected pressure of 4.2 lb per sq in., the pressure per square foot would be about 600 lb. Although it is not known what the soil constant, in pounds per square foot per inch of soil compression, would be for the silt around the tunnel, an assumed value of 1,000 lb, for the purpose of discussion, would seem reasonable. Thus, the tunnel diameter would have to increase $2 \times \frac{600}{1{,}000} = 1.2$ in. to develop the passive pressures applied as corrections; also the decrease of the shortened diameter would be reduced by 1.2 in. However, the measurements show that the elongation in one direction was equal to the shortening at right angles and the changes in diameter were about 1.5 in. Had the tunnel stretched in accordance with the assumption of a 1,000-lb soil constant, the total elongation of one diameter would have been 1.5 in. + 1.2 in., or 2.7 in., whereas the net shortening of the diameter at right angles would have been 1.5 in. − 1.2 in., or 0.3 in. If a larger soil constant had been assumed, although the nature of the soil does not seem to warrant it, the necessary differences between the increase and decrease in diameters would have been proportionately less than 2.7 − 0.3, or 2.4 in., but still of a magnitude that would have shown up in the measurements. Even for a soil constant of 5,000 lb, the difference between the elongation of one diameter and the shortening of the one at right angles to it would have been about 0.5 in. Also, the tendency of the tunnel to stretch, caused by the tensile stresses set up by the internal air pressures, is offset by the ring shortening due to the compressive stresses caused by the larger external active pressure. Furthermore, as the internal air pressure did not exceed 28 lb per sq in., which was less than the minimum external water pressure, then, at any point on the tunnel, the active outer pressure was greater than the inner air pressure. It is difficult to understand, therefore, how the internal air pressure could induce a passive pressure in the surrounding soil.

John M. Bird,[7] Assoc. M. Am. Soc. C. E.—This paper is an excellent interpretation of field data collected, for the most part, from measurements taken during and after the construction of the Lincoln Tunnel under the Hudson River at New York City. In addition to analyzing these data, Professor Krynine has compared the pressures on the Lincoln Tunnel with those on the Central Avenue Pipe Tunnel in Detroit. A few data referring to the Chicago Subway are also cited by the author. All three tunnels were constructed in plastic soil. This paper is a definite contribution to the extremely limited literature on earth pressures on tunnels. The writer feels that, in interpreting these field data, Professor Krynine has revealed a very important pattern that the earth pressures on tunnels constructed in plastic soils appear to follow. A study of the field data for the Detroit Tunnel indicates a pressure pattern similar, in part, to that of the Lincoln Tunnel. A study of the earth pressures observed on other tunnels seems to substantiate the existence of a definite pattern that the earth pressures follow.

The writer will discuss conclusions 1 to 7 in three parts. Conclusions 1, 2, 4, and 5 will be discussed in Part 1, conclusion 3 in Part 2, and conclusions 6 and 7 in Part 3.

Part 1.—The author states (conclusion 1):

> "During the construction of the Lincoln Tunnel, the weight of the overburden above the tube was relieved by the upward vertical shearing stresses."

This fact appears to be unassailable if the field data are taken at face value. The relief in pressure during construction and continuing for a certain short period after construction has been completed, as brought out in conclusion 4, is the first phase in the pattern followed by earth pressures on the lining. Apparently, there are two stages of pressure variation that must be considered in an analysis of data concerning pressure on the lining of a tunnel whether the tunnel be subaqueous or subterranean. The first stage is one in which pressures exist due to the action of a disturbed soil mass that is in a condition of temporary equilibrium. During the second stage, pressures exist due to the action of a soil mass which is undergoing readjustment in reaching a final condition of equilibrium. The first stage takes place during construction and for a short time following completion of construction. During this first stage, the vertical pressures on the lining are decreasing. Pressure-variation records for the Detroit Tunnel indicate that the vertical pressure on the lining decreased for a period of approximately three months. Similar records for the Lincoln Tunnel show that the average vertical pressure, after having been reduced to a specified standard loading, decreased systematically for the 253 days of observation "until it apparently assumed a constant value" (see conclusion 4). It is evident that the equilibrium of the earth mass was disturbed by driving the lining through the soil. Also, the soil mass is in a temporary condition of equilibrium during this stage since another variation in pressure, indicative of a readjustment of the soil mass, must occur before the final equilibrium is reached. Since long-time pressure observations were made at the Detroit Tunnel (from December, 1930, to January, 1941), it is possible, by examining the pressure variation during this period, to find evidence of the two stages of pressure variation. These records indicate that a decrease in the vertical pressure on the lining prevailed for a period of approximately three months (stage 1) and thereafter the pressure was constantly increasing for several years (approximately five years) until a final and permanent condition of equilibrium was reached (stage 2). Since, after this five-year period, the vertical pressure appeared to remain fairly constant, it is not unlikely that a final condition of equilibrium was reached. The period of observation for the Lincoln Tunnel is short, and, as the author states, no definite conclusions can be drawn from the information published to date. It is likely, however, that the period during which a steady decrease in the vertical pressure was noted (253 days) corresponds to the first stage of pressure variation and that a second stage during which the vertical pressures increase steadily will follow. In the case of the Detroit Tunnel, the vertical pressure increased until it nearly equaled the static head at the elevation of the measured pressure. Probably, a similar stage occurred in the case of the Lincoln Tunnel. The author states, however, that a final stabilization of pressure was reached at the end of the stage of decreasing vertical pressure. This seems unlikely to the writer.

---

[7] Asst. Prof., Civ. Eng., Univ. of Tennessee, Knoxville, Tenn.; on loan to Civ. Eng. Dept., Univ. of Texas, Austin, Tex.

As the author states in conclusions 1 and 2, the decrease in pressure is caused by vertical shearing stresses within the earth mass. It must follow that an increase in pressure, as was noted on the lining of the Detroit Tunnel, is due to the diminishing or vanishing of these shearing stresses. During the period of temporary equilibrium when the vertical pressures are decreasing,[8] "* * * maximum resistances in the mass are being mobilized to transfer weight away from the tunnel," and, during the period of increasing vertical pressures culminating in final equilibrium, there is a transfer of some pressure to the tunnel. The writer believes that the soil mass, upon being disturbed, tends to form an arch above the tunnel, transmitting the pressure of much of the overlying soil through the soil arch to the earth mass adjacent to the tunnel. This idea was presented by the late J. C. Meem, M. Am. Soc. C. E., in 1907.[9] The two ideas, one of arch action within the soil and the other the relief in pressure through vertical shearing stresses, are merely two aspects of the same phenomenon. For subaqueous tunnels, it may be considered impracticable to assume that a definite relief in pressure will result from such arch action. However, in a material such as the organic clayey silt of the Hudson River and the blue clay in which both the Detroit and Chicago tunnels are built, a soil arch is probably formed. In the case of the Lincoln Tunnel, the creation of the bulge or the ridge at the top boundary of the earth mass during the initial period of the soil's disturbance appears to indicate that this arch action is initially in effect. It is unlikely that the soil arch will endure for a long period of time; in other words, it is unlikely that the vertical shearing stresses set up to relieve the pressure will continue indefinitely. In some way, due to some cause, the arch action will break down and transmit back to the tunnel lining some, if not all, of the load of the overburden (preconstruction pressure). The writer likens this breakdown of the arch action in the soil mass to the action that would take place within an asphalt beam that was initially deflected upward and allowed to remain over its end supports for an indefinite time. Although the beam would maintain this deflection for a certain period, eventually, due to its own weight and possibly due to vibrations from external causes, a form of plastic flow would cause the beam to return to its original horizontal position.

[8] "Earth Pressure on Tunnels," by W. S. Housel, published as part of the Symposium on "Earth Pressure and Shearing Resistance of Plastic Clay," *Transactions*, Am. Soc. C. E., Vol. 108 (1943), p. 1045.

The nature of the stresses set up to relieve the vertical pressure on the tunnel lining is of great interest to the foundation engineer. Of much greater importance, however, is the necessity of answering the following three questions:

1. How much decrease in pressure can be expected from vertical shearing stresses, and for what period of time will this relief exist?
2. Why is not this relief in weight permanent, and during how long a period do the shearing stresses diminish?
3. Do the shearing stresses finally vanish or do they transmit, permanently, some part of the load from the tunnel lining to the adjacent earth mass?

Answers to these three questions will come only as a result of (1) many more field studies like those for the Lincoln and Detroit tunnels and (2) an interpretation of the data from these field studies like that in this paper.

To know fully how much decrease in pressure can be expected, more information as to the shape of the area on which the shearing stresses act must be secured. The straight-line shearing surfaces in Fig. 2(*a*) are but crude approximations. The exact shape of these surfaces is indeterminate and depends on the type and condition of the soil mass in which the shearing stresses occur. The period of time during which the relief in pressure exists is a variable dependent on local conditions. For the Detroit and Lincoln tunnels, the period lasted from three months to a year, approximately. The answer to the question as to why the arch action or the shearing stresses diminish lies, possibly, in the effects of vibrations set up as a result of externally applied forces. Even a slight vibration might cause sufficient readjustment of the soil particles to cause a redistribution of stress. The period of time for the transfer of load back to the tunnel is a variable dependent on local conditions. It may be a few months but, as was the case for the Detroit Tunnel, it may be a number of years. That some permanent or residual shearing stresses exist in the soil mass as a result of the disturbance to its equilibrium is indicated by the fact that the lateral pressures against the tunnel lining of the Detroit Tunnel remained fairly constant and were substantially less than the static head after final equilibrium was reached. W. S. Housel, M. Am. Soc. C. E., states[8] that an indication of a permanent change in the condition of equilibrium in the soil mass from its preconstruction state may be found in the fact that the tunnel structure weighed less than the displaced earth and yet, in final equilibrium, vertical stresses of approximately the same magnitude as the static head existed.

---

[9] "The Bracing of Trenches and Tunnels with Practical Formulas for Earth Pressures," by J. C. Meem, *Transactions*, Am. Soc. C. E., Vol. LX (June, 1908), p. 1.

Fig. 10 shows the variation of the average vertical pressure with time. The writer has computed what may be termed the average static head by averaging the pressures due to the weight of the overburden at points O, D, C, and B in Fig. 3(*a*). A similar procedure was used by the author in determining the average p_d in Table 1. A value of 39.2 lb per sq in. is thus obtained for the average static head. A comparison of the average vertical pressure and the average static head should indicate that the corrected average pressure stabilized at 36.9 lb per sq in. on April 13, 1935, is still considerably below the average static head value of 39.2 lb per sq in. Probably some increase in the average vertical pressure has occurred since this date. It is possible that the pressure will become approximately equal to the static head, as was the case for the Detroit Tunnel.

Part 2.—The author states under the heading, "External Forces Acting on the Lining and on the Adjacent Silt Mass: Interpretation of the Curve $W_a - P_d$," that

> "Due to symmetry, there can be no horizontal shear and hence no vertical shear at point O (center line of lining). In other words, there can be no relief in the weight of the overburden at that point."

In conclusion 3, Professor Krynine states that

> "A diagram of shearing stresses for different points of the periphery, plotted from a horizontal line, has a zero ordinate and a horizontal tangent at the center line of the lining."

Unquestionably, due to symmetry, there can be no vertical shear at point O, but, if there is to be no relief in the weight of the overburden at that point, the rate of change of the shear $\frac{ds_s}{dx}$ is assumed to equal zero at point O. For example, if an element of the soil mass of unit thickness is taken directly above point O, as shown in Fig. 11, the shearing stress on a vertical section a distance

Δx from point O will be $\frac{ds_s}{dx}\,\Delta x$. The pressure at the base of the element is p pounds per square inch, which corresponds to the measured p_d shown in Table 1. Writing the equation $\sum F\,v = 0$ for the forces on the element:

$$\gamma\, h\, \Delta x - p\, \Delta x - \frac{ds_s}{dx}\,\Delta x\, h = 0 \ldots\ldots(3)$$

and

$$\gamma\, h - p = W_a - P_d = \frac{ds_s}{dx}\, h \ldots\ldots(4)$$

in which the weight of the overburden expressed in pounds equals $\gamma\, h\, \Delta x$; and γ = unit weight of the mass.

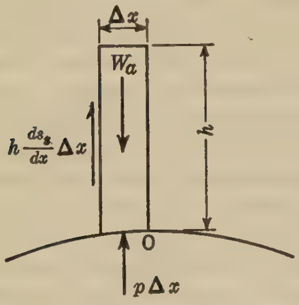

FIG. 11

To have no relief in weight at the center line, the rate of change of the shearing stress $\frac{ds_s}{dx}$ must equal zero at point O. The author apparently makes this assumption in conclusion 3 by stating that the diagram of shearing stress has a horizontal tangent at the center line. The writer admits that this may be the case. Evidence of such a condition will come only through experimental study. However, it does appear that the field data fail to support this theory, provided symmetry is assumed. A study of Fig. 7 shows that, on July 8, 1935, there is an overload at point O (P_d being greater than W_a) and also that downward vertical shearing stresses exist, although the values of these stresses have been omitted from Fig. 7. The writer has drawn the complete ($W_a - P_d$)-curve for this date and has determined the downward vertical shearing stress at point O in an approximate fashion (see Fig. 12). In making this rough computation of the vertical shearing stress at point O, the writer followed a method similar to that used by the author in his determination of the shearing stresses at the other points on the periphery. The area under the ($W_a - P_d$)-curve between the zero point (4.8 ft to the left of point O) and point O was computed on the basis that the curve was parabolic. This area, represented by $2/3 \times 4.8 \times (1.6 \times 144)$, equals 740 lb—the accumulated relieved weight between the two points in question. The area of action of the shearing stress is 28 sq ft, using the value of 28 ft for the height of the silt column above point O in Fig. 3(*b*). The approximate downward shearing stress equals $\frac{740 \text{ lb}}{28 \text{ ft}}$ or 26.4 lb per sq ft. On July 8, 1935, the vertical downward pressure P_d equaled 39.1 lb per sq in., the weight of the overburden W_a equaled 37.5 lb per sq in. (showing an overload of 1.6 lb per sq in.), and the vertical shearing stress (downward) was approximately 26.4 lb per sq ft. Fig. 7 shows that, on July 16, 1935, and on August 8, 1935, the weight of the overburden was relieved by the action of upward vertical shearing stresses. The field data show that, on August 29, 1935, no relief in weight, and thus no shearing stresses, existed at point O. Accepting the field data as exact, it must follow that on the first three dates symmetry was lacking and the rate of change of the shearing stress $\frac{ds_s}{dx}$ was not equal to zero at point O. If pressure intensities had been taken at corresponding points on each side of the center line of the lining, it would have been possible to determine if symmetry did exist. Reviewing Table 1, downward pressures, p_d, appear to have been taken only at points O, D, C, and B on the periphery; thus, it is impossible to tell whether there was a symmetrical condition about the center line on the aforementioned four dates. The deformations arising from the decrease in the horizontal diameter of the lining that commenced as the lining was being driven through the silt may have caused the symmetry to be broken.

(b) AVERAGE SHEARING STRESS

(Upward) $-s_s$ (Downward)

FIG. 12.—COMPLETE ($W_a - P_d$)-CURVE FOR JULY 8, 1935

Part 3.—The decrease in the horizontal diameter commencing immediately after the erection of the lining is an extremely interesting phenomenon. The undeniable implication arising from this occurrence is that the horizontal pressure on the lining must exceed the vertical pressure. Such a relation between the horizontal and vertical pressure is not commonly expected in an undisturbed soil mass. The ratio has been found to be approximately 0.7 for plastic soil of the type of the Hudson River silt.[10] It appears logical that this phenomenon should occur only in soils that have a considerable ratio of the horizontal pressure to the vertical pressure in the mass. Since the field data for the Lincoln Tunnel show that the ratio of horizontal pressure to vertical pressure is less than unity (0.74 on August 29, 1935), an explanation of this phenomenon is necessary. The writer feels that the author's explanation—namely, that its cause must be sought at the very beginning of the shoving—is a probable answer.

---

[10] "Design of Tunneled Sewers in Unstable Ground," by Robert G. Hennes, *Civil Engineering*, April, 1932, p. 248.

An examination of Fig. 9 showing the horizontal pressures on the tunnel lining indicates to the writer that the general shape of the curve from point O to point B′ (P to N) follows the straight-line law (triangular pressure distribution) as used by Rankine in his formula. This would lead to the conclusion that the Rankine formula may be applied without serious error to the determination of lateral pressures from point O to point B′. Conclusion 7 is excellent. It is logical that the Rankine formula should not be used for determining lateral pressure below point B′ since the pressure on this section of the lining is shown by Fig. 9 to be fairly uniform.

General Remarks.—Great care should be exercised in interpreting field data such as those for the Lincoln Tunnel. Fig. 7 shows that the maximum relief in weight, occurring at point B on the periphery, ranges from 2.7 lb per sq in. on July 8 to 5.8 lb per sq in. on August 29. Also, at the center line of the lining (point O) the "relief in weight" varies from an overload of 1.6 lb per sq in. on July 8 to a load of O lb per sq in. on August 29. In view of the fact that the accuracy of measurements made with the special silt gage and plugs was limited to the range, 1 lb per sq in. to 2 lb per sq in., it is entirely possible that much of the difference in W_a and P_d may have been caused by the inability of the gages to record true pressures. Certainly the overload at point O on July 8 could be attributed to this cause. It is within the realm of possibility that there was no relief in pressure. Although the writer acknowledges that this is not likely, he merely wishes to state that a slight inaccuracy in the pressure-gage measurements could easily account for a difference in pressure of 2.7 lb per sq in. In Fig. 3, the author presents the computed values of the overburden pressure W_a at ten points on the periphery, using in these computations a value of 64 lb per cu ft as the density of the Hudson River water and a value of 104 lb per cu ft as the weight of the saturated clayey silt. An error of as little as 4 lb per cu ft in estimating the density of the silt could produce a change in pressure on the lining equal to some of the values considered in this paper as relief in weight. To illustrate the effect of a variation in density of the silt on the lining pressure, a column of the silt mass 20 ft high and 1 sq in. in cross section, with a volume of 240 cu in. or 0.14 cu ft, has been selected. A variation in density of 4 lb per cu ft would cause a change in pressure of 0.56 lb per sq in. at the base of this column. Such an error in determining the density of the silt mass is certainly possible, since there is doubt in the writer's mind that a homogeneous, uniform material exists for 20 ft below the bed of the Hudson River. In addition, it does not seem likely that the bed of the Hudson River is a level ground surface. Therefore, it is difficult to justify using values for the height of the silt columns above the tunnel lining expressed to the nearest 0.1 ft. Certainly field measurements of this accuracy would be most difficult to make in the near fluid silt. A slight variation in the height of the overburden could cause substantial changes in the values of W_a and could be responsible for some of the difference between W_a and P_d hitherto attributed to relief in weight. Inaccuracies in gage readings, errors in estimating the density of the silt mass, and errors in determining the height of the silt column above the tunnel lining could produce results giving a pressure difference less than that which actually existed. The only purpose in emphasizing these possible sources of error is to caution against too strict an interpretation of the field data. Unless these data are exact (a fact which any engineer familiar with field and laboratory measurements will doubt), misleading results may be obtained. No criticism of the author's valuable interpretation of the field data on the Lincoln Tunnel is intended.

This excellent paper is a real contribution to the literature on earth pressures on tunnels. Many more similar studies are needed before definite conclusions can be reached as to the variations in pressure on tunnel linings constructed in plastic soils.

D. P. KRYNINE,[11] M. AM. SOC. C. E.—The possibility of the transfer of the weight of the overburden above a tunnel to the adjacent earth or rock mass is evident from the simple analogy shown in Fig. 13. If body A (weight W) is pressed between two plates B, it will not fall, provided the force of friction between body A and plates B balances the weight W. A system of shearing stresses acting upward is created in body A. Presumably, this system of shearing stresses extends into plates B. Another set of shearing stresses is created in plates B to balance the former system and to transmit the weight W to the earth. This analogy corresponds to the case of a tunnel in rock which may be in equilibrium without lining, or to the case of holes pierced in a masonry wall.

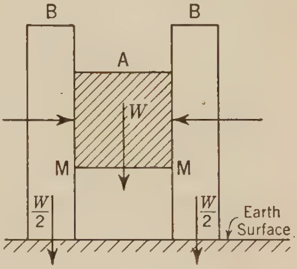

FIG. 13.—FRICTION ANALOGY

If friction between body A and plates B still exists but is not strong enough to prevent body A from falling, an upward force F, with a value less than W, may support body A in equilibrium. In this case, a system of shearing stresses with a resultant $W - F$ is set up in body A. Shearing stresses in plates B transmit part of the weight $W - F$ of body A to the earth. This situation corresponds to that in a tunnel provided with lining or to the redistribution of the weight of grain in a bin. The force F is analogous to the pressure absorbed by the lining of a tunnel or by the bottom of a bin, respectively, whereas the balance of the weight $W - F$ is transmitted to the mass surrounding the tunnel or to the walls of the bin, respectively. Secondary forces and stresses are introduced into the mass during construction of a tunnel so that the analogy of Fig. 13 may be complicated or altered.

Two extreme cases of circular tunnels in plastic soils are: (*a*) Circular holes in plastic rocks such as granite or basalt, when no lining is required because of the high shearing strength of the rock material; and (*b*) circular tunnels in plastic organic silt of restricted shearing strength of the Lincoln Tunnel type. Circular tunnels in weak plastic rocks or in plastic clays are classified between the two limits.

Shear Diagram for the Case of a Tunnel in Rock.—Fig. 14 represents a circular hole in rock, the radius of the hole being r and the height of the overburden above the level of the sides (haunches) being *h*. Because of symmetry, there is no vertical shearing stress along the center line OO′. The weight of the part of the overburden AOO′B, separated from the remainder of the mass by section AB, is carried by that section in cantilever action. The average shearing stress (in tons per square foot) acting along section AB equals area AOO′B (in square feet), divided by ordinate AB (in feet) and multiplied by the unit weight of the rock material (in tons per cubic foot). The shear diagram, at the bottom of Fig. 14, has been plotted for a shallow tunnel ($h/r = 2$) and a rather deep tunnel ($h/r = 6$). For plotting purposes, the weight of the rock material has been assumed at 1 ton per cu ft, the vertical scale of shearing stresses (tons per square foot) being the same as that of horizontal distances (in feet). To use this diagram, the ordinates must be multipled by the actual unit weight of the rock material (in tons per cubic foot), and due correction must be introduced for the actual ratio of the vertical and horizontal scales. From Fig. 14 it is evident that the average shearing stress at the sides (haunches) of a tunnel in rock without lining cannot be larger than $r\,\gamma$, in which r is the radius of the tunnel in feet and γ is the unit weight of rock material in tons (or in pounds) per cubic foot. Assume that the maximum shear on some oblique plane may be twice the vertical shear; then it may be concluded, as an example, that a circular tunnel (r = 30 ft) would stand without lining at any depth in

---

[11] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

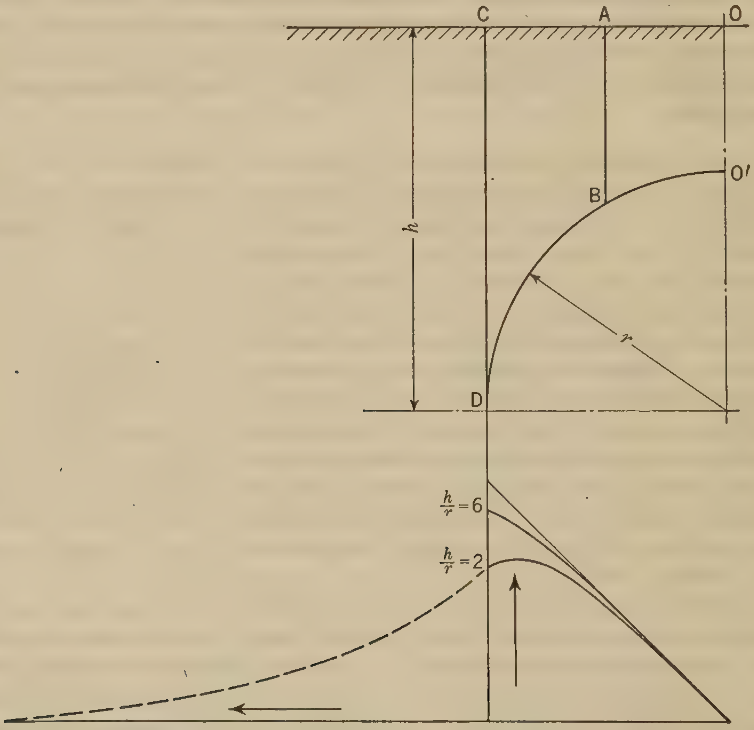

Fig. 14.—Shear Diagram for the Case of a Tunnel in Rock

rock weighing 160 lb per cu ft, if the shearing strength of that rock is 2 × 30 × 160 = 9,600 lb per sq ft, or about 66 lb per sq in. Although the diagram in Fig. 14 shows that the average shearing stress at the sides (haunches) of a tunnel in rock, without lining, increases only slightly with the depth of the tunnel, geological conditions, such as fissures or cleavage planes, may change the foregoing computations substantially.

In a semi-infinite mass, of rock or of earth, there is a certain ratio between the horizontal and vertical pressures which is assumed constant. It is termed "coefficient of pressure at rest" and is often designated by the symbol K_o. As soon as a tunnel is constructed, the value of K_o next to the tunnel (and, theoretically, throughout the entire rock mass) decreases. The coefficient of pressure at rest preserves its original value K_o only at an infinite distance from the tunnel. Thus, the mass tends to move toward the tunnel; hence, the horizontal shearing stresses acting against the impending movement of the mass are directed from the tunnel. Shearing stresses in the overburden COO′D (Fig. 14) itself obviously act in the same direction (shown by an arrow in Fig. 14). Since there is no horizontal shear at infinity, the diagram of shearing stresses beyond the sides (haunches) of the tunnel must have the shape indicated by the dashed lines in Fig. 14. The shape of the shear-stress diagram for deep tunnels suggests the possibility that the maximum average shear may occur somewhere beyond the sides (to the left of the haunches in Fig. 14). It is needless to add, however, that both Figs. 14 and 15 are considered simple freehand sketches and that no attempt has been made to correlate Fig.14 with Fig. 15. Both of these illustrations are intended to furnish qualitative pictures of corresponding phenomena only.

The shear diagram in Fig. 14 refers to both horizontal and vertical stresses. It may be concluded that the weight of the rock mass close to the boundary is relieved by shearing stresses not only above the tunnel but also on both sides of the tunnel; and nowhere close to that boundary is the mass overloaded. To determine what part of the mass takes care of the relieved weight, the pattern of principal stresses around the tunnel must be considered.

Principal Stresses Around a Tunnel in Rock.—Before the construction of the tunnel, the principal stresses run vertically (the major principal stress) and horizontally (the minor principal stress). This original pattern is shown in Fig. 15(*a*). Since the piercing of a circular hole originates shears both vertically and horizontally, the directions of principal stresses change. However, a major principal stress (for instance, that emanating from point 2, Fig. 15(*b*)), after being distorted by the shearing stresses, tends to return to its original vertical line, reaching the line at an infinite depth below the hole. This is necessarily so, since at an infinite depth the hole exerts no influence. Since the major principal stress above and below the hole is distorted in two opposite directions, the shearing stresses above and below the tunnel act in opposite directions. Thus, the relieved weight close to the boundary of the mass is transmitted to that part below the sides (haunches) of the tunnel.

The vertical shearing stresses, which relieve the weight of the silt mass, become changed in sign at the horizontal line passing through the sides (haunches) of the tunnel H (Fig. 15) so that this horizontal line is the locus of zero vertical and horizontal shear. Mathematical analysis (which is beyond the scope of this paper) may show a more precise position of the locus. The principal stresses along the locus in question are vertical and horizontal; hence, the tangent to the distorted trajectory of the major principal stress is vertical.

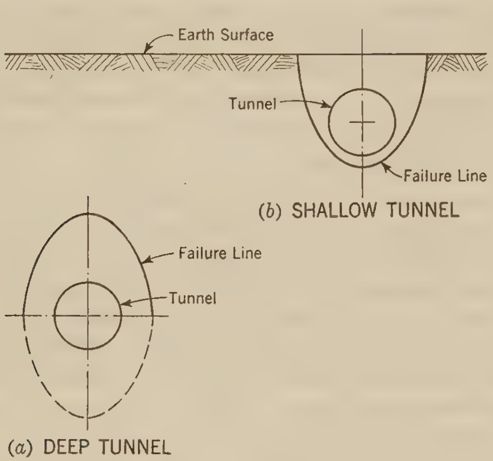
FIG. 15.—PATTERN OF PRINCIPAL STRESSES BEFORE (*a*) AND AFTER (*b*) CONSTRUCTION OF A TUNNEL IN ROCK, WITHOUT LINING

The trajectory of the major principal stress at the center line of the hole consists of two vertical straight lines and a semicircumference belonging to the hole. All other trajectories of major principal stresses (for instance, the trajectories emanating from point 2, Fig. 15(*b*)) consist of four distinct parts: (*a*) From the boundary to which the trajectory is normal to the inflection point A; (*b*) from the inflection point A to the intersection with the locus of zero vertical shear (point B); (*c*) back to the inflection point C, and (*d*) finally to infinity. The vertical shear along the trajectory increases from zero at the boundary to a maximum at the inflection point A. Another maximum value, but of the opposite sign, is found at the inflection point C. At the center line of the hole, O′ and O″ are considered inflection points.

Arching in Rock.—It has been suggested that an arch forms in the material above the tunnel. As far as rock or other homogeneous plastic material of considerable shearing strength is concerned, there is no such arch. The relief in pressure above the tunnel is due to the action of shearing stresses which transmit part of the weight of the rock mass close to the boundary to the lower strata. As the result of the action of the shearing stresses, straight trajectories of major principal stresses become distorted as in Fig. 15(*b*).

Case of Insufficient Shearing Strength of the Plastic Material Surrounding the Tunnel.—If a lateral support of a semi-infinite mass (such as a retaining wall) yields, a wedge separates from the remainder of the mass. In a similar way, if the lining of a tunnel is flexible and yields, there may be considerable settlement above the tunnel which is analogous to the yield of a lateral support.



(*b*) SHALLOW TUNNEL

(*a*) DEEP TUNNEL

FIG. 16.—SCHEMATIC DIAGRAMS OF FAILURE ZONES AROUND TUNNELS

In both cases, a failure line (sliding surface) is formed. In the case of a tunnel, this failure line bounds a closed zone in which rock or clay material tends to descend toward the opening. J. R. Dinsdale has shown[12] how the material falling from the roof and sides of a mine tunnel was gradually replaced with logs until the final closed failure zone was reached. Fig. 16 shows schematically a closed and an open failure zone, the latter taking place if the tunnel is a relatively short distance underground. R. Fenner makes some simplifying assumptions and, using abundant mathematics, even determines the ratio of the axes of the elliptical failure line.[13] This ratio is given as tan $\left(45° - \frac{\phi}{2}\right)$, ϕ being the angle of internal friction of the material in which the tunnel is built. According to Mr. Fenner, in the case of a shallow tunnel, the failure line is parabolic. Of course, the question of the theoretical shape of the failure zones above a tunnel is subject to discussion. The writer believes, however, that the basic idea of a closed failure zone above a deep tunnel, or of an open failure zone in the case of a shallow tunnel, is sound. The same considerations as those for a hole pierced in rock may be applied to a closed failure zone. Thus, the distorted trajectories of major principal stress run around the closed failure zone, and the weight of the material above the zone is transferred by the shearing stresses to sections at and close to the bottom of the failure zone. The lining is loaded by the weight of the material inside the failure zone only.

---

[12] "Ground Pressures and Pressure Profiles Around Mining Excavations—1," by J. R. Dinsdale, *Colliery Engineering*, December, 1935, Fig. 8, p. 409.

[13] "Untersuchungen zur Erkenntniss des Gebirgedruckes," by R. Fenner, *Glueckauf*, Vol. 74, 1938, pp. 681 and 705.

Before applying these considerations to tunnels in silt of the Lincoln Tunnel type, it is necessary to determine whether a failure line due to downward motion of the silt material may be formed above a tunnel of this type. It should be realized also that, in a general case, shearing stresses above the tunnel are due to two causes—(*a*) consolidation of the silt layer of variable thickness, and (*b*) deflections of the lining. Even when no failure zone is formed, there are upward shearing stresses, the magnitude of which is controlled by the value of the vertical displacements due to causes (*a*) and (*b*).

Subaqueous Tunnels in Silt Constructed by the Shield Method.—The pressure on the lining of subaqueous tunnels in silt, constructed by the shield method, passes through the following stages:

(1) When the lining is shoved and the bulge is being formed, a frictional force along the shearing surfaces (Fig. 2(*a*)) acts downward, thus increasing the preconstruction weight of the overburden. This increase in weight lasts until the bulge starts moving downward. It is quite possible, therefore, that, on July 8, 1935 (see Fig. 7 and Table 1), there was an overload at the center line of the lining of 1.6 lb per sq in. (The lining is deflected during the shoving more than in the subsequent stages of the work when pressure and, hence, deflections are relieved by erosion, dredging, and upward shear and are perhaps somewhat redistributed.)

(2) Because of erosion and especially dredging of the bulge, the pressure on the lining decreases. At the same time two processes start—consolidation of the silt mass above the lining and healing of bonds along the sliding surfaces, as shown in Fig. 2. In stage 2, the pressure on the lining first decreases to its preconstruction value and afterward becomes less than that value. This statement is made with the understanding that a correction for compressed air has been introduced.

(3) Consolidation and healing of the mass proceed, and the pressure on the lining decreases. Examination of Fig. 3 shows that tunnels of the Lincoln Tunnel type are too shallow to develop a closed failure zone at this stage. In addition, it is possible that an open failure zone such as that shown in Fig. 16(*b*) cannot form since there are already sliding surfaces, as shown in Fig. 2. Examination of Fig. 7 reveals also that the shearing stress at the sides (haunches) of the tunnel practically equaled the shearing strength of the silt. Hence, although in a general case it is possible to decrease the pressure on the lining by making it more flexible, in the case of the Lincoln Tunnel there was little chance to do so. The relieving shearing stresses at this stage were mostly due to differential settlement (that is, to differences in the thicknesses of the consolidating silt layer at the center and at the sides (haunches) of the tunnel). The question "For what period of time will this relief exist?" may be answered only on the basis of the existing data—for about 253 days in the case of the Lincoln Tunnel and for about 90 days in the case of the Detroit Tunnel.

(4) The final stage, if any, could be characterized by the tendency of the earth mass to return to the preconstruction stress condition. The record period in the case of the Lincoln Tunnel was too short, and there is no published evidence of such return. The Detroit Tunnel data cannot be applied to the Lincoln Tunnel unconditionally since the method of construction in both cases

was not the same. The writer does not know whether or not, in a general case, the plastic mass, in which a circular tunnel is built, returns completely to its preconstruction-stressed state.

Vertical and Horizontal Silt Pressure on the Lining.—There was a relief in weight of the overburden in the case of the Lincoln Tunnel equal to about 10% at the sides (haunches) and to practically nothing at the center line, the average relief being about 6%. The diagram of actual vertical silt pressure may be obtained easily from Fig. 3(*c*) by introducing corrections from Fig. 7. The diagram in question is not a rectangle as is sometimes assumed.

In regard to the horizontal pressure on the lining, the writer believes that the Rankine formula is applicable—at least at the upper part of the tunnel. To be more precise, there is triangular lateral pressure distribution in the upper part of the lining. The question of lateral pressure is closely connected with that of the angle of internal friction in silt (or a similar value of the angle of repose). When the Holland Tunnel was designed, the angle of internal friction of 20° was assumed; and, using a certain conventional computation procedure, results very close to those measured during the construction of the Lincoln Tunnel were obtained. With an angle of internal friction of 9°, and using a somewhat different computation procedure, acceptable results may be obtained. In reality, neither 20° nor 9° is a correct value. The angle of internal friction of nonconsolidated plastic clays (and the Hudson River silt is very similar to such clay) is not far from zero. The writer believes firmly that this is true for the Lincoln Tunnel silt. Additional empirical formulas for the determination of the lateral pressure in the Hudson River silt may be proposed, for instance: "Compute the hydrostatic pressure at the given depth and add 10% for silt action." Such a recipe furnishes even better results than the formulas.

If another tunnel is ever built in the Hudson River silt, the lateral pressure may be computed in the foregoing conventional manner by assuming a 20° angle of friction, provided, however, that such a new tunnel is driven to the same depth and under the same loading conditions as the Lincoln Tunnel. In such a case, however, it is easier to scale the lateral pressure directly from Fig. 9.

Shearing Surfaces; Angle of Repose of the Silt.—As Mr. Bird rightly states, the straight-line surfaces in Fig. 2(*a*) are only crude approximations. The statement which Mr. Drucker attributes to Jacob Feld,[6] M. Am. Soc. C. E.—namely, that the angle which the shearing surfaces make with the vertical equals the angle of friction—is also perfectly correct, provided, however, that the soil under consideration is cohesionless sand with an angle of friction of 30°. However, this condition is not true for the Hudson River silt. Some idea of the "angle of repose" of the Hudson River silt is afforded by the following fact concerning the organic silt in the Thames River in Connecticut (which is very similar to that of the Hudson River). During the construction of the first bridge at New London, Conn.:

> "The dredging was * * * performed as an independent preliminary operation, with a clam-shell dredge, and carried down 18 to 23 feet below the river bottom, the material standing on a slope of one to one * * *."[14]

---

[14] *The Engineering and Building Record and the Sanitary Engineer*, October 11, 1890, p. 296.

In other words, the angle of repose of the silt in question is 45°. Obviously, this value is only apparent and is due to the cohesion of the material. The writer has had opportunities to observe the behavior of the Thames River silt when excavation for the piers of the highway bridge (opened in 1943) was in progress. Large silt blocks extracted from the bottom of the river maintained their shapes—sometimes with practically vertical faces.

Tangent to the Shear Diagram at the Center Line of the Tunnel.—The writer originally assumed that this tangent to the diagram of the relieving shearing stresses at the center line was horizontal. Whether or not this assumption is true can be determined only from a considerable number of observations. In any case, the writer does not insist on this horizontality, especially because in the diagram, Fig. 14, the tangent in question is oblique. It should be explained, however, that the angle in Fig. 14 varies according to the change in ratio of the vertical and horizontal scales of the drawing.

Compressed Air Action, Passive Resistance, and Soil Constant.—If a circular metallic tube of a certain thickness is subjected to internal pressure, stresses develop in the tube, the radial stress at the outside surface of the tube being zero, because of boundary conditions. If the tube is buried in earth, the tube and the surrounding earth mass work as a unit. The combined system "tube plus soil mass" may be visualized as a tube of a very large (in some cases infinite) thickness made of a nonhomogeneous material; and, if the tube proper is subjected to internal pressure, the entire mass of surrounding soil is stressed, the radial stress being zero only at the boundary of that earth mass (in some cases at infinity). At the outside surface of the tube proper, there is a radial stress. Since action and reaction are equal, the radial stress equals the stress in the earth mass at the given point.

If the soil mass surrounding the tube in question is loaded for the first time, the use of the "soil constant" is fully justified; but, if the soil mass is already heavily stressed, an additional stress increment would produce only a very restricted displacement. Stress-strain diagrams of a heavily loaded soil mass illustrate this fact clearly when a further increment of load produces a surprisingly small strain. Thus, in the design and analysis of earth structures, the live load is not considered at all. The live load certainly produces stresses in the earth structure, but causes practically no deformations.

The so-called "soil constant" is a conventional "tool" used by some tunnel designers for convenience in computations. Deflection values computed using the "soil constant" are excessively large if the mass has been previously loaded. Therefore, the belief that passive resistance of a certain magnitude can be developed only by producing the displacement computed from the corresponding "soil constant" is decidedly erroneous.

Conclusion.—The writer greatly appreciates the valuable discussions by Messrs. Drucker and Bird which have offered the writer an opportunity to clarify several important points in the theory of tunnels. Many thanks are due to both discussers for their painstaking work. Many more field observations, analyses of data, and discussions by the profession are needed, however, before the problem of pressures on tunnels can be definitely solved.

STABILITY AND STIFFNESS OF CELLULAR COFFERDAMS

By Karl Terzaghi,[1] M. Am. Soc. C. E.

With Discussion by Messrs. G. G. Greulich, Raymond P. Pennoyer, Dean P. Tsagaris, R. T. Colburn, A. F. Hedman, Adolph J. Ackerman, Savile Packshaw, Martin W. Lautz, J. S. Miller, Robert F. Legget, D. P. Krynine, J. J. Polivka, and Karl Terzaghi.

Synopsis

The incentive for preparing this paper was given by observations made during and after the construction of a cellular cofferdam which constitutes the side-walls and the middle wall of a shipway. A digest of these and various other observations on cellular cofferdams indicated that the theories on which the design of these cofferdams is usually based give the designer an inadequate conception of the factors that determine the stability of cofferdams.

The paper is divided into three parts. The first deals with past experiences with cellular cofferdams in general, the deflection of the crests of cofferdams, and the permeability of the sheet-pile enclosures. In the second part current methods for designing cellular cofferdams on rock, sand, and clay foundations are reviewed, examined, and revised. The third part contains conclusions. Discussion is specifically limited to cellular cofferdams whose cells are filled with sand or sand and gravel.

Part I. Practical Considerations

Experiences with Cellular Cofferdams.—The first cellular cofferdam was built in 1908 or 1909 at Black Rock Harbor, Buffalo, N. Y. (1).[2] It consisted of seventy-seven prismatic cells, whose horizontal dimensions were 30 ft by 30 ft. It rested on a rock foundation. Since all the walls were straight, it was inevitable that the longitudinal walls should bulge badly between the cross-walls. In one of the cells, the inner wall, with an unsupported height of about 30 ft, bulged 3.45 ft between cross-walls; yet it is reported that the inward movement of the crest of the wall at the cross-walls nowhere exceeded about 1 in.

Note.—Published in September, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

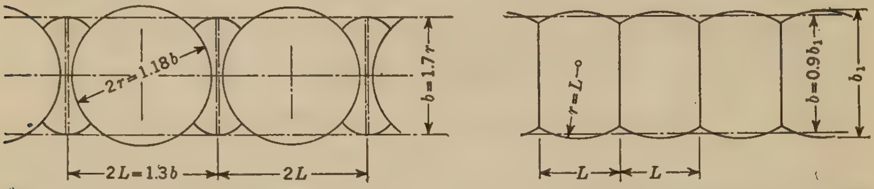
[2] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (see Appendix I).

In 1910 a cellular cofferdam was built in connection with the raising of the battleship *Maine* in the harbor of Havana, Cuba (2). It consisted of twenty cylindrical cells of the type shown in Fig. 1(a), interconnected by short arcs on the outer side of the dam. The subsoil consisted of a stratum of soft silt and mud resting on medium soft clay. The cells were filled with clay. It was expected that the dam would be self-supporting. However, while the salvage crews were pumping inside the cofferdam, the inward deflections increased so alarmingly that it was decided to increase the stability of the structure by adding an inner berm. During the last stage of excavation and pumping it was even considered necessary to brace the cofferdam against the hull of the *Maine.*



(*a*) CIRCULAR CELLS (*b*) SEMICIRCULAR CELLS

FIG. 1.—PRINCIPAL TYPES OF CELLULAR COFFERDAMS

In spite of the difficulties encountered, some engineers realized that the basic idea of the design of the cofferdam for the *Maine* was sound. Therefore, many cofferdams of a similar type have since been constructed. They are known as cellular cofferdams with circular cells.

In 1915 or 1916 the U. S. Army Engineers repeated the Black Rock Harbor experiment by building a similar cofferdam in Troy, N. Y. (3). Since nature gave a drastic hint at Black Rock Harbor that straight-length walls were not appropriate, the cross-walls were connected by arcs. The success of this dam initiated the development of cellular cofferdams with semicircular cells, Fig. 1(*b*).

Some engineers have expressed the opinion that cellular cofferdams are less reliable than other types because several important cellular cofferdams have failed. The design of such cofferdams on a base other than rock requires more judgment and experience than does the design of a double-wall cofferdam with a broad inner berm on a similar base. Hence failures of cellular cofferdams due to faulty design may be more frequent than similar failures of double-wall cofferdams; yet failures of this category cannot be ascribed to an inherent defect of the type of construction.

The only inherent weakness of the cellular cofferdams is the vulnerability of the locks. One or several cells of a cofferdam may burst while all the others remain intact. An individual cell may fail either because of a defect in the material of one of the locks or because a sheet pile was driven out of a lock without the incident being noticed; yet the number of failures due to both causes combined is so small, and, on an average, the costs of remedying the consequences of the incident are so unimportant that the hazard is far more than compensated for by the economic advantages. This statement is corroborated by the fact that large construction organizations have used the cellular cofferdam type many times.

Since cellular cofferdams are both economical and durable, they can also be used to great advantage as parts of permanent structures such as shipways, quay walls, breakwaters, and the like, provided the foundation conditions are satisfactory and suitable material for filling the cells can be secured at low cost.

Deflection of Cellular Cofferdams.—Experience indicates that the sheet-pile walls of cellular cofferdams can stand a horizontal deflection of the crest of the cofferdam equal to more than 10% of its height without injury to the locks. On the landward section of the cellular cofferdam, built about 1916 at the site for a lock at Brown's Landing on the Cape Fear River, North Carolina (4), the top of four cells moved in a distance of 7 ft 6 in. (25% of the free height of the cofferdam) because the pin connection of diagonal tie rods attached to the cross-walls failed; yet the published description of the incident indicates that the locks of these cells remained intact.

The deflection of a cellular cofferdam with given dimensions depends, quite obviously, to a large extent on the elastic properties of the fill in the cells. As a consequence, the relation between the unbalanced horizontal pressure on a cofferdam and the corresponding deflection is very similar to the relation between stress and strain in soils in general. The strain in soils increases roughly with the square of the stress and the deflection of the crest of the dams increases roughly with the square of the unbalanced horizontal pressure. Both the strain in soils and the deflection of the crest of cofferdams increase at slowly decreasing rates under constant stress or pressure conditions.

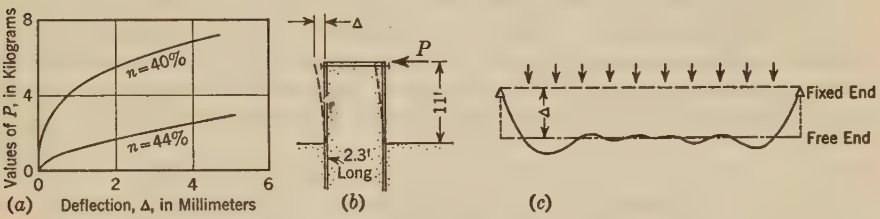


Fig. 2.—Deflection of Cellular Cofferdams

The decisive influence of the elastic properties of the fill on the horizontal deflection of a cofferdam was demonstrated experimentally by I. A. Rimstad with tests on a small-scale model of a double-wall, sheet-pile cofferdam (5). In one of the tests the space between the two walls was filled with loose sand (porosity $n = 44\%$) and in the second with the same sand in a compacted state ($n = 40\%$). In Fig. 2(*a*) the ordinates represent the unbalanced horizontal force and the abscissas the corresponding deflection of the crest of the dam.

In many instances the ends of a cellular cofferdam are tied to rigid structures or to cross-walls which prevent the horizontal pressure from producing a deflection of the ends. A cofferdam between two such ends may be considered as a thick, rectangular slab whose lower edge is fixed and whose vertical edges are freely supported. The upper edge is free. The theory of the horizontal deflection of such slabs under the influence of water pressure—which leads to the conclusion that the upper edge would deflect as indicated in Fig. 2(*c*)—is beyond the scope of this paper. Each half of the section between the two deflection maxima resembles the graphic representation of damped vibrations. The peculiar shape of the deflection curve is due to the resistance of the wall against bending in horizontal planes. If the distance between the end supports is not greater than a few times the height, the two maxima are absent, the elastic line is roughly parabolic, and the maximum deflection is very much smaller than the deflection Δ indicated in Fig. 2(*c*).

From the foregoing, it is evident that the deflection of a cofferdam with a given cross section acted upon by a given system of horizontal forces depends not only on the elastic properties of the cells but also, to a certain extent, on the ratio between the length and the height of the dam. Since a cellular cofferdam consists of two very different materials, steel and soil, its elastic properties can be compared to those of a composite construction material such as reinforced concrete. These properties are chiefly governed by those of the soil in the cells, but the steel walls are likely to stiffen the structure very considerably (see Part II).

The elastic properties of a given soil in a cell depend to a large extent on the method of filling the cell. There is no laboratory procedure that would yield reliable advance information on the state of the soil in the cell and on the corresponding elastic properties of the soil. Quantitative information regarding the stiffening effect of the sheet-pile walls also is not yet available. However, experience indicates that the crest of a cellular cofferdam really deflects approximately as theory leads one to expect. Fig. 3 represents the deflection of the crest of the cofferdam for the land section of the piers between West 44th Street and West 47th Street on the east side of the Hudson River in New York, N. Y. Similar curves were obtained from deflection observations on a very much wider cofferdam between West 47th Street and West 52d Street (6). In both instances the inside of the cofferdam was supported by a rock berm which was provided in the original design. In spite of the presence of this berm, the crest of both dams assumed the characteristic W-shape shown in Fig. 2(*c*) at an early stage of unwatering.

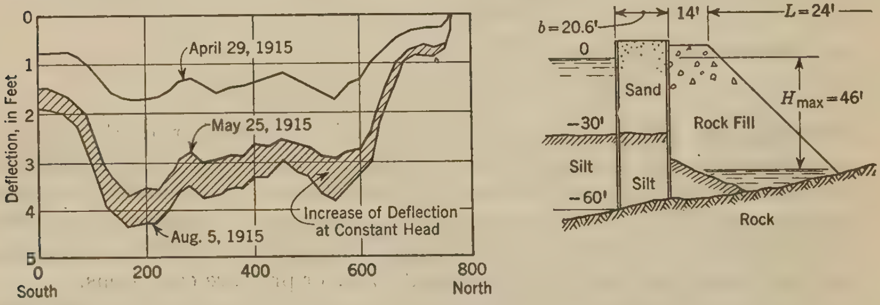

Fig. 3.—Deflection of Cofferdam Crest for the Land Section of Hudson River Piers (H = 46 Ft)

The same general tendency was noticed while the water was pumped out of two full-length submerged shipways whose walls consisted of self-supporting cellular cofferdams of the diaphragm type (7). The deflection of two of the longitudinal (east–west) walls is represented in Fig. 4. The reason for the excessive deflection near the west end of the wall in Fig. 4(*a*) will be discussed subsequently. The deflection of the two short walls was roughly parabolic, and, in accordance with theory, the greatest deflection of these walls was very much smaller than that of the long ones; yet there was no difference between the east–west sections and the north–south sections except in length.

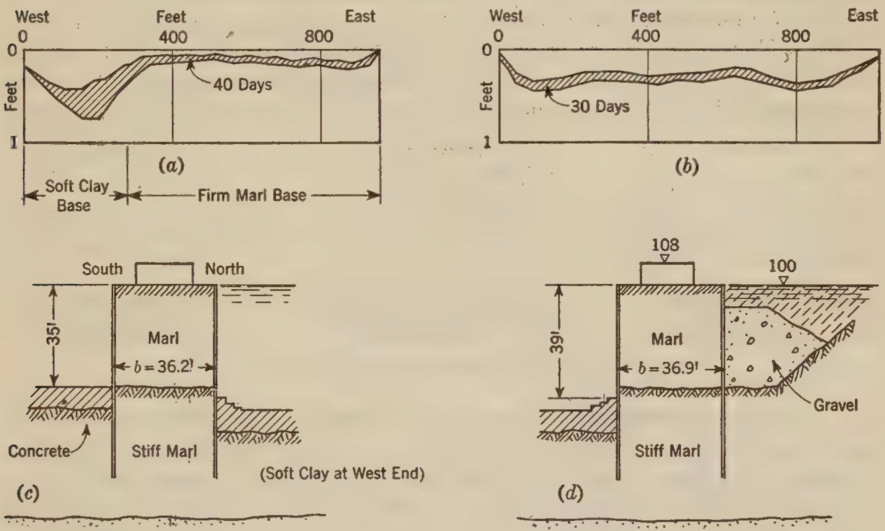

Fig. 4.—Deflection of a Steel Sheet Cofferdam for a Submerged Shipway

Permeability of Cellular Cofferdams and of Their Sheet-Pile Enclosures.—The water that percolates across a cellular cofferdam must pass through two different mediums—the rows of sheet piles and the soil between the sheet piles. The passage through each medium causes a loss of head, disclosed by a difference in the position of the line of saturation on either side of the obstacle against flow. If the cells of a cofferdam are filled with fairly clean sand and gravel, the loss of head is almost exclusively caused by the outer row of sheet piles. All engineers who have reported on experiences with cellular cofferdams filled with sand and gravel emphasized the fact that they had no trouble with water. Many single-wall cofferdams consisting of a row of steel sheet piles have leaked so badly that it was necessary to stop the flow through the locks by artificial means such as washing cinders or sawdust into the leaky locks. Hence, the consistently favorable reports on pumping between cellular cofferdams suggest that the relative watertightness of these dams is primarily due to the tension in the locks. Since there is tension only above the level of the base of the fill in the cells, that part of the rows of sheet piles below the level of the base is likely to be much more permeable than the upper part.

Favorable experiences with pumping from the space within cellular cofferdams filled with sand and gravel have led many engineers to believe that the practical implications of the permeability of the rows of sheet piles are negligible under any circumstances and that a cellular cofferdam with weep holes constitutes a mass of soil enclosed between one impermeable wall and one permeable wall. This conception may be justified under certain conditions, but it is unwarranted under others and it can lead to false conclusions.

Fig. 5 represents vertical sections through a cellular cofferdam, backed by water. The cofferdam rests on an impermeable base and the inner row of sheet piles is provided with weep holes. If the cofferdam is filled with clean, coarse sand (Fig. 5(*a*)), the quantity of water that leaks through the joints of the outer wall is very small. Hence, only the bottom of the cell will be covered with water. If the cells are filled with fine, silty sand (Fig. 5(*b*)), the quantity of water that flows through the outer wall is still smaller because the fill constitutes one more obstacle against the passage of the water. Nevertheless, the line of saturation in the cell should occupy a high position, because the permeability of the fill is so low that the discharge even of a small quantity of water requires a steep hydraulic gradient. Finally, if the cells are filled with clay (Fig. 5(*c*)), the loss of head caused by the passage of the water though the outer row of sheet piles is negligible compared to the loss of head in the clay. As a consequence, the water percolates through the dam as if the outer row were nonexistent.

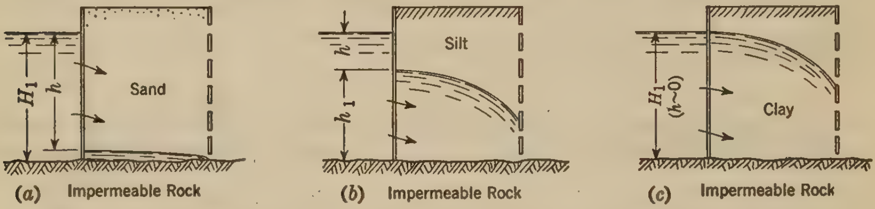

FIG. 5.—CELLULAR COFFERDAMS ON ROCK FOUNDATIONS

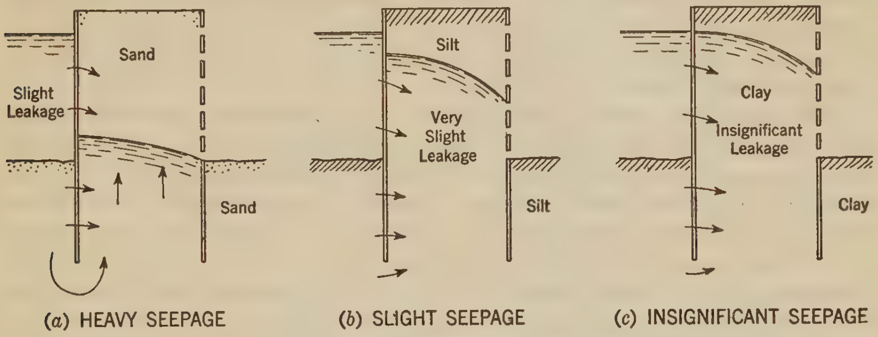
In practice the condition illustrated by Fig. 5(*a*) has rarely been encountered. The cells of the cofferdam for building the Troy dam and locks were filled with sand and gravel (3); yet the line of saturation started at the outside a short distance below water level. The average slope of the line was 1 (vertical) on 2 (horizontal). This observation suggests that the silt content in the fill of the cells was sufficient to establish conditions almost identical to those illustrated by Fig. 5(*c*). The cells of the cofferdam at Pickwick Landing (Tennessee Valley Authority) in Tennessee were filled with sand and gravel, and the inner wall of the cofferdam was provided with weep holes (8). Nevertheless, the line of saturation started at the outside of the dam only a few feet below the free water level, and it was almost horizontal over three fourths of the width of the cells. In spite of these experiences and observations, the customary methods of computing the tension in the locks of the sheet piles are based on the tacit assumption that the weep holes suffice to drain the fill in the cells almost completely, provided the fill consists of sand and gravel.

The cofferdams illustrated by Fig. 5 rest on an impermeable rock foundation. The seepage across a cofferdam with such a foundation merely affects the tension in the locks. If a cofferdam rests on a soil foundation, the effect of the seepage on the subsoil must also be taken into consideration. Fig. 6 shows three vertical sections through cofferdams resting on the same kind of soil as that with which the cells are filled. Because of the permeability of the subsoil, the water which seeps across the outer row of sheet piles combines with that which detours the buried part of the outer row and rises through the subsoil. This additional flow raises the line of saturation to a position slightly above that shown in Fig. 5. Otherwise the flow diagrams are identical.



(*a*) HEAVY SEEPAGE (*b*) SLIGHT SEEPAGE (*c*) INSIGNIFICANT SEEPAGE

FIG. 6.—CELLULAR COFFERDAMS ON A SOIL FOUNDATION

The conditions illustrated by Fig. 6(*c*) existed in the cofferdam around the hull of the *Maine* in Havana. Since the flow toward the pumps across the cofferdam with a total length of about 1,000 ft was less than 4 gal per sec, the engineers who worked on the dam were surprised by the high position of the line of saturation. They seem to have expected conditions like those illustrated by Fig. 6(*a*).

The water that passes through openings in the locks of the buried part of the inside row of sheet piles flows through the soil along the inside of this row in a vertical upward direction toward the surface adjoining the inside of the cofferdam. The mechanical effects of such a flow through clay are usually so insignificant that they cannot be noticed, because clay has a great resistance against scour. On the other hand, if the sheet piles were driven into fine silt, which has almost no resistance against scour, conditions are different. Because of the percolation through the locks, "boiling" may start inside the sheet-pile cutoff in silt at a small fraction of the head which would be required to produce the same effect in the same material on the inside of a perfectly impermeable cutoff. Hence, in connection with cofferdams on silt the permeability of the sheet-pile walls is a factor that must be considered.

PART II. DESIGN OF CELLULAR COFFERDAMS

General Considerations.—Cellular cofferdams may fail by bursting of the cells, by sliding on their base, by the shear deformation created by an inward tilt, or by a failure of their foundation.

Practically all the failures by bursting which occurred during or immediately after filling the cells can be traced back to the driving out of the lock. There seems to be no record to indicate that the cells of a cofferdam burst during application of the overturning moment, unless the cofferdam was in an advanced state of tilting, accompanied by a deflection of the crest of 20% or 25% of the height. There seems to be no record of a failure by sliding. All the failures by overturning that have come to public attention, such as the failures of several cellular cofferdams on the Mississippi River (6) and of the one at Grand Coulee (9) in the State of Washington have been preceded by boiling or piping. Since the foundation conditions have a decisive influence on design, the cellular cofferdams on rock, sand, and cohesive soil will be discussed under separate subheadings.

Notation.—The letter symbols in this paper are defined where they first appear, in the text or by diagram, and are assembled for reference in Appendix II. To simplify equations for the stability of cellular cofferdams, it is customary and justified to assume that the curved inner and outer rows of sheet piles are replaced by fictitious straight ones spaced a distance b apart (see Fig. 1). For cofferdams with circular cells (radius r) $b = 1.7\,r$, and for those with semicircular cells (outside width b_1) $b = 0.9\,b_1$. The lengthwise walls of the ideal substitute for cofferdams with circular cells (Fig. 1(a)) will be assumed to be interconnected by straight cross-walls. These substitute cross-walls are arranged in pairs between the cells. The space between the two walls of each pair is assumed to be empty, but very narrow. The distance between two consecutive pairs is $2\,L$. The cells are assumed to be filled with sand unless some other material is specified in the text.

Cellular Cofferdams on Rock.—The customary methods for designing cellular cofferdams on rock were well described in 1934 by Raymond P. Pennoyer, Assoc. M. Am. Soc. C. E. (10). Rules that can be considered representative of current methods have been published by the Carnegie-Illinois Steel Corporation (11). According to these rules, the sliding resistance on the base per unit of length of the dam is given by the formula,

$$F_b = b\,H\,\gamma\,\tan\rho \qquad (1)$$

and the corresponding factor of safety of a cofferdam, acted upon by a horizontal force P per unit of length, with respect to sliding is

$$G_s = \frac{b\,H\,\gamma\,\tan\rho}{P} \qquad (2)$$

Since the force which tends to displace the dam by sliding also produces an overturning moment, the unit pressure on the base of the dam increases from a minimum at the outer toe to a maximum at the inner one as indicated by the plain curve cd in Fig. 7(a). The area abdc is equal to the product $b\,H\,\gamma$ in Eq. 1. This equation is based on the assumption that the cofferdam does not fail by sliding until the shearing stress at every point of the base of the dam is equal to the normal stress at that point multiplied by the coefficient of friction, $\tan\rho$. Hence the distribution of the shearing stresses at the instant of failure should be given by the dash-dotted line ef whose ordinates are equal to those of curve cd times tan ρ. By the laws of mechanics it can be shown that the shearing stress at the outer toe must be almost equal to zero and at the inner toe it cannot be greater than the friction between the fill and the inner row of sheet piles per unit of area of the sheet piles at the elevation of the base. Hence, the shear-stress line is as indicated by the upper boundary of the shaded areas and the real sliding resistance is equal to the area abef $= b\,H\,\gamma$ tan ρ reduced by the shaded areas. However, the amount of reduction is not sufficiently great to require consideration.

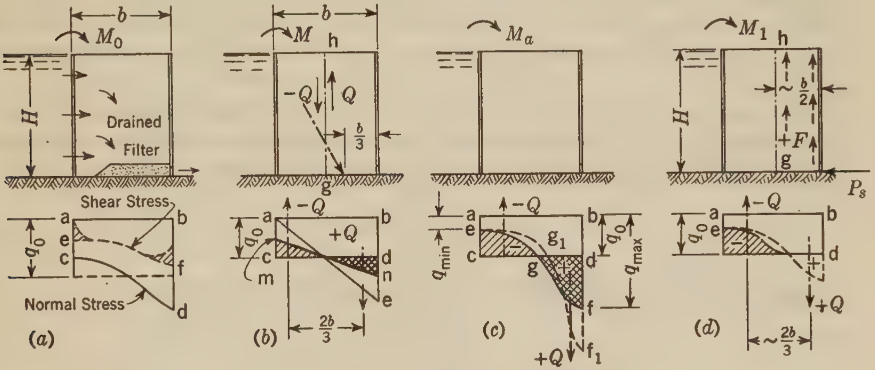


FIG. 7.—CELLULAR COFFERDAMS ON ROCK

Since γ in Eq. 2 represents not the submerged but the real unit weight of the fill in the cells, the equation is not valid unless the fill in the cells is almost completely drained. However, as stated, there is no record to indicate that this condition ever existed. If the line of saturation is at an average height H_s above the base of the dam, the corresponding sliding resistance F_{bs} is lower than F_b, Eq. 1.

The pressure that produces friction is equal to the difference between the total pressure and the water pressure on the base. Since the unit weight of the fill in a saturated state is but slightly greater than the unit weight γ of the fill in a moist state, the shearing resistance on the base of a fill saturated to a height of H_s above the base is:

$$F_{bs} = b\,(H\,\gamma - H_s\,\gamma_w)\tan\phi \qquad (3)$$

On the cofferdams at Troy and at Pickwick Landing the value H_s was almost equal to H. Nevertheless, the dams did not fail by sliding. Failure was probably prevented by the roughness of the rock surface which compensated for the effect of incomplete drainage. If the rock surface is rough, the coefficient of sliding of the fill on the base is much closer to the coefficient of internal friction of the fill than to the customary value of 0.5 which represents the coefficient of friction between sand and fairly smooth rock. The sliding resistance of a cofferdam on rough rock is further increased by the resistance against the sliding of the lower edge of the inner row of sheet piles on the rock surface. Since the sheet piles of the inner row are pressed down by wall friction, this supplementary resistance may be very considerable. However, if the rock surface is smooth, these factors do not apply, and hence the incomplete drainage of the fill may lead to failure by sliding. Therefore, if the rock surface is not very rough, Eq. 2 should not be used unless the designer takes care that the cells are really drained. This can be done by covering the bottom of the cells with a filter layer which communicates through weep holes with the space surrounded by the dam as shown in Fig. 7(*a*). The effect of the drainage provisions should be supervised on the job by means of telltale pipes.

In formulating the condition that the cofferdam should be safe with respect to overturning, it is generally assumed that the cofferdam can be regarded as a gravity wall. The moment required to overturn a gravity wall is

$$M_{\max} = \frac{b^2}{2} H \gamma \qquad (4)$$

and the factor of safety of the wall with respect to overturning is

$$G_s = \frac{M_{\max}}{M} \qquad (5)$$

If a perfectly elastic gravity wall with a rectangular cross section rests on a perfectly rigid base, the overturning moment M_a required to shift the point of application of the resultant pressure on the base from the center point to the inner boundary of the middle third is, approximately,

$$M_a = \frac{1}{3} M_{\max} = \frac{b^2}{6} H \gamma \qquad (6)$$

If the overturning moment is equal to M_a, the unit pressure on the base increases from zero at the outer edge to $2 H \gamma$ at the inner edge as indicated by the straight line ae in Fig. 7(*b*), and the corresponding factor of safety is

$$G_s = \frac{M_{\max}}{M_a} = 3 \qquad (7)$$

If a cofferdam is acted upon by an overturning moment M, Eq. 7 is satisfied, provided the average width b of the dam is equal to

$$b_m = \sqrt{\frac{6\,M}{H \gamma}} \qquad (8)$$

Because of Eq. 7, a cofferdam with width b_m (Eq. 8) is considered safe, provided it is safe with respect to sliding. This conclusion is open to serious objections.

According to the theory on which Eqs. 4 and 6 are based the distribution of the unit pressure over the base of a cofferdam is determined by a straight-line law as indicated by the straight line mn in Fig. 7(*b*). As soon as the overturning moment M becomes equal to M_a, Eq. 6, the unit pressure at the outer edge of the cofferdam should become equal to zero (pressure area abe); yet it is obvious that this condition cannot exist in a dam whose cells are filled with sand. Even if arching develops above the outer part of the base of the fill to the fullest possible extent, the pressure on the outer part of the base must have a considerable positive value $q_{\min}$, which cannot decrease in spite of an increase of the overturning moment. Hence, the most unequal distribution of the pressure on the base that can possibly develop under the influence of an overturning moment M_a, Eq. 6, must be like that shown by the curve ef in Fig. 7(*c*). Since $q_{\min}$ cannot decrease, an increase of the overturning moment and the corresponding increase of the force Q in Fig. 7(*c*) to Q_1 must cause the neutral point g to shift toward the right. The pressure line egf moves into the position eg_1f_1. The base of the cross-shaded pressure triangle dfg decreases, but its area increases from Q to Q_1. Hence the toe pressure $q_{\max}$ increases not in simple proportion but roughly with the square of the overturning moment, and the cofferdam would fail by overturning while the point of application of the resultant pressure on the base is still fairly close to the middle third, provided the locks could stand the tension due to the rapidly increasing side pressure at the toe.

However, before this failure occurs, the cofferdam is likely to fail from another cause which has never received any attention. To demonstrate the existence of this cause in simple terms, the customary assumption is made that the distribution of the pressure on the base of the dam is such as shown by the straight line mn in Fig. 7(*b*). The shearing stresses that act at the surface of contact between the fill in the cells and the sheet piles prior to the application of the overturning moment will be disregarded. In Fig. 7(*b*) the shaded areas indicate the stresses on the base due to the overturning moment M. If Q is the total force represented by each triangle, one can write $M = \frac{2\,b}{3}\,Q$; or

$$Q = \frac{3\,M}{2\,b} \qquad (9)$$

Equilibrium requires that the total shearing force on the neutral plane gh per unit of length of the dam should be equal to Q. The shearing resistance on this plane, S' per unit of length of the dam, is equal to the earth pressure P_e times the coefficient of internal friction $\tan\phi$ of the fill. The earth pressure per unit of area of a vertical section through the fill at depth Z is equal to the vertical unit pressure, $\gamma\,Z$, in the fill at that depth multiplied by an empirical constant C known as the coefficient of earth pressure

$$p_e = \gamma\,C\,Z \qquad (10)$$

The earth pressure on gh per unit of length of the dam is

$$P_e = \tfrac{1}{2}\,\gamma\,C\,H^2 \qquad (11)$$

and the shearing resistance S' is

$$S' = P_e \tan\phi = \tfrac{1}{2}\,\gamma\,C\,H^2 \tan\phi \qquad (12)$$

To the value S' must be added the friction in the locks, because no failure by shear along gh, Fig. 7(*b*), can occur without simultaneous slippage in the lock in this plane. If p_e, Eq. 10, is the unit earth pressure on gh at depth Z, the tension in the locks of an arc with radius r at depth Z is

$$t = r\,p_e = r\,\gamma\,C\,Z \qquad (13)$$

Total tension in a lock with length H is

$$T = \tfrac{1}{2}\gamma C H^2 r \dots\dots (14a)$$

and the total resistance against slippage in the lock is

$$T f = \tfrac{1}{2}\gamma C H^2 r f \dots\dots (14b)$$

wherein f is the coefficient of lock friction. Since the rows of sheet piles intersect the **Y**-piles at an angle of 120°, the tension in the locks of the cross-walls and the corresponding lock friction is equal to that in the arcs. The cofferdams with circular cells contain two cross-walls per cell and the length of each cell is $2L$; those of the diaphragm type contain one cross-wall per cell and the length of each cell is L. Hence, the resistance to shearing along gh contributed by the lock per unit of length of either type of cofferdam is

$$S'' = \frac{T f}{L} = \tfrac{1}{2}\gamma C H^2 \frac{r}{L} f \dots\dots (15)$$

To obtain the total average shearing resistance S on gh per unit of length of the cofferdam, S'' must be added to S', Eq. 12, whence,

$$S = S' + S'' = \tfrac{1}{2}\gamma C H^2 \left(\tan\phi + \frac{r}{L} f\right) \dots\dots (16)$$

The ratio $\frac{r}{L}$ is close to or equal to unity. Hence, approximately,

$$S = \tfrac{1}{2}\gamma C H^2 (\tan\phi + f) \dots\dots (17)$$

The corresponding factor of safety G_s with respect to failure by shear along gh is equal to the ratio between the shearing resistance S (Eq. 17) and the shearing force on gh which is equal to Q (Eq. 9) or

$$G_s = \frac{S}{Q} = \gamma \frac{b H^2}{3 M} C (\tan\phi + f) \dots\dots (18)$$

If one face of the cofferdam with height H is acted upon by water pressure, the overturning moment is

$$M_0 = \frac{1}{2}\gamma_w H^2 \frac{H}{3} = \frac{1}{6}\gamma_w H^3 \dots\dots (19a)$$

and

$$G_s = 2\frac{\gamma b}{\gamma_w H} C (\tan\phi + f) \dots\dots (19b)$$

The customary theories of cofferdams are based on the assumption that every vertical section through the fill in the cells is acted upon by the active Rankine pressure, P_A per unit of width of the section, involving

$$C = \tan^2\left(45 - \frac{\phi}{2}\right) \dots\dots (20)$$

To visualize the practical implications of Eqs. 19b and 20, it is assumed that $\phi = 30°$, $f = 0.3$, $\gamma = 110$ lb per cu ft, $\gamma_w = 62.5$ lb per cu ft, and $b = 0.85\,H$.

Evaluating Eq. 5 on the basis of these data it is found that the factor of safety with respect to overturning should be 3.8. In reality, it is certainly not greater than about 2. However, the factor of safety with respect to shear, Eq. 19*b*, is only $G_s = 2 \frac{110}{62.5} \frac{0.85\,H}{H} 0.577^2 (0.577 + 0.3) = 0.87$. In other words, the cofferdam would fail by shear along gh, Fig. 7(*b*), although even the real factor of safety with respect to overturning is still excessive for a temporary structure. Replacing $\phi = 30°$ by $\phi = 34°$ and $\phi = 40°$, the values of $G_s = 0.82$ and 0.74 instead of 0.87 are obtained.

The average width *b* of the cellular cofferdams with circular cells which were built on a rock foundation is not greater than about 0.85 *H*. The width of some of them was somewhat smaller; yet none of them failed by shear along gh, Fig. 7(*b*). The coefficient of friction on this plane cannot be greater than tan ϕ. Therefore, the normal pressure on this plane, and, as a consequence, the horizontal earth pressure in the entire fill in the cells, must be considerably greater than the active Rankine pressure involving

$$C > \tan^2\left(45° - \frac{\phi}{2}\right) \qquad (21)$$

Comparing Eq. 17 with Eq. 12, it can be noted that the lock friction increases the average coefficient of shearing resistance along gh (Fig. 7(*b*)) from tan ϕ to (tan $\phi + f$). The value of f is likely to be fairly close to 0.3. If $\phi = 30°$ and tan $\phi = 0.58$, the lock friction increases the factor of safety with respect to failure by shear by about 50%. Hence, the stabilizing influence of the lock friction is by no means negligible.

Because of the lock friction a cellular cofferdam may be as much as 50% more stable than a double-wall cofferdam with equal width and height, but without cross-walls. If the inner side of a cellular cofferdam is supported by a berm whose height is almost equal to the height of the dam, both the cross-walls and the inner row of sheet piles are acted upon by equal earth pressures from both sides. This condition practically eliminates the tension in the locks, but it also eliminates the lock friction. The lock friction becomes fully operative at a very much smaller deflection of the cofferdam than does the shearing resistance of the fill in the cells. Therefore, a cellular cofferdam with a free inside wall (self-supporting cellular cofferdam) is likely to deflect less than a cofferdam reinforced by an inner berm. In this connection, it may be mentioned that the crest of one of the two cofferdams with rock-fill berms between West 44th Street and West 49th Street in New York deflected more than 4 ft (Fig. 3) and the other one more than 6 ft. This is far in excess of the usual deflection of the crest of self-supporting cellular cofferdams.

On some cofferdams, the locks were lubricated to facilitate pulling the sheet piles. From a functional point of view, it would be preferable to increase the lock friction by artificial means.

Finally the possibility of a failure of cofferdams by a bursting of the locks must be considered. The tension per unit of length of a lock is given by Eq. 13. The greatest value which Z in this equation can assume is H. For

$Z = H$, t becomes equal to

$$t_1 = r \gamma C H \qquad \text{(22a)}$$

The standard method for computing the greatest tension per unit of length in a lock is based on the assumption that C in Eq. 22*a* is equal to the coefficient of the active Rankine pressure, $\tan^2\left(45° - \frac{\phi}{2}\right)$, whence

$$t_1 = r \gamma H \tan^2\left(45° - \frac{\phi}{2}\right) \qquad \text{(22b)}$$

The sheet piles are chosen so that t_1 is equal to or smaller than the allowable lock tension which in turn is equal to the failure tension divided by about 2.5. Hence, the factor of safety with respect to a failure by tension in the locks is assumed to be about 2.5. However, the discussion of the resistance of the cellular cofferdams against shear has led to the conclusion that the factor C in Eq. 22*a* is considerably greater than $\tan^2\left(45° - \frac{\phi}{2}\right)$. Hence, the factor of safety with respect to a failure of the locks by tension is smaller than 2. Furthermore, the method of computation represented by Eq. 22*b* fails to consider that the application of the overturning moment may increase the pressure in the fill at the inner toe. According to the standard concept, the application of the overturning moment should change the initial pressure area abdc, Fig. 7(*b*), for a cofferdam with the customary dimensions to about abe which involves an increase of the soil pressure at the inner toe by roughly 100%. This would reduce the factor of safety to less than unity and the cells would fail by bursting. In reality the lower boundary of the pressure area for the base of a cofferdam is not straight as indicated by the lines mn and ae in Fig. 7(*b*) but curved as shown by the line ef in Fig. 7(*c*). Hence the real increase of the lock tension due to the overturning moment is still more important.

Finally, Eq. 22*b* involves the tacit assumption that the fill in the cells is almost completely drained. If the line of saturation is close to the top of the fill as it was in the cellular cofferdams at Troy and at Pickwick Landing, the cells not only should burst; they should explode.

In contrast to this conclusion, experience has demonstrated the following fact: If the locks are strong enough to stand the lateral pressure of the fill before an overturning moment is applied, they are also strong enough to stand the subsequent changes produced by the overturning moment, provided the cofferdam is safe in every other respect. Hence, the increase of the lock tension due to the overturning moment cannot possibly be important. As a matter of fact, there is no evidence that the real factor of safety with respect to a failure by bursting of the cells of any one of the successful cellular cofferdams was appreciably smaller than 2; yet equilibrium requires that the overturning moment be fully counterbalanced by a couple on the base of the dam. Hence the question arises: "What is the nature of the forces which constitute this couple?"

To answer this vital and obvious question, the interaction between the fill in the cells and the adjoining sheet piles must be considered. If there were no initial shearing stresses at the surface of contact between the fill and the inner row of sheet piles, the vertical unit pressure in the fill adjoining the inner row at any depth Z below the top of the cells would be γZ, and at the inner edge of the base it would be γH. Any increase of the vertical pressure in the fill beyond these values involves a shortening of the height of the fill, and the shortening is resisted by the friction between the fill and the sheet piles. Since an insignificant slip along the surface of contact between fill and sheet piles is sufficient to mobilize the full sliding resistance along this surface, the unit pressure on the inner part of the base cannot increase beyond γH until the shearing stresses on the inner contact face become equal to the full value of the friction between sand and sheet piles. At that stage the pressure on the base of the fill is about as shown by the area abde in Fig. 7(*d*). On the inside (right-hand side) of the neutral plane gh the unit pressure on the base of the fill is still γH, but the vertical contact faces of the fill are acted upon by vertical friction forces, F_1 per unit of width of the sheet piles or Q per unit of length of the dam. Since the sand pressure per unit of width is equal to $\frac{1}{2} \gamma H^2 C$, the friction force F_1 is

$$F_1 = \tfrac{1}{2} \gamma H^2 C \tan \delta \qquad (23)$$

The total perimeter of one cell with length $2L$ of a cellular cofferdam with cylindrical cells, Fig. 1(*a*), on one side of the neutral plane gh, is $(2L + b)$ or

$$l = 1 + \frac{b}{2L} \qquad (24)$$

per unit of length of the dam. Hence,

$$Q = l F_1 = \tfrac{1}{2} \gamma H^2 C \left(1 + \frac{b}{2L}\right) \tan \delta \qquad (25a)$$

Since $\frac{L}{b}$ is roughly equal to 0.65 or $\frac{b}{2L} = 0.77$,

$$Q = 1.77 \times \tfrac{1}{2} \gamma H^2 C \tan \delta \qquad (25b)$$

The sum of all the vertical reactions produced by the overturning moment is equal to zero. Therefore, the sum of the forces acting on the fill on the outside (left-hand side) of the neutral plane gh must be equal to $-Q$ per unit of length of the dam. Assuming that the lever arm of the couple constituted by the forces $+Q$ and $-Q$ is roughly equal to $\frac{2b}{3}$, the overturning moment M_1 required to establish the state of stress on the base of the fill, indicated by the area abde in Fig. 7(*d*), is

$$M_1 = \tfrac{2}{3} b Q = 1.18 b \times \tfrac{1}{2} \gamma H^2 C \tan \delta \qquad (26a)$$

The overturning moment produced by the water pressure on one side of the dam is given by Eq. 19*a*:

$$M_0 = \tfrac{1}{6} \gamma_w H^3 \qquad (26b)$$

and the ratio m between the required moment M_1 and the acting overturning moment M_0 is

$$m = \frac{M_1}{M_0} = 3.54 \frac{b}{H} \frac{\gamma}{\gamma_w} C \tan \delta \qquad (27)$$

The average width of the base of cofferdams on rock which are built to withstand full water pressure is usually about 0.85 H. Assuming $\gamma = 110$ lb per cu ft, $\gamma_w = 62.5$ lb per cu ft, $C = 0.4$, and $\tan \delta = 0.4$, $m = 0.85$. This value, $m = 0.85$, indicates that about 85% of the total overturning moment M_0 is carried by the couple $+Q$ and $-Q$. In other words the unit pressure at the inner edge of the base of the fill does not begin to increase until about 85% of the total overturning moment M_0 is applied. The increase of the unit pressure due to the remaining 15% of the overturning moment is well within the margin of safety. This explains the empirical fact that the cells of a cofferdam with the customary dimensions burst either before the overturning moment is applied or not at all. However, once the overturning moment becomes equal to 1.2 M_1 or 1.3 M_1, a further increase of the moment must cause as rapid an increase of the soil pressure at the inner toe as it would from the very outset under the fictitious conditions illustrated by Fig. 7(*c*). Hence, after the overturning moment becomes greater than 1.2 M_1 or 1.3 M_1, the danger of a failure due to the bursting of the cells increases rapidly.

The maximum lock tension is further reduced by the forces which counteract an inward movement of the lower edge of the inner row of sheet piles. According to Eq. 22*a* the lock tension should increase in simple proportion to the depth below the top of the cells. Assuming that the elongation of the sheet-pile walls increases in simple proportion to the lock tension, the vertical section through the inner row of sheet piles should be fairly straight at any stage of filling and pumping, and its lower edge should move inward. However, experience indicates that the inner row of sheet piles bulges at an elevation $\frac{H}{4}$ or $\frac{H}{3}$ above the level of the base and that the lower edge of the sheet piles does not move. Such a deformation can occur only if the distribution of the tension along a lock is similar to that indicated by the area acc$_1$ in Fig. 8. Since there is little doubt that the earth pressure increases from the top of the cells toward the bottom as indicated by the pressure area aa$_1$c, equilibrium requires that the lower edge of the sheet piles be acted upon by a horizontal force P_s. The origin of this force is obvious. The force F_1 (Eq. 23) presses the lower end of the sheet piles to the rock surface and the pressure produces a frictional resistance, P_s. Fortunately for the cofferdam, the force P_s acts precisely at the point where the lateral earth pressure is greatest. Hence, the greatest lock tension is considerably smaller than that which would correspond to the soil pressure at the base. At the lower edge of the sheet piles where, according to theory, the lock tension should be greatest, it is equal to zero.

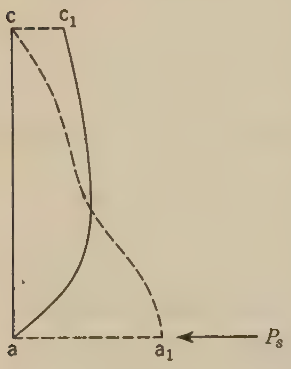

Fig. 8

To make the statement of the fundamental assumptions complete, it should be mentioned that throughout the discussion the empirical factor C in Eq. 10 was tacitly assumed to have the same value for every point in the fill of the cells. This is certainly not more than a very crude approximation. First, by analogy to the conditions in the backfill of a retaining wall it is very probable that the value C for the central part of the fill is much greater than that for the fill adjoining the inner row of sheet piles. Second, if C were a constant along every horizontal section through the inner row, the arcs should remain circular. However, the observations described subsequently show that this conclusion is not even approximately correct. The laws according to which the value C varies within the fill of the cells are still unknown. Hence, an attempt to evaluate the greatest lock tension on a purely theoretical basis would appear rather futile.

The preceding leaves no doubt that two of the three customary equations for the design of cellular cofferdams (Eqs. 8 and 22*b*) are inadequate. The third, Eq. 1, is based on the assumption that the fill in the cells is almost completely drained; yet this formula has been advocated without a statement of the important fact that weep holes alone may not suffice to drain the cells although they may be filled with sand or sand and gravel. So far the equations have not done any harm because they have fortunately been used on the basis of very conservative values for the soil constants. However, some day an ambitious designer may conceive the idea of determining the soil constants by laboratory tests and using the values furnished by the tests. The result could be fatal for the cofferdam.

The equations derived by the writer contain an empirical factor C (ratio between horizontal and vertical soil pressure in fill of cells) whose value could be determined only by actually measuring both the horizontal and the vertical soil pressures at different points in the fill of the cells in full-sized cellular cofferdams before and after the application of the overturning moment. So far no such observations have been made. On the basis of the known behavior of cellular cofferdams, the writer estimates that the value C for the middle part of the fill in the cells ranges between 0.4 and 0.5. Along the inner row of sheet piles it may be considerably smaller. In no event could C be determined by laboratory tests.

In the preceding paragraphs an attempt was made to analyze the conditions that determine the stability of cellular cofferdams on rock. The analysis disclosed the existence of a potential source of failure by shear along vertical planes (Eq. 19*b*) which has been ignored in the past, although it is much more likely to take place than failure due to overturning. It also demonstrated the decisive influence of the lock friction and of the friction between the fill and the walls of the cells on the strength and stability of the dam (Eqs. 17 and 22*a*). This opens up at least a theoretical possibility for increasing the stability or for reducing the dimensions of cellular cofferdams by artificially increasing the roughness of the surface of the steel. Since all the equations contain the empirical factor C whose value, for the time being, can only be guessed at, the equations cannot yet be used directly in connection with the design of cellular cofferdams. Pending further development, it seems safest to proceed on the basis of past experience as explained in the following paragraphs.

The average width b_0 of all the cellular cofferdams built to date on a rock foundation to sustain nothing but one-sided water pressure was about equal to 0.85 H. The water pressure that acts on the outside of the cofferdam per unit of length of the dam at the instant of overtopping will be designated by P_0 and the corresponding overturning moment is equal to M_0, Eq. 19*a*. Experience has shown that cofferdams with such dimensions are fully adequate; yet the preceding numerical computations have demonstrated that their factor of safety with respect to failure by shear along the neutral plane is certainly not greater than 1.5. Hence, the ratio, $\frac{b_0}{H} = 0.85$, may be considered an acceptable basis for design. To keep the factor of safety of a cofferdam with respect to sliding (Eq. 2) unaltered while increasing the unbalanced horizontal pressure from P_0 to $P = n_1 P_0$, it is necessary to increase its width from b_0 to $\frac{b_0 P}{P_0} = n_1 b_0$. To maintain the same condition with respect to a failure by shear along a vertical plane (Eq. 18), while increasing the overturning moment from M_0 to $M = n_2 M_0$, it is necessary to increase the width from b_0 to $\frac{b_0 M}{M_0} = n_2 b_0$. Hence, if a cofferdam with height H on a rock foundation is acted upon by a horizontal force $P = n_1 P_0$ producing an overturning moment $M = n_2 P_0$, it should have an average width,

$$b = n\, b_0 = 0.85\, n\, H \quad \text{(28a)}$$

in which n is the greater one of the two values n_1 and n_2.

According to the assumption illustrated by Fig. 1(*a*), the radius r of circular cells is $r = 0.59\, b$, whence,

$$r = 0.59\, b = 0.59\, n\, b_0 = 0.59 \times 0.85\, n\, H = 0.50\, n\, H \quad \text{(28b)}$$

The outside width b_1 of cellular cofferdams with semicircular cells (Fig. 1(*b*)) is 1.11 b; thus:

$$b_1 = 1.11\, b = 1.11\, n\, 0.85\, H = 0.94\, n\, H \quad \text{(28c)}$$

The distance L between the cross-walls of such dams is 0.65 b (±), whence,

$$L = 0.65\, n\, 0.85\, H = 0.55\, n\, H \quad \text{(28d)}$$

Since the arcs intersect the cross-walls at the Y-piles on an angle of 120°,

$$r = L = 0.55\, n\, H \quad \text{(28e)}$$

The maximum lock stress is given by Eq. 22*b*. The writer is not aware that any designer has ever used a value of much less than 0.4 for C in Eq. 22*a*. As a result of this wise practice, there have been no serious failures due to the bursting of cells. Therefore, the writer suggests that the greatest lock tension in the walls of cells filled with sand, or sand and gravel, be expressed by means of the empirical equation,

$$t = 0.4\, \gamma\, r\, H \quad \text{(28f)}$$

Eq. 28*f* does not create the illusion that it rests on a scientific basis and leaves no margin for misinterpretation. If the cells are filled with a soil with a high clay content, the resistance of the soil against sliding is likely to be deficient. If the surface of the rock is not very rough, adequate provisions should be made for draining the fill in the cells and the state of drainage should be ascertained at different stages of pumping within the cofferdam by measuring the elevation of the water level in telltale pipes whose lower ends are located at different depths below the crest—for instance, $\frac{H}{4}$, $\frac{H}{2}$, and $\frac{3\,H}{4}$. It is also advisable to observe the deflection of the crest of the dam during, and after, the time when the space between the cofferdams is being pumped out.

The cross-walls of some of the older cellular cofferdams, such as those of Troy (3), Cape Fear River (4), and St. Louis Intake (12) were reinforced by diagonal tension rods or tension beams. These members increased the stiffness of the cofferdams very considerably. This was demonstrated impressively on the Cape Fear River, where the failure of the pin connection of the tie rods in four cells caused the top of these cells to advance a distance up to 7.5 ft, whereas the deflection of all the other cells was unimportant. To utilize the tie-rod principle to full advantage, it would be necessary to make the pin connections strong enough to permit stretching of the tie rods well beyond the yield point. Otherwise, the pin connections fail before the shearing resistance of the fill in the cells is fully active.

Lubrication of the locks may facilitate pulling the sheet piles, but it reduces, very considerably, the strength and stiffness of the cofferdam.

Cellular Cofferdams on Deep Sand Strata.—A review of current methods of designing cofferdams on sand reveals an amazing situation. The design of permanent storage dams on sand is governed by the necessity of eliminating the danger of the formation of boils at the downstream toe. All other requirements are of secondary importance and can easily be satisfied. In contrast to this sound practice, in all the theories pertaining to cofferdams on sand, such as those of H. Krey (13), K. Hager (14), Mr. Rimstad (5), and Bureau of Public Roads (15), the water is replaced by a continuous horizontal load equivalent to a water pressure on the outside of the dam and the other far more dangerous mechanical effects of the water are not even mentioned. The relative frequency of the failure of cofferdams on sand suggests that this unnatural mental attitude toward the problem is not limited to the writers of theories.

The mechanical effect of seepage on the stability of cofferdams had not received any adequate attention in engineering literature until it was treated by Lazarus White and Edmund A. Prentis, Members, Am. Soc. C. E. (6), in 1940. This work contains the first vigorous and well-documented protest against the prevailing indifference regarding the effect of seepage on the stability of cofferdams on sand. The following paragraphs contain a brief review of the mechanics of the formation of boils and of the means for preventing this dangerous phenomenon.

Fig. 9(*a*) is a vertical section through a prismatic element of a mass of sand with a volume V and a length l. The water percolates through the sand in the direction of the dashed arrow. Let γ' = submerged unit weight of the sand; γ_w = unit weight of the water; h = loss of hydraulic head associated with flow of water through distance l; and $i = \frac{h}{l}$, the corresponding hydraulic gradient.

In Fig. 9(*a*) the loss of head h is given by the vertical distance between the water levels in two standpipes whose lower ends are at the center of the entrance and the exit surface of the prismatic element. A loss of head h reduces the water pressure per unit of area of a plane section at a right angle to the direction of the flow by $\gamma_w h$. Hence, the percolating water adds to the submerged weight, $\gamma' V$, of the prismatic element (Fig. 9(*a*)), an unbalanced pressure $\gamma_w h$ per unit of area of its base ab acting in the direction of the dashed error. Since the length of the element in the direction of the flow is l, the unbalanced

FIG. 9.—CELLULAR COFFERDAMS ON DEEP STRATUM

force is equal to

$$g_s = \gamma_w \frac{h}{l} = \gamma_w i \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29a)$$

per unit of area and unit of length, in other words per unit of volume. This force represents the seepage force. If the water flows through a mass of sand vertically upward, the seepage force g_s acts in a direction opposite to that of gravity. If $g_s = \gamma_w i_1 = \gamma'$—

$$i_1 = \frac{\gamma'}{\gamma_w} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29b)$$

the resultant of the hydrostatic pressures counterbalances the force of gravity, and the sand should behave like a liquid (16). To verify Eq. 29*b*, a cylindrical vessel (Fig. 9(*b*)) was filled with sand, and water was allowed to percolate through the sand in an upward direction. The lines along which the water particles travel are marked by arrows. As long as the hydraulic gradient i was smaller than i_1, Eq. 29*b*, the sand grains were motionless and the permeability of the sand was unaltered. However, at the instant when i became equal to i_1, the sand started to boil and its permeability increased abruptly. Before the test a brass weight W was placed on the surface of the sand. As i approached the value i_1, the weight settled progressively, and when i became i_1 the weight disappeared in the boiling sand.

Fig. 9(*c*) is a vertical section through a cellular cofferdam on sand. The design of such a dam must satisfy three independent conditions: (*a*) The sand along the outer face of the cofferdam should be protected adequately against erosion; (*b*) the dam should be able to withstand the overturning moment produced by the water pressure on its outer face; (*c*) the subsoil should be able to carry the pressure on the base of the dam in spite of the tendency of the seepage forces to liquefy the sand at the inner toe. The practical implications of surface erosion have been presented expertly by Messrs. White and Prentis (6). In this paper only conditions (*b*) and (*c*) will be discussed; and for the sake of clarity they will be considered independently.

In the discussion of the stability of cofferdams on a rock foundation, illustrated by Figs. 7(*c*) and 7(*d*), it was shown that the inner row of sheet piles is pressed down by a friction force F_1, Eq. 23, per unit of length of the row. If the sheet piles move down under the influence of this force, the cofferdam is likely to fail by bursting of the locks. To prevent such a failure of a cofferdam on sand, the sheet piles of the inner row should be driven deep enough into the sand to withstand the vertical load F_1 (Eq. 23) per unit of length of the row of sheet piles without perceptible penetration. This condition is scarcely satisfied unless the sheet piles are driven to a depth of at least $\frac{2}{3} H$ into the sand.

To plan appropriate measures for the prevention of boiling, it is necessary to consider the flow of water through the subsoil of the cofferdam. In Figs. 9(*c*) and 9(*d*) the flow lines are marked by arrows. They were traced in such a manner that the quantity of water v_d which percolates between two flow lines is the same for every pair of flow lines. If this condition is satisfied, it is easy to realize that the spacing d between the flow lines indicates the distribution of the seepage force g_s (Eq. 29*a*) throughout the subsoil of the cofferdam.

The quantity of water that flows between two adjoining flow lines per unit of the distance between these flow lines is $\frac{v_d}{d}$. It is called the rate of percolation. According to Darcy's law the rate of percolation is equal to

$$\frac{v_d}{d} = k\,i \qquad (30)$$

in which k is a constant, the coefficient of permeability. Hence, $i = \frac{v_d}{d\,k}$ and

$$g_s = i\,\gamma_w = \frac{v_d\,\gamma_w}{d\,k} = \frac{1}{d} \text{ times a constant} \qquad (31)$$

According to Eq. 31, the seepage force g_s is inversely proportional to the spacing of the flow lines. As shown in Fig. 9(*a*), it acts at every point in the direction of the tangent to the flow line through this point.

The flow lines in Figs. 9(*c*) and 9(*d*) were constructed on the assumption that the rows of sheet piles are perfectly impermeable and that the sand is perfectly homogeneous. The short horizontal lines in Fig. 9(*c*) represent the lower ends of observation wells. The height to which the water would rise in each well is represented by a black column. Methods of constructing the flow lines and determining the height of the rise of the water in the wells have been discussed elsewhere (17). These methods also permit a determination of the seepage pressure g_s (Eq. 29*a*), for every point of the subsoil.

The water that percolates through the soil beneath the cofferdam escapes from the soil in a vertical upward direction as it does in the vessel shown in Fig. 9(*b*). The seepage velocity and the corresponding seepage force that tends to lift the sand are greatest next to the toe of the dam. Therefore, the floor of the excavation adjoining the toe constitutes an area of potential boiling. This will be called the danger zone. Boiling eliminates the resistance of the sand against an inward movement of the buried part of the inner row of sheet piles. It reduces the resistance of the inner row of sheet piles against penetration under the influence of the force F_1 (Eq. 23), and the cofferdam fails by toppling inward. The failure is either preceded or followed by a bursting of the cells. Several failures of this type have occurred on the Mississippi River (6).

The formation of boils can be prevented by two different methods: (*a*) By covering the danger zone with a loaded, inverted filter; and (*b*) by increasing the length of the path of percolation by means of a berm with a wide base. The inverted filter which constitutes the essence of method (*a*) is indicated in Fig. 9(*c*) by dashed lines. Since the filter material is much more permeable than the protected soil, the presence of the filter has no influence on the shape of the flow net, but the load that acts on the filter counteracts the vertical component of the seepage forces which tend to lift the sand beneath the danger zone.

Method (*b*) is illustrated by Fig. 9(*d*). The berm can be made of dredged material. Although the downstream ends of the flow lines in Fig. 9(*d*) are not vertical, they are spaced fairly closely, producing a tendency of the toe of the berm to slump due to backward erosion. This can be prevented by a gravel toe.

If an inverted filter made out of clean, coarse gravel or broken stone is used to cover the surface of the danger zone in a mass of sand, the sand is washed into the interstices of the gravel. One piece of gravel after another sinks into the sand and finally the filter ceases to function. Therefore, the filter material should satisfy two independent conditions. It should be coarse enough to permit free discharge of the seepage water, and, at the same time, its voids should be small enough to exclude the possibility of an invasion of finer soil particles from below. By experimenting with different subsoils and filter materials, the writer arrived at the empirical rule illustrated by Fig. 9(*e*). The abscissas of this diagram represent the logarithm of the grain size and the ordinates the percentage of the total weight composed of grains smaller than the size denoted by the abscissa. Curve S is the grain-size curve for the soil which should be protected. Abscissas of points c and d represent four times the grain size D_{15} and D_{85}, corresponding to the points a and b on the grain-size curve S. If the grain-size curve F for a filter material intersects the line dc, it can be considered suitable.

When building a cofferdam on an alluvial deposit, suitable filter material can usually be obtained by screening the soil which needs to be protected and by wasting the finest fractions. By wasting 50% of the soil represented by curve S in Fig. 9(*e*), one obtains the material represented by curve F which satisfies all the requirements. A filter bed on a flooded surface can be constructed only by means of one of the methods which are used for pouring concrete under water. If the filter material is simply dumped into the water, the coarsest particles settle first, and the result of the operation is a stratified layer which does not satisfy the essential requirements. The functioning of the filter should be supervised by means of observation wells whose lower ends are a short distance below the base of the filter. If the filter functions properly, the water should not rise in the wells more than a few inches above the base of the filter.

In 1923 the writer equipped the foundation for a permanent storage dam on sand and gravel with a filter designed on the basis of Fig. 9(*e*), and in 1925 he repeated the procedure on another dam on sand. Since both experiments were successful, he used the filter principle in the design of many dams and all the filters functioned as anticipated. On the basis of these experiences he recommends the design illustrated by Fig. 9(*c*) as an alternative to the customary berm type shown in Fig. 9(*d*), provided the rules for grading and constructing the filter are strictly adhered to and the functioning of the filter is conscientiously supervised.

The preceding comment furnishes a basis for the design of cellular cofferdams on sand. The width of the dam can be determined by Eq. 28*a*. The maximum lock tension is computed by Eq. 19(*b*). Boiling can be prevented by either one of the methods illustrated by Figs. 9(*c*) and 9(*d*). If a filter is used, the sheet piles should be driven to a depth $\frac{2\,H}{3}$ or until they bear on a hard stratum. The final choice between the two methods depends on the estimated cost and on the width of the space available for constructing the cofferdam. It is obvious that the unit price for the filter layer is much higher than that for a berm made of dredged material and the necessity for expert supervision during and after construction is a distinct liability in connection with temporary structures; but the berm requires much more space than the filter, as indicated in Figs. 9(*c*) and 9(*d*).

Figs. 9(*c*) and 9(*d*) represent two different ways for preventing boils by means of berms. If the local conditions do not permit the construction even of a narrow berm, the filter can be established at the base of the fill in the cells, in the position occupied by the filter in the cofferdam shown in Fig. 7(*a*). If an untried method is to be considered, it is necessary to investigate the mechanical efficacy of the proposed method by means of a flow net. The flow net can be constructed (17) or it can be obtained experimentally (6). Some engineers prefer the experimental method. The graphical method is cheaper, more expedient, and somewhat more accurate, but the experimental method carries more conviction with those engineers who are not accustomed to scientific reasoning.

The results obtained by either method are strictly valid only if the rows of sheet piles are perfectly impermeable and if the natural sand stratum is perfectly homogeneous. In reality neither one of the two conditions is satisfied and the resulting error can be very important. Hence, whatever method of investigation is used, it is imperative to discover by means of observation wells on the job whether the flow of seepage is at least approximately similar to that anticipated by the designer. If the discrepancy is on the unsafe side, supplementary measures of protection should be adopted during construction.

Fig. 9(*f*) is a vertical section through a breakwater. During storms breakwaters are subject to a pulsating water pressure. While the waves pound against the outside of the breakwater during a storm, the hydrostatic pressure on the outside of the breakwater varies between the values represented by the pressure triangles ab_1c_1 and ab_2c_2. The hydrostatic pressure at the outer toe oscillates between $[\gamma_w \, (H_w + h')]$ and $[\gamma_w \, (H_w - h'')]$, in which H_w is the depth of the water adjoining the breakwater before the storm. The values h', h'', and h in Fig. 9(*f*) depend on H_w, the wave length, and the height of the waves. A theory for estimating the wave pressure on the uppermost part of the exposed face of the breakwater was presented in 1935 by the late D. A. Molitor, M. Am. Soc. C. E. (18). A comparison between computed and observed values of wave pressure was made by T. L. Condron, M. Am. Soc. C. E. (19). Equations for computing the wave pressure over the entire exposed face were derived by M. Sainflou in 1928 (20). Since the excess hydrostatic pressure on the outside of the breakwater has the character of a pulsating force, it produces vibrations in both the structure and the subsoil. Because of the vibrations, the settlement is likely to be much more important than that produced by a static system of forces under similar circumstances (17). If the sand on which the breakwater rests is loose, the vibrations may cause a spontaneous settlement associated with temporary liquefaction of the sand whereupon the breakwater would suddenly sink into the sand as if the sand were a liquid. Thus, if the sand is loose, the construction of the breakwater should be preceded by compacting the sand beneath and on both sides of the breakwater by artificial means to a depth which is equal to at least 1.5 times the height H. This can be accomplished, for instance, by driving sand piles or by the "vibroflotation method" (21).

Cellular Cofferdams on Clay.—The only attempt to design a cofferdam on clay on a purely theoretical basis was made by H. Epstein (22), who computed stability on the assumption that the cofferdam can be regarded as a simple gravity wall. The highly controversial aspects of this assumption have already been discussed herein under the heading, "Cellular Cofferdams on Rock." In estimating the required depth of penetration of the sheet piles, the vertical forces transmitted from the fill in the cells through side friction to the sheet piles, and through the sheet piles to the foundation, have not been considered. The computations themselves involve an unwarranted generalization of the Rankine-Résal equations. For these reasons, the analysis fails to furnish a satisfactory basis for the design of a cofferdam on a clay foundation.

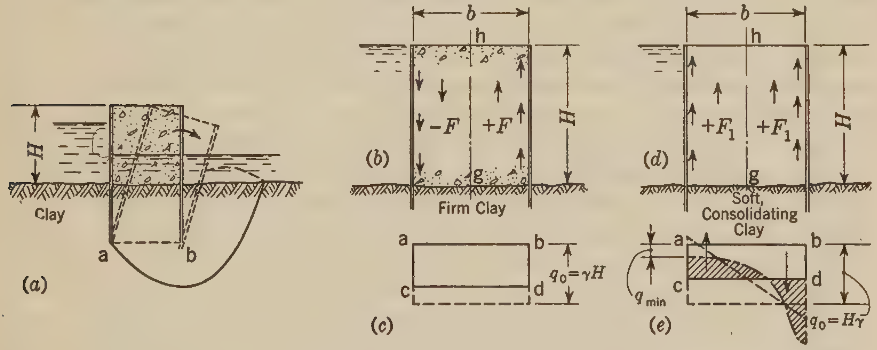

FIG. 10.—CELLULAR COFFERDAMS ON CLAY

The first requirement for the stability of a cofferdam on clay is that the clay stratum should be strong enough to sustain the weight of the cofferdam. The ultimate bearing capacity of an undisturbed, homogeneous clay stratum depends only on the average cohesion c of the clay. This statement has been confirmed repeatedly by experience—most recently by the failure of a large footing on soft clay (23) reported in 1942. Fig. 10(a) is a vertical section through a cellular cofferdam that rests on a homogeneous clay stratum of great depth. Before the cofferdam is acted upon by one-sided water pressure, it represents a continuous uniformly loaded footing whose base ab adheres to the supporting clay. If the upper surface of the clay were at the elevation of the base of ab, the failure load (in excess of the pressure which acted on ab before the construction of the cofferdam) would be equal to 5.7 c (17). The layer of clay above the level of ab in Fig. 10(a) increases the bearing capacity slightly. Hence, if the weight of the cofferdam, γH per unit of area, is equal to 5.7 c, the clay would be able to carry slightly more than the weight of the cofferdam. However, subsequent application of a one-sided water pressure would cause the cofferdam to fail by inward tilting as indicated by the dashed lines in Fig. 10(a). From the expression, $\gamma H = 5.7\ c$, the value,

$$H = 5.7 \frac{c}{\gamma} \quad \text{.........................} (32)$$

is obtained. The height of the cofferdam should not exceed 0.7 H. Otherwise, the cofferdam would fail on account of a failure of its foundation although it may be safe in every other respect. The value of γ is usually about 110 lb per cu ft, and the value of c for soft clay ranges between 400 and 1,000 lb per sq ft. The corresponding values of H are 20 ft and 50 ft. The danger of a foundation failure can be disregarded only if the clay is stiff or if the sheet piles are driven into a stratum of sand or stiff clay. A method of evaluating the average cohesion c of natural clay strata has been described elsewhere (24).

The stability of a cellular cofferdam itself depends to a considerable extent on the compressibility of the soil between the base of the fill in the cells and the level of the lower edge of the sheet piles. The following investigation of the influence of the compressibility of the base of the fill in the cells on the stability of a cellular cofferdam is based on the simplifying assumption that the fill obeys Hooke's law and that the intensity of the vertical friction forces which act on the rows of sheet piles is independent of the distance from the neutral plane, gh in Fig. 10(*b*). The second assumption is justified by the empirical fact that a very small displacement between sand and wall suffices for mobilizing the full frictional resistance (25). A further displacement has no more influence on the shearing stresses at the contact face. It is further assumed that the sheet piles are driven deep enough into the clay to sustain the vertical forces without noticeable vertical displacement. The fill in the cells is assumed to be completely drained, and the horizontal pressure of the fill on the walls of the cells is assumed to be determined by Eq. 10, regardless of the state of stress on the vertical boundaries of the fill.

The overturning moment M can be divided into two parts, M_s and M_f. One part, M_s, is carried directly by the sheet-pile enclosure of the cells without the assistance of the shearing resistance of the fill. The other one, M_f, is carried by the fill.

In the following computations the sheet-pile enclosures of the cells are considered prismatic boxes with lengths 2 L and widths b. In Fig. 1(*a*), these boxes are represented by dash-dotted lines. The lower edge of the boxes is fastened to the ground by the buried part of the sheet piles. The shearing strength of the walls along the locks is equal to the lock friction. Application of an overturning moment increases the pressure at the lower edge of the boxes on the inside of the neutral plane gh (Fig. 10(*b*)) by Q_p per unit of width of the sheet piles, and it reduces the pressure on the outside by the same quantity. The sum of all the vertical pile reactions on one side of the neutral plane of one cell is $Q_p\,(2\,L + b)$. At the instant of the first slip in the locks, this force must be equal to the friction $2\,T\,f$ (Eq. 14*b*) in the two locks located in the neutral plane of the cell. Hence, $Q_p\,(2\,L + b) = 2\,T\,f = 2 \times \frac{1}{2}\,\gamma\,H^2\,r\,C\,f$; or

$$Q_p = \tfrac{1}{2}\,\gamma\,H^2\,C\,f\,\frac{r}{L + 0.5\,b} \cdots\cdots\cdots\cdots\cdots (33)$$

The couple formed by the equal and opposite sheet-pile reactions on the two sides of the neutral plane of one cell is $2\,M_s\,L = 2\,L\,Q_p\,b + 2\,Q_p\,\frac{b}{2} \times \frac{b}{2}$;

whence,

$$M_s = Q_p \frac{b}{L} (L + 0.25\, b) = \tfrac{1}{2}\, \gamma\, H^2\, C\, r\, f\, \frac{b}{2}\, \frac{L + 0.25\, b}{L + 0.5\, b} \ldots\ldots (34a)$$

Introducing the customary values for cofferdams with circular cells, $b = 0.85\, H$, $L = 0.55\, H$, and $r = 0.50\, H$:

$$M_s = 0.3\, \gamma\, H^3\, C\, f \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34b)$$

The value M_s is independent of the compressibility of the base of the fill in the cells, because it depends only on the lock friction. On the other hand, the second part, M_f, of the resisting moment depends on the compressibility of the base, because the compressibility has a decisive influence on the stress conditions at the surfaces of contact between fill and sheet piles.

After a cell has been filled with sand all the vertical boundaries of the fill are acted upon by side friction in an upward direction, because the fill settles due to its own weight while the sheet piles are stationary. At that stage (that is, prior to the application of an overturning moment), the distribution of the pressure on the base of the fill is approximately uniform as indicated in Fig. 10(*c*) by the horizontal line cd and the total pressure is equal to the difference between the weight of the fill and the total side friction.

If the fill rests on an unyielding base such as firm clay, the application of an overturning moment reverses the direction of the friction forces on the vertical boundaries of the outer part of the fill, as indicated in Fig. 10(*b*), because the height of the outer part of the fill increases slightly while the height of the sheet-pile enclosure remains unchanged. The greatest value which the friction on the vertical boundaries can assume is F_1 per unit of length of the row of sheet piles. The value of F_1 is given by Eq. 23. The displacement between fill and sheet piles required to increase the friction forces F to their maximum value F_1 is very small. Hence the distribution of the pressure on the base of the fill remains approximately uniform until F becomes equal to F_1.

As long as the distribution of the pressure on the base of the fill is uniform, requiring $F < F_1$, the cofferdam can fail only by shear along the neutral plane. As soon as the unit pressure on the inner side of the base starts to increase ($F = F_1$), the cofferdam may also fail by a bursting of the locks of the inner row of sheet piles. In order to find out which one of these two types of failure is to be expected, compute the overturning moment required to produce a failure by shear and determine the corresponding friction value F. If the value thus obtained is smaller than F_1 the cofferdam fails by shear before the lock tension starts to increase appreciably.

The following computation is based on the assumptions illustrated by Figs. 10(*b*) and 10(*c*): The neutral plane passes through the center line of the crest of the cofferdam, the friction forces F which act on the vertical contact faces of the fill on either side of the neutral plane are equal and opposite, and the distribution of the pressure on the base of the fill is approximately uniform. On these assumptions the cofferdam fails as soon as the total friction force on the vertical boundaries of the fill on one side of the neutral plane, $F\,(2\,L + b)$ per cell of a cofferdam with circular cells, becomes equal to the total shearing resistance, $2\,L\,S'$, on the neutral plane of the fill in one cell. The value of S'

is given by Eq. 12. Since $2\,L\,S'$ must be equal to $F\,(2\,L + b)$,

$$F = \tfrac{1}{2}\,\gamma\,H^2\,C\tan\phi\,\frac{L}{L + \frac{b}{2}} \quad \text{(35a)}$$

The greatest value that F can assume is

$$F_1 = \tfrac{1}{2}\,\gamma\,H^2\,C\tan\delta \quad \text{(35b)}$$

The value $\tan\phi\,\frac{L}{L + \frac{b}{2}}$ in Eq. 35*a* is commonly smaller than the value $\tan\delta$ in Eq. 35*b*. Hence, the cofferdam is likely to fail by shear before the friction between fill and sheet piling is fully mobilized. The overturning moment for one cell at which failure occurs is $2\,L\,M_f = 2\,F\,L\,b + 2 \times F\frac{b}{2} \times \frac{b}{2}$. Hence,

$$M_f = F\,b\left(1 + \frac{b}{4\,L}\right) = \tfrac{1}{2}\,\gamma\,H^2\,C\,b\,\frac{1 + \frac{b}{4\,L}}{1 + \frac{b}{2\,L}}\tan\phi \quad \text{(36a)}$$

per unit of length of the cofferdam. Assuming $b = 0.85\,H$, $L = 0.55\,H$, and $\phi = 34°$, $\tan\phi = 0.675$,

$$M_f = 0.22\,\gamma\,H^3\,C \quad \text{(36b)}$$

The total overturning moment M_t required to produce the failure is equal to the sum of M_s (Eq. 34*b*) and M_f. Assuming f in Eq. 34*b* to be equal to 0.3 the value—

$$M_t = \gamma\,H^3\,C\,(0.09 + 0.22) = 0.31\,\gamma\,H^3\,C \quad \text{(37)}$$

—is obtained.

Since the shearing force on the outside contact faces of the fill in the cell is most likely smaller than that on the inside, the cofferdam must be expected to fail at an overturning moment of less than M_t. Whatever the critical value of the overturning moment may be, the stability of the cofferdam is higher than that of a cofferdam with similar dimensions on a rock foundation, because the outer row of sheet piles is anchored in the subsoil. The anchorage increases the stability of the dam. Therefore, it is safe to design the cofferdam on the basis of the same semiempirical rules that have been proposed for the design of cellular cofferdams on a rock foundation.

The sheet piles are acted upon by the sum of the vertical forces Q_p (Eq. 33) and F (Eq. 35*a*). The depth of sheet-pile penetration is determined by the condition that the sheet piles should be able to sustain these forces without noticeable displacement. The bearing capacity and the skin friction of the sheet piles can be determined by pulling tests on test sheet piles on the job.

If a cofferdam rests on a base that continues to yield under the influence of the weight of the fill in the cells while the overturning moment is applied, the fill slides along the sheet piles in a downward direction. Because of friction, all the contact faces of the sand are acted upon by a force F_1 per unit of width acting in an upward direction as indicated in Fig. 10(*d*) by arrows. The pressure on the base of the fill is equal to the difference between the weight of the fill and the full side friction (pressure area abcd in Fig. 10(*e*)). The overturning moment causes the cofferdam to tilt inward, but, since the sand continues to slide along the sheet piles in a downward direction, the tilt cannot alter the shearing stresses on the vertical contact faces. This fact constitutes a vital difference between the conditions for the stability of the cofferdams on a firm base (Fig. 10(*b*)) and on a consolidating base (Fig. 10(*d*)). Since the shearing stresses on the vertical boundaries of the fill in the cells have a constant value, no increase of the overturning moment beyond M_s (Eq. 34*b*) is conceivable without a corresponding change of the pressure on the base of the fill in the cells. In Fig. 10(*e*), the change of the pressure on the base, caused by the overturning moment, is indicated by shaded areas.

Hence as soon as the overturning moment becomes greater than M_s, Eq. 34*a*, the unit pressure on the inner part of the base increases rapidly and a failure due to bursting of a lock of the inner row of sheet piles becomes imminent, irrespective of the state of stress on the neutral plane. On account of the increase of the pressure on the inner part of the compressible base, an increase of the overturning moment beyond M_s should be associated with a conspicuous inward tilt of the cofferdam.

Only three cellular cofferdams on a soft, highly compressible base have come to the writer's attention. One of them is the cofferdam for raising the battleship *Maine*; the second is the western part of the middle wall of the shipways described by C. B. Jansen, M. Am. Soc. C. E. (7); and the third is a bulkhead adjoining one of these shipways.

Fig. 11(*a*) is a simplified vertical section through the cofferdam around the *Maine*. The cofferdam consisted of circular cells with a radius of 25 ft. The stratum between the base of the fill in the cells at El. − 35 and the surface of the clay at El. − 65 was described as a red loam with shells (26). The cells were filled with heavy clay excavated by means of a hydraulic dredge. The progressive consolidation of the clay beneath the base of the fill in the cells was demonstrated by the fact that the wooden drain boxes which were built into the fill of the cells settled 4 ft to 5 ft (26). As soon as the water level inside the cofferdam was lowered 15 ft, the inward tilt of the cofferdam in-

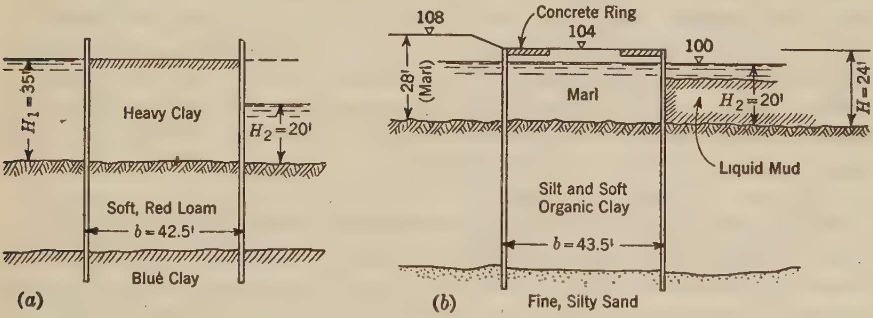

Fig. 11

creased so considerably that it was decided to increase the stability of the dam by constructing an inner berm. At that stage the overturning moment produced by the unbalanced water pressure was about 370 kip-ft per ft. To correlate the known behavior of the cofferdam with the results of the preceding analysis, the overturning moment M_s, which the sheet-pile enclosure of the cells can stand without the assistance of the shearing resistance of the fill in the cells, will be computed.

To determine the moment M_s, it is necessary to estimate the lock friction. If P_t denotes the difference between the horizontal pressure on the inside and that on the outside of the inner row of sheet piles of the cofferdam per unit of width of the sheet piles, the total friction in one lock is $P_t r f$. Using the same procedure which led to Eq. 34*b*, the formula,

$$M_s = P_t r f \frac{b}{L} \times \frac{L + 0.25\,b}{L + 0.50\,b} \quad \ldots\ldots\ldots\ldots\ldots\ldots (38)$$

is obtained. For the cofferdam around the *Maine*, the writer assumes $\gamma = 110$ lb per cu ft, $\gamma' = 50$ lb per cu ft, $\gamma_w = 63.5$ lb per cu ft, and $C = 1.00$. The corresponding value of M_s is 490 kip-ft per ft. The deflection of the cofferdam became conspicuous as soon as the overturning moment became equal to 371 kip-ft per ft $= 0.76\ M_s$.

In Fig. 4(*c*) is shown a section through the middle wall of the shipways described by Mr. Jansen (7). The cells were filled with a stiff, calcareous clay known as marl. The height H of this cofferdam is 35 ft, $r = L = 24.3$ ft, $\gamma = 120$ lb per cu ft, and $\gamma_w = 63.5$ lb per cu ft. Assuming $C = 1$, the value M_s (Eq. 38) is equal to 625 kip-ft per ft. When the shipway south of the wall was pumped out, the unbalanced water pressure on the north side of the wall produced an overturning moment $M = 456$ kip-ft per ft $= 0.73\ M_s$. At that stage, the average deflection of that part of the cofferdam which rested on stiff marl was less than 2 in.—which is negligible. However, the deflection of the westernmost part which rested on a soft, dark clay with a natural water content of about 70% was almost 8 in. as shown in Fig. 4(*c*). It increased so rapidly that it was decided to stop the movement by constructing a temporary support. This is a good illustration of the detrimental influence of a soft base on the stability of a cellular cofferdam.

Fig. 11(*b*) is a section through the cellular bulkhead adjacent to the aforementioned shipways. The cells are cylindrical and are filled with marl. The fill in the cells rests on a highly compressible stratum consisting of an irregularly stratified mass of silt, soft and dark, and organic clay with a very high water content. Evaluating Eq. 38 on the basis of $H = 24$ ft, $H_1 = 20$ ft, $\gamma = 120$ lb per cu ft, $\gamma' = 57$ lb per cu ft, $C = 1.00$, and considering, in addition, the side pressure of the liquid mud on the river side, with a submerged unit weight of 34 lb per cu ft, the value $M_s = 178$ kip-ft per ft was obtained.

The bulkhead is acted on by the active earth pressure of a mass of marl whose surface is at El. 108. The marl was excavated in a borrow pit by means of a hydraulic dredge, transported through pipe lines and deposited in such a manner that it displaced the river mud adjoining the land side of the bulkhead and forced part of the mud out into the river through a temporary gap in the bulkhead. The overturning moment produced by the active earth pressure of the marl was estimated on the assumption that the angle of internal friction of the marl is zero and that the cohesion is between 250 and 300 lb per sq ft. Thus, a moment M between 116 lb-ft per ft and 155 lb-ft per ft (0.65 to 0.88 M_s) was obtained.

During the construction of the backfill, the crest of the dam moved out to distances as great as 7 in. During the following 1.5 years the deflection increased by amounts as great as 15 in. which indicates that the overturning moment is fairly close to the maximum value which the cofferdam can safely stand. To prevent a distortion of the cells, a massive concrete ring was poured on the surface of the fill in every cell. Because of the consolidation of the fill and of the base of the fill, the concrete rings settled along the waterfront as much as 2 ft. On the land side the settlement is less than one half of that on the water side, which indicates that the pressure on the base increased from the land toward the water side. However, the overturning moment was still considerably smaller than M_s (Eq. 38).

By the theoretical analysis presented herein, the cofferdams represented in Fig. 11 should have shown no signs of distress until the overturning moment M became equal to M_s (Eq. 38); but all of them started to deflect quite alarmingly as soon as M became greater than about 0.75 M_s. Hence, it seems that the evaluation of M_s involves a considerable error on the unsafe side. The error may be due to the real lock tension being smaller than the estimated value, to the coefficient of lock friction being less than 0.3, or to both causes combined. Because of this error, cellular cofferdams on a soft base should be designed so that the computed resisting moment M_s is at least equal to 1.5 times the overturning moment.

If the construction of a cellular cofferdam on a clay foundation involves lowering the water level on one side of the cofferdam, the effect of the seepage pressure on the foundation of the cofferdam and on the subsoil of the unwatered area must be considered independently. In many instances it is possible to eliminate undesirable hydrostatic pressure conditions by simple drainage. The discussion of the drainage devices is beyond the scope of the paper.

Part III. Conclusions

Eleven conclusions seem indicated from the foregoing:

1. The traditional assumption that a cellular cofferdam can be regarded as a gravity wall leads to erroneous conclusions regarding the distribution of the soil pressure on the base of the dam.

2. Because of the friction between the fill and the sheet-pile walls of the cells, the increase of the soil pressure at the inner part of the base of a cellular cofferdam with conventional dimensions due to the overturning moment produced by the water pressure is negligible, provided the base is firm.

3. The lock friction in the cross-walls adds materially to the stability of the cofferdam, and it reduces very considerably the deflection of the crest. This fact constitutes an important advantage of the cellular cofferdam over the double-wall cofferdam.

4. The assumption that the weep holes in the inner wall of cells filled with sand suffice to drain the cells is not necessarily justified.

5. The lateral earth pressure of the fill in the cells on the sheet-pile enclosure of the cells is not even approximately equal to the Rankine pressure. Therefore, the greatest lock tension can only be estimated on a semiempirical basis.

6. The required depth of penetration of the sheet piles of cofferdams on a sand or a clay foundation is determined by the condition that the bearing capacity of the sheet piles per unit of width should be equal at least to 1.5 times the shearing force which acts per unit of width between the fill and the length rows of sheet piles at maximum overturning moment. Since the vertical forces that act on the sheet piles can be estimated in advance, the required depth of sheet-pile penetration can be determined by means of pulling tests on test sheet piles in the field.

7. Cellular cofferdams on a sand foundation require, in addition to adequate sheet-pile penetration, a protection against the formation of boils. Protection can be achieved with either a loaded, inverted filter or a plain sand berm with a broad base. If an inverted filter is used, its functioning requires supervision by means of telltale pipes.

8. Rows of steel sheet piles in contact with, or embedded in, fine silt or clay do not intercept the flow of seepage.

9. The principal dimensions of cellular cofferdams on stiff clay can be determined by means of the same semiempirical equations that have been proposed in this paper for the design of cellular cofferdams on a rock foundation.

10. If the fill in the cells of a cofferdam rests on a compressible stratum which continues to consolidate after the overturning moment has been applied, a relatively small moment suffices to produce a very unequal distribution of the pressure on the base of the fill in the cells. Such a cofferdam should not be expected to carry more than about 0.7 times the overturning moment M_s (Eq. 38). The degree of stability of the cofferdam is practically independent of the strength of the fill in the cells.

11. The shearing resistance on vertical sections through the fill in the cells and the lock friction can only be estimated. Since the stability of every cellular cofferdam depends to a large extent on these quantities, no theoretical refinements in the design of such dams are warranted and no equation pertaining to such dams can be used safely unless its approximate validity has been repeatedly demonstrated by construction experience. Therefore, the principal sources for increased knowledge on cellular cofferdams are accurate field observations.

APPENDIX II

NOTATION

The following letter symbols, used in this paper, conform essentially with "Soil Mechanics Nomenclature,"[3] adopted by the Society's Board of Direction in 1941:

b = width; width of equivalent cofferdam with straight walls:

  b_1 = outside width of the real cofferdam (Figs. 1(a) and 1(b));

  b_0 represents an empirical value for the width b of equivalent cofferdams whose outside is acted upon by water pressure only;

  b_m (Eq. 8) = value of b for a cofferdam with a theoretical factor of safety G_s = 3 with respect to overturning;

C = coefficient of earth pressure, an empirical constant;

c = cohesion; average cohesion of clay per unit area;

D = diameter;

d = distance between flow lines (Fig. 9);

F = total frictional resistance on a surface of contact, per unit width:

  F_b = value of F on the base of a cofferdam (Eq. 1);

  F_{bs} = value of F at the base of a cofferdam which is completely saturated to a height H_s above the base;

  F_1 = resistance against sliding along surface of contact between fill and sheet piles, per unit of width of the row of sheet piles;

f = coefficient of lock friction;

G_s = factor of safety;

g = a force per unit of volume; g_s = seepage force in Eq. 29a;

H = height of a cofferdam:

  H_s = average elevation of line of saturation above base of a partially saturated cofferdam;

  H_w = depth of water adjoining a breakwater, between storms;

  H_1 = elevation of level of water adjoining the outside of a cofferdam, if the highest water level is below the crest of the dam (Fig. 5);

  H_2 = elevation of level of water adjoining the inside of a cofferdam, with reference to base of dam (Fig. 11);

  H_{max} = greatest vertical distance between level of water on two sides of a cofferdam (Fig. 3);

---

[3] *Manual of Engineering Practice No. 22,* Am. Soc. C. E., 1941.

h = loss of hydraulic head that is caused by flow of water through distance l in a mass of sand (Fig. 9(a)) or through the locks of a row of sheet piles (Fig. 5); also maximum temporary excess head on wind side of a breakwater during a storm (Fig. 9(f)):

  h_1 = hydrostatic head on the inside of the outer row of sheet piles of a cofferdam (Fig. 5(b));

  h' = hydrostatic excess head at heel of breakwater while a wave breaks (Fig. 9(f));

  h'' = drop of head at heel of breakwater after a wave has spent itself;

i = hydraulic gradient h/l (Fig. 9(a)); $i_1 = \frac{\gamma'}{\gamma_w}$ (Eq. 29b) = hydraulic gradient in the case of upward seepage at the instant when boiling begins;

k = a constant = coefficient of permeability;

L = half the spacing of circular cells in cofferdams (Fig. 1(a)), or the distance between cross-walls in cellular cofferdams of the diaphragm type (Fig. 1(b));

l = length of a cubical element of a mass of sand (Fig. 9);

M = overturning moment per unit length per unit of length of a cofferdam:

  M_a = the moment required to move the point of application of the resultant pressure on the base of a gravity wall from the center to the inner boundary of the middle third (Eq. 6);

  M_f = the part of an overturning moment carried by the fill within the cells of a cofferdam on stiff clay;

  M_s = the part of an overturning moment carried by sheet-pile enclosures of the cells of a cofferdam on clay without the assistance of the shearing resistance of the fill;

  M_t = total overturning moment required to produce failure of a cofferdam on stiff clay;

  M_0 = overturning moment produced by the water pressure on the outside of a cofferdam after the outside water level has arrived at the level of the crest of the dam (Eq. 19a);

  M_1 = overturning moment required to increase the pressure on the inner part of the base of a cofferdam on a rock foundation (Fig. 7(d));

  $M_{\max}$ = moment required to overturn a gravity wall;

m = ratio between M_1 and M_0 (Eq. 27);

n = the greater of two values n_1 and n_2; $n_1 = \frac{P}{P_0}$ and $n_2 = \frac{M}{M_0}$;

P = resultant of all the horizontal forces which act on a cofferdam, per unit of length of the dam:

  P_A = active Rankine pressure on a row of sheet piles or on the neutral plane of a cofferdam, per unit of width;

  P_e = earth pressure on a row of sheet piles or on the neutral plane of a cofferdam, per unit of width;

P_s = horizontal force which prevents the inward movement of the lower edge of the inner row of sheet piles of a cofferdam on a rock foundation per unit of width of the row (Fig. 8);

P_t = difference between pressure which acts on inside and outside of inner row of sheet piles of cofferdam on clay, per unit of width of sheet piles;

p = pressure per unit of area; p_e = earth pressure per unit of area of a vertical surface, at depth Z below top of fill;

Q = equal and opposite vertical forces per unit of length of a cofferdam constituting a couple which is equal to the total overturning moment or to part of it; Q_p = vertical force per unit of width of sheet-pile enclosure of cells of a cofferdam on clay constituting a couple equal to the overturning moment M_s per unit of length of the dam;

q = pressure per unit of area of base of a cofferdam:

q_0 = average unit pressure, equal to weight of fill in the cells divided by area of its base;

$q_{\min}$ = smallest value which the unit pressure at outer edge of the base of cells filled with sand can assume;

r = radius of circular cells or arcs;

S = average shearing resistance per unit of width of neutral plane of a cofferdam:

S' = that part of S which is due to shearing resistance of fill in cells;

S'' = that part of S which is due to resistance against slippage in locks;

T = total tension in one lock;

t = lock tension per unit length at depth Z; t_1 = greatest unit tension in a lock (Eq. 22*b*);

V = volume;

v_d = quantity of water which flows through space between two adjoining flow lines per unit of time and unit of length of the dam;

W = weight;

Z = depths measured from the tops of cells;

γ = unit weight of moist fill in cells; γ' = submerged unit weight of fill in cells;

γ_w = unit weight of water;

Δ = deflection;

δ = angle of friction between substances such as the fill in a cell and sheet piles;

ρ = angle of friction for sliding; and

ϕ = angle of internal friction.

DISCUSSION

G. G. GREULICH,[4] M. AM. SOC. C. E.—Some new methods, and an expansion of some old ones, for the precise mathematical evaluation of certain phenomena relating to cofferdam design are offered in this paper. The phenomena have been noted before, and empirical allowances have been made for their design and construction. The new concepts of analysis presented in the paper should be useful in providing additional cross checks for the adequacy of a cofferdam design. However, the use of precise mathematical evaluations can result in misleading, erroneous, and dangerous conclusions in the hands of inexperienced individuals, when dealing with such uncertain quantities as the widely divergent materials in ordinary soils whose properties and resulting physical characteristics and effects can vary widely due to either man-made or natural changes or disturbances.

Deflection of Cellular Cofferdams.—In cellular cofferdams, the nature of the deflection depends largely not only on the elastic properties of the fill in the cells, but also on the method of depositing the fill. For example, fill deposited in cells inundated in water will not produce the immediate tamping or packing effect obtained by ordinary methods of dry filling. Tightening the interlocks by removing loose play, as well as by stretching the entire cell, aids materially in reducing the deflection. The analogy is similar to the comparison of an empty headless barrel or keg with dried-out staves and loose hoops to one with tight hoops and staves in solid contact. Even without fill, the tight barrel will stand considerable lateral pressure at the top without appreciable deflection when the bottom is fixed. The loose barrel, of course, will rack far out of position. Where cells have been built and filled in deep water, the deflections under load are less for subsequent unwaterings than for the first unwatering because the consolidation and settling effect from the first drainage of the fill in the cells is still felt during later cycles of filling and emptying the cofferdam. The deflection is also affected appreciably by the character of backfill material and the method of its deposition.

Permeability of Cellular Cofferdams and of Their Sheet-Pile Enclosures.—With reference to the permeability of sheet piling near the base of cells, tension in interlocks also prevails for a short distance below the base of fill. The softer the foundation material, the greater the depth of tension will be.

Resistance Against Sliding; Cellular Cofferdams on Rock.—Sheet piling is usually "toed in" on rock by driving so that it penetrates the soft upper layers of the rock. Where the rock is too hard to be penetrated by the sheet piling, mechanical methods such as dowels grouted into the rock have been proposed to prevent sliding. The method of grouting dowels into rock is highly objectionable due to intermittent supports and high stress concentrations at the points of support which would tend to rupture the sheet-pile interlocks. Another proposed method, which presents some very difficult construction problems, is the concreting of sheet piles in trenches cut into the rock.

---

[4] Cons. Engr., Specialty Div., Sales Dept., Carnegie-Illinois Steel Corp., Pittsburgh, Pa.

Prior to the early 1930's, cofferdam design methods were based largely on "rule of thumb" and on precedent. The customarily accepted Pennoyer method (10)(11) was offered as a rationalized, simplified procedure, and not as a perfected, all-inclusive scientific approach to the problem.

As Professor Terzaghi states (see text concerning Eqs. 1 and 2), the Pennoyer design method disregards some factors that may reduce the margin of stability. When these factors are omitted, greater sliding resistance is indicated than is really the case when the actual shear distribution and height of saturation are taken into consideration. Inasmuch as there seem to be no sliding failures on record, the Pennoyer method has apparently been adequate, even though the factor of safety was not as high as computed. A more precise approximation can easily be obtained by applying the author's method. However, as Professor Terazghi states (see paragraph introducing Fig. 3), there is at present no reliable method of determining in advance the state and properties of the soil in the fill; and quantitative data on the stiffening effect of the sheet-pile walls are not available. Therefore, during the present state of the art, any precise mathematical analysis can at best be considered only an approximation.

Resistance Against Internal Shear; Cellular Cofferdams on Rock.—The author is in error in stating (see paragraph introducing Eq. 9) that possible failure by shear along the vertical neutral plane in the cells has never received any attention. Colonel Pennoyer has called attention to the investigation of internal shear resistance and its relation to the safety of the cofferdam (10*a*)(10*b*).

Resistance Against Overturning; Cellular Cofferdams on Rock.—The preceding remarks on resistance against sliding are also applicable to the factor of safety against overturning. Since the factor of safety of 3.8 suggested by the method of Colonel Pennoyer when applied to the selected example (see text following Eq. 20) is based on premises that may not actually exist, the factor with the assumed values, as asserted by Professor Terzaghi, is still about 2, which should be adequate. The writer presumes that in making this assertion Professor Terzaghi considered that the limitations imposed by internal shear are largely offset by the benefits of soil compaction and of friction in the interlocks.

With respect to overturning, fortunately the cellular type of cofferdam can be widened at practically no additional cost. Extension of the width makes the spacing greater between cross-walls so that the amount of steel is not increased in circular cells and is increased very little on the straight diaphragm wall type. In any case, the extra fill is a minor item. Of course, the allowable interlock tension may limit the width for a given height. In general, the cofferdam should be made as wide as reasonable limits allow. This increases stability and also helps in reducing permeability.

The increased stiffness of cellular cofferdams, as compared with other types, has been recognized in many ways, and lock friction (see second paragraph following Eq. 21) has been assigned an important place as a factor in increasing the stiffness of the cells. Colonel Pennoyer has mentioned this fact (10*b*). Heretofore, it has been difficult to evaluate the combined effect of the shear resistance of the fill and of the steel interlocks. It is recognized (returning to the loose barrel-stave analogy) that deflection or racking of the top of the cofferdam soon tends to increase the sliding resistance of one piece of sheet piling against the other in the cross-walls and that a large percentage of the total resistance to shear may be developed by the steel before the earth fill is distorted enough to contribute its complementary shear resistance. Therefore, the true value may lie somewhere between the value for earth fill alone and the combined value, as determined in the paper. Professor Terzaghi has proposed a method of approximating the combined values which appears to be simpler and more rational than any that has previously been brought to the writer's attention. The author's method, however, does not take care of another factor introduced by the sheet piling. The added factor is the direct tension introduced in the sheet piling when the cells cant or lean inward. This movement crowds the interlocks together so that individual pieces can exert tremendous resistance to sliding or upward movement. Because of these phenomena, the diaphragm or cross parts of steel sheet-pile walls are capable of transmitting some direct tension from the inside top of the cell, diagonally down to the outside bottom of the cell. In other words, the effect is similar to the introduction of stay rods from the inner top to the outer base of the cell.

The fact that interlock tension failures, as observed by Professor Terzaghi, usually occur before overturning moment is applied to the cells (see second paragraph preceding Eq. 23) seems to indicate that internal pressures and shear resistance in the fill are considerably more than the Rankine active pressure. This is probably due to the tamping effect of dropping fill in cells, as well as to a squeezing and consolidating effect occurring as the partly filled cells weave and stretch during filling and drainage of water. These factors all contribute to the ultimate stiffness and stability of the cofferdam.

There could be considerable danger of interlocks failing by tension at the inner toe of a cofferdam on rock if the piling were not toed or bedded in the rock. Only the most foolhardy individual would permit such construction, especially on wide cells. It is generally recognized that driving on rock tends to damage the lower ends of the sheet piling and may produce incipient unlocking of adjacent piles. For this reason, manufacturers always recommend, and sound practice should dictate, the secure embedment of the lower ends on bare rock.

Even if the vertical reaction of the piles from overturning moment is theoretically sufficient to hold the piles in place as is repeatedly demonstrated by the shape of the bulge above the inner toe, the remarks regarding embedment of the lower ends still apply. Although, as Professor Terzaghi has emphasized (see third paragraph following Eq. 27), two of the three customary equations may be inadequate and the third is open to question, the fact remains that comparatively little trouble has been experienced with cellular cofferdams. As the author states, in the application of these equations, very conservative values have been used for soil constants. He expresses concern that an ambitious designer some day might use soil constants determined by laboratory tests, with fatal results. Fortunately, cofferdams usually represent the expenditure of considerable sums, and the final decisions regarding design and construction have been in the hands of mature, experienced individuals. The writer knows of no serious failures in which customary practices were followed by engineers, who generally allowed ample margins beyond the values obtained by the equations. Such practices may have been needlessly extravagant, and, admittedly, more exact methods of design are desirable to prevent future economic waste. There are also cases in which cofferdams with dimensions smaller than those indicated by the usual equations have been used without encountering difficulties; although in a few of such instances the factors of safety were so low that disaster could have followed any minor disturbance of soil or water level. In general, however, unanticipated forces or acts of nature have caused disasters which conceivably could have occurred regardless of any kind of theoretical analysis.

Penetration of Sheet Piling; Cellular Cofferdams on Deep Sand Strata.—Aside from consideration of uplift of sand due to percolation, it is believed that the depth for driving the sheet piling in sand need not be $\frac{2}{3}$ H (see second paragraph following Eq. 29*b*) but that $\frac{1}{2}$ H would be ample—because the sand in the cells can grip only one side of the piling, whereas, when driven, the piling is gripped on both sides.

Bearing and Extraction Values of Sheet Piling; Cellular Cofferdams on Deep Sand Strata.—Sheet piles in pairs may be driven and then loaded or extracted by means of hydraulic jacks to determine the forces required to shove down or pull out the piles (see second paragraph following Eq. 37). In similar soils, the values for a given depth of penetration are approximately uniform. It is easier to make an extraction or pulling test than a load test on the sheet piling, as anchor piles are not needed and the required pull may be exerted against cribbing on the ground. The bearing capacity may be safely assumed to be 15% greater than the extraction value, although, where piling is driven to rock, bearing value might be much greater than extraction value. The evaluation of vertical load capacities on sheet piling by means of hammer formulas is a very uncertain practice. The resistance of the interlocks when driving in a wall is a greatly varying factor—so great in some instances as to prevent driving to moderate depths. The values for the sheet piles in the soil must be determined on piles separate from a continuous wall.

Conclusions.—The conclusions are most excellently stated. However, conclusion 2 needs further clarification and possible expansion. With respect to conclusion 5, the reduced pressures seem to be due to arching or cohesive action, or to a combination of both, since the Rankine theory is conservative and deals with granular materials only. In conclusion 6, the depth of penetration of sheet piling can be dictated by requirements of watertightness which, in some cases, may indicate a greater depth than is needed for load capacity.

Cellular Versus Double-Wall Cofferdams.—The author's comments about the superiority of the cellular, as compared to the double-wall, cofferdam are true only when full consideration has been given to adequate foundation support and the reduction of permeability in the supporting soil. Inasmuch as double-wall cofferdams usually have inner, and often outer, berms, their service record has been about as good as that of the cellular type. There have been failures of individual cells due to boils or undermining from percolation which might not have occurred on a wide-bermed, double-wall installation.

General Remarks.—Professor Terzaghi has presented an analysis which should lead to further inquiring study and observation. He has provided another readily understood and practical series of steps for checking the design of any type of cellular cofferdam.

With this paper at hand, the designer may readily differentiate between an ultraconservative design for a permanent cofferdam or bulkhead and that for a temporary structure which, although it must be safe, may be allowed to have more deflection or movement while in use. If the movement becomes excessive in a temporary structure, it may be checked by one of the several known effective methods.

The author is to be commended for the thorough, thoughtful, and orderly presentation of a comparison between old and entirely new mathematical approaches on this subject. He deserves the wholehearted thanks of the engineering profession for assembling into convenient reference form much valuable historical and technical data on cofferdams, as well as for providing a most complete Bibliography on this difficult, complicated, and abstruse subject about which considerable quantitative information and experience must still be gathered.

Acknowledgment is made to J. R. Woods, sales engineer, Carnegie-Illinois Steel Corporation in Pittsburgh, Pa., for a constructive review of this discussion.

RAYMOND P. PENNOYER,[5] ASSOC. M. AM. SOC. C. E.—The basic computation to determine the necessary width of a cellular cofferdam, by bringing the intersection of the resultant of the moments created by two opposing forces (the lateral overturning force and the weight of the contents of the cells) within the middle third of the base, is expressed by Eq. 8. The author has stated that "This conclusion is open to serious objections." The only substitute offered in the paper for this basic determination is a statement that the "average width" of circular cells built on a rock foundation has been 0.85 H, in the past (see paragraph containing Eq. 27). All the remainder of the paper analyzes the theoretical internal stresses in a cell on the basis of this ratio.

Overturning Moment; Width of Cells.—The writer believes that 0.85 H has been more nearly the minimum width of completely excavated and unwatered cellular cofferdams than the average value. Furthermore, the proper and safe width of cellular cofferdams from which Professor Terzaghi has derived this questionable average has been determined, for years, by the very equation he states is open to serious objections.

It would seem axiomatic that, since the weight of the material contained in a cell determines its capability to resist the overturning moment, this material should receive careful consideration. Broken stone, gravel, sand, sand and clays, etc., have different weights, as have the undisturbed soils in which cells are built to various elevations. The analyses in the paper have all been based on sand weighing 110 lb per cu ft throughout the cell. No mention has been made of the possible buoyancy of water within the cells in so far as it will alter the weight of the contained soil (that is, the submerged weight); nor does Professor Terzaghi explain how he proposes to adjust the width of the cells to make the cells safe against overturning when there are almost infinitely variable factors affecting the weight of the contents.

---

[5] Col., Corps of Military Police, U. S. Army (Inactive), Pittsburgh, Pa.

No method is proposed to determine the width of cell necessary to resist the lateral or overturning forces safely. The paper deals only with an analysis of a cofferdam built in water on bare rock, with no submerged soil overburden. This condition is extremely rare in practice and always requires that sheet piles be driven into empty cells on the rock—a major construction problem. The width of a cofferdam in salt water should be different from that in fresh water, even under such conditions. Likewise, there must be an adjustment in width to resist the lateral pressures of submerged soils, for various elevations, in combination with layers of natural soil or fill above such submerged soil. There must also be an adjustment to resist other possible lateral forces due to construction equipment, storage loads, railroads, derricks, wave action, ice, swiftly flowing water, etc. This basic consideration has been dismissed in the paper by stating that the average width of cellular cofferdams in the past has been 0.85 H, and further that this ratio may be considered an acceptable basis for the design of cofferdams in clear water on rock.

Eq. 7, with its supporting text, is offered under the assumption that a cellular cofferdam filled with soil has a factor of safety of 3 when the width is calculated to bring the resultant of the forces within the middle third of the base. This formula is in serious error since the soil within the cells must be assumed incapable of resisting any tension or uplift along the outside face (the heel) of the cofferdam. The width of a cell must be adjusted to bring the stress to zero at this point (neither tension nor compression) and, as a consequence, the factor of safety against overturning is actually unity, which means that no factor of safety exists. Professor Terzaghi then discusses the possible, theoretical distribution of pressures under the cells (Fig. 7) and decides that, since a sand-filled cofferdam having a width of 0.85 H actually has its theoretical factor of safety reduced from 3.8 to not more than 2, the internal shear becomes the critical consideration.

Internal Shear.—An attempt was made in 1934 to explain mathematically occasional leaning or distortion of the cells because of evident lack of internal shear resistance of the soil contained in the cells (10). At this time, the writer offered the following formula (10*c*) for vertical and horizontal shear, s, at a given point:

$$s = \frac{3\,P}{2\,b} \qquad (39)$$

in which, in addition to the notation of the paper, P equals the total lateral external load above the given point. Eq. 9, giving the total shear along the so-called neutral plane of the cell for a given moment, results in exactly the same value as Eq. 39 for maximum shear. Several successful bulkheads have been built which, upon analysis, were not more than 60% safe in internal shear, but which, at the same time, had a width sufficient to resist the estimated overturning based on the "middle third" method of determination. A mathematical theory of analysis will never serve as more than a guide based on precedent, because the assumption that the soil fails, along a plane of maximum shear, called the vertical axis, similar to a beam, seems fallacious.

What actually happens is that the entire mass of confined soil changes shape simultaneously. This action can best be described as a universal plastic flow, or distortion, which bears no relation to the strains set up in an elastic homogeneous mass that can resist shear, compression, and tension—with special emphasis on tension. When a cell leans inward, as a result of the simultaneous distortion, or flow, of all the contained material, the sheet piles in the internal, or diaphragm walls, remain parallel to each other and necessarily maintain their original length to lean into a parallelogram. Under this condition, all the interlocks in a cross-wall, or interior wall, slip the same amount at the same time, irrespective of their position in relation to the fictitious neutral axis.

As the writer stated previously (10), the resistance to lateral deformation of the bulkhead, through friction in the interlocks of the sheet piles, affords an indeterminate factor of safety in the calculation of internal shear. This still seems true despite the author's able mathematical analysis of this feature for a hypothetical cofferdam with a width of 0.85 H. With sufficient sand trapped and wedged into the interlocks, or sufficient penetration to develop frictional resistance against the sliding, the shear resistance of a cross-wall might be equal to that of a continuous plate of steel over the entire cross-wall. It is likewise possible that the assumption of the frictional value of an interlock as three tenths of the actual tension may be entirely too high. A cellular bulkhead built in undisturbed virgin soil, followed by excavation on one side, is a case in point. There might be no tension on the interlocks before the cells became distorted laterally.

Furthermore, the paper states (see sentence following Eq. 21) that the friction value f "is likely to be fairly close to 0.3" of the tension per unit of length on a sheet-pile interlock—with no explanation as to the basis for this seemingly arbitrary assumption. If this factor was assumed analogous to the coefficient of friction of steel on steel, the statement would seem fallacious. Interlocks of sheet piling are designed for the least frictional resistance when setting up, driving, and extracting, with emphasis on reducing the area of contact between surfaces to a minimum and on eliminating wedging action from forces tending to separate the interlocks. There is no relation between the frictional value of two pieces of steel in what amounts to line contact and the coefficient of friction of steel on steel times a tension force per unit of length, when no area of contact can be assumed. In the discussion of the bulkhead in Fig. 11, Professor Terzaghi has expressed some doubt as to the safety of using three tenths of the tension for the frictional value of an interlock in his analysis of the actual distortion of the cells.

Tension in Interlocks.—The author recommends that the method of approximating the possible maximum interlock tension by the so-called Rankine formula, using $\tan^2\left(45° - \frac{\phi}{2}\right)$ to arrive at the conversion factor between the vertical and horizontal pressure, be abandoned in favor of using 0.4 when the cells are filled with sand and gravel. He states that this method does not create the illusion of resting on a scientific basis. It is seldom, however, that a cell entirely filled with sand is encountered in actual practice. Consequently, the paper leaves the reader without a practical basis for analyzing the problem that generally confronts him. As a result, use of the factor 0.4 might be worthless or even dangerous.

Professor Terzaghi indicates that designers seldom, if ever, use a conversion factor of much less than 0.4 for the lateral pressure of the contents of a cell filled with sand or gravel, completely drained and founded on rock. With a working stress of 4,000 lb per lin in. in tension for the interlock of the sheet pile, cellular cofferdams would be limited to a height of approximately 48 ft and a maximum radius of cell of about 24 ft. With a working stress of 6,000 lb per lin in., the limitations would be a height of about 58 ft and a radius of approximately 29 ft. Since there are many successful examples of bulkheads in service with dimensions considerably beyond these limits and containing soils far less ideal than the assumed sand and gravel, this conversion factor of 0.4 does not agree with actual practice. A conversion factor as low as 0.17 has occasionally been used without any indication that the lateral pressures in the cells were underestimated. Obviously, the relieving effect of wall friction, even to the point where a complete arch is formed as described subsequently, is an important factor to be considered when establishing the conversion factor for use in any specific instance.

The paper offers no suggestions for approximating the possible interlock tension: (1) When the cells are partly full of water and submerged soil (see "Part I. Practical Considerations"); (2) when the cells have a layer of clay or other soils at the bottom or at various heights as part of the original soil on which the bulkhead is built; or (3) when possible surcharge loads are present. Another common condition not discussed in the paper is that in which the contained soil is not fill but is composed of various types of undisturbed soil into which the bulkhead is built before excavation on one side proceeds.

In his prior paper (10*d*)(10*e*), the writer illustrated a case in which external and internal earth pressures differ which included weep holes, submerged soil, and water levels at various heights. In the light of the practical problems illustrated and discussed, and considering the complexity of conditions encountered in practice, the writer feels that Professor Terzaghi has oversimplified the problem by assuming a cell width of 0.85 H and a conversion factor of 0.4 to develop the bursting pressures.

Probably no one realizes more clearly than the writer that, at best, the use of the Rankine conversion factor is a very approximate assumption. He will continue to use it, however, until something better is available, especially since water and submerged soil seldom are the critical considerations in overturning forces, weights of material, and bursting pressures. In the light of many precedents, the use of this method is a guide which helps the experienced engineer to determine the border line between conditions in which trouble with broken interlocks is likely to be encountered, on the one hand, and the likelihood that construction will be completed successfully, on the other hand. Mathematics is only one consideration in reaching this decision, because the final verdict must take into account the strength of the sheet piling as manufactured, precedent, the variety of conditions into which the sheet piling is set up and driven, and the experience, ability, and equipment of the constructer. Interlocks can be ruptured by sand trapped in the bowls during the pile driving; builders can fail to set and drive the sheet piling accurately; or the final closure pile can be used to pull the remainder of the wall into its proper place. In all such cases, indeterminate stresses are created in the steel, or an interlock is ruptured in the process. Certainly, mathematics is futile under such conditions.

Sand and gravel, or rock, may actually arch and form a complete bottom in cells above the base of the sheet piling. About 1932 the writer had occasion to inspect a bulkhead composed of a series of diaphragm-type cells, about 35 ft by 27 ft between cross-walls and 35 ft high, the sheet piling being driven into sand and gravel along a river bank. With the bulkhead in place, the sand and gravel on the river side were excavated to bare rock and used to fill the cells to the top. As excavation proceeded, it was found that the sheet piling had been driven through a layer of boulders to about 12 ft from the bottom and had been twisted and bent, the interlocks being ruptured in many places. Water coming through the bulkhead had washed away the original soil through the gaps in the piling up to the top of the breaks, some 12 ft off the rock, leaving three or four of the cells completely empty to about that elevation. The cells were standing, however, and were resisting the maximum lateral load from the river bank as intended. Above the 12-ft elevation, the sand and gravel had formed into about as perfect a dome arched between the side-walls, front-walls, and back-walls, as could have been built deliberately in brick or stone. There was an occasional sloughing off of sand in the dome, to be sure; yet, after the cells has been repaired, the superintendent reported, a week or ten days later, that a bucket actually had to be used to break the dome, so that the fill could settle to the bottom.

An analogy may be found in a pail filled with water. Its resistance to overturning depends upon its weight, height, and cross section. All shear is taken by the steel shell of the pail as water has no shear or frictional resistance value. Other material, such as sand and gravel, does have a high shear and frictional value and consequently possesses the inherent ability to arch as described in the aforementioned example. Thus, the shear stresses in a steel bulkhead would be relieved by the soil or fill material, whereas in the pail of water the total shear would have to be transmitted by the walls of the pail without relief.

If the foregoing theory is correct in principle, it would indicate that perhaps the "middle third" limitations on width are conservative and do have a factor of safety because the "bottom" is actually able to resist some uplift at the heel. This may be one reason why mathematical analyses of internal shear seem at wide variance with the actual resistance of cells to leaning or distortion in some cofferdams. Calculations of interlock tension of moist (not submerged) soil would thus become a study in the theory of pressures in bins. This may account for the fact that the maximum pressure seems to be at the zone of greatest bulge in a cell, ordinarily about halfway up the height, although it has been observed that this varies slightly for different soils. The maximum bulge may occur at the level of the first actual "bottom." Of course, such a theory cannot be used when there is water in the cells, but the bursting pressure from the soil alone might safely be ignored under ideal conditions below the point of maximum bulge. It is difficult to imagine a condition for which the pressure of the water in the soil at the bottom could be critical, especially if the bulkhead had weep holes.

Furthermore, if the foregoing theory is correct, the distribution of pressures at the surface of the rock (Fig. 7) would differ from the true conditions, because all the pressure at the toe would have been transmitted to the steel by friction and arching. Observers have long noted that the overturning moment does not create any consequential added bursting pressure in the interlocks of the sheet piling because no consequential added deflection of the steel has been perceived. The arching theory suggested herein may account for that phenomenon also, since interlocked sheet piling is a fully supported column.

FIG. 12

In general, it has been difficult for the writer to be completely satisfied with any of the theories as to why cellular bulkheads function successfully without adding the thought that arching of the fill actually forms a "bottom" or "bottoms" to the "pail" or cell. When a material like plastic clay or mud is used to fill the cells, the action becomes uncertain, variable, and completely different from the action caused by materials like rock, sand, or gravel. It may be that the incapacity of such plastic material to arch accounts for the difference.

The writer has watched the action of many cellular cofferdams since observing the sand dome in the broken cells as described herein, and as yet has found nothing to disprove his surmise. On the contrary, when such an actual bottom is assumed, the guides obtained from the application of the basic mathematical analyses are reassuring when compared with the characteristics and action of cofferdams in service.

Cellular Cofferdams in Clay.—In his former paper (10), the writer did not attempt to discuss cellular cofferdams founded on anything except rock, because he considered there were sufficient intangibles involved in that problem. Even with Professor Terzaghi's contribution, it would seem that the proper design of cellular cofferdams in clay (or even through overlying strata of clay or silt on top of stable strata), especially when submerged, is still largely dependent on making mathematics coincide with what experience, observation, and practice dictate to be adequate construction.

The determination of the proper width of a cellular structure, founded on a stratum of unstable soil, is still a problem largely dependent upon judgment based on precedent and experience. It is axiomatic that, as soon as the sheet-pile structure extends into soil, it becomes partly a cantilever structure. If it extends deep enough and has insufficient width (weight of contents), it no longer is a gravity structure but a cantilever structure. So far as the writer knows, no attempt has been made, even theoretically, to design a cellular sheet-pile structure acting entirely as a cantilever. When all the intangible factors are taken into consideration, the problem would seem to be indeterminate.

Fig. 12 illustrates a design problem quite usual in practice, to the solution of which the paper has rendered little of tangible value. In this figure, in addition to the notation of the paper, R is the resultant of all applied forces, vertical and horizontal; and X' and X'' are moment arms as shown. Successful practice has indicated that a bulkhead can be considered as a gravity structure down to an assumed elevation, or "bottom." The selection of this fictitious bottom is a matter of judgment, taking all factors into consideration, including the resulting width of the cell. This elevation is not selected where the "countermoment" due to the passive resistance of the soil balances the overturning moment (because the calculated width of the cell would indicate a greater width than experience dictates is necessary) but at a somewhat higher elevation. One cannot take into consideration, either, the countermoment on the outside (heel) of the structure, because in this case the structure would be assumed capable of resisting the support stresses of a cantilever and there is no certainty that the structure is capable of transmitting the internal stresses properly. That part of the structure below the assumed "bottom" is thus considered as a foundation only for the gravity structure above this elevation, transmitting the compression forces due to the overturning moment and weight of cells into the soil below. Such resistance as that of this foundation—a cantilever against overturning, tension at the heel, and shear resistance against lateral distortion—may be assumed to be an indeterminate, but added, factor of safety.

The structure above this elevation of the assumed "bottom" is then analyzed for proper width, based on the width necessary to bring the intersection of the resultant of the forces represented by the weight of the contents of the cell and the overturning moment within the middle third of that bottom. The size of the cells must also be brought within a proper radius so as not to exceed the safe interlock tension in the sheet piles. Sliding is no longer a consideration and theoretical figures for shear resistance are balanced with precedent.

Professor Terzaghi states that the familiar "middle third" method of approximating the proper width of cell "is open to serious objections" (see sentences following Eq. 8); but he has proposed no alternate solution. The problem of how to determine the proper width of a cell under the aforementioned conditions, which are subject to variation on every project, has been dismissed with the very doubtful statement that the average width of such structures on rock has been 0.85 H and with the further note that internal shear is usually the governing factor. Obviously, the shear resistance of the contents of a structure under the aforementioned conditions could be much greater than the shear resistance of the contents of a structure founded on rock, which does not have the cantilever supporting value that the "foundation" gives to the sheet piling, with special reference to the internal walls. Eq. 32 giving the vertical maximum height H for a given bearing value of clay is of questionable practical value because the distribution of the pressure at the toe of the cofferdam, due to friction between the soil and the sheet piling, has been disregarded; the deeper the sheet piling is driven, the greater the distribution will be. Safe construction, as it concerns possible settlement at the toe, has always been assured when the sheet piling was driven to high resistance against further penetration, provided, of course, that there was no underlying unstable stratum below the bottom of the sheet piles.

After reaching the conclusion expressed by Eq. 32, the author proceeds to analyze mathematically the internal stresses in cellular cofferdams on a compressible base, using the "customary" values of $b = 0.85\ H$, etc., which, in Part I, he stated were the average ratios for sand-filled cells built upon rock. In practice, there is no relation between the two conditions; nor is the ratio of $b = 0.85\ H$ applicable, except by chance after the "middle third" method determines the proper width based on the assumed overturning moment and the weight of material in the cells.

Also, the author has analyzed the division of the total overturning moment on a cellular bulkhead (see Fig. 11) between the shear resistance of the fill and the sheet piling. He attributes the fact that the bulkhead began to deflect alarmingly (in spite of theoretical analysis) to the probability that the real lock tension (friction) might actually have been smaller than calculated. The writer doubts whether the actual overturning moment could be determined as accurately as outlined, since a few of the uncertain factors involved include the assumption as to lateral forces, the arm of the overturning moment or point of rotation, the fact that the structure is partly a cantilever and partly a gravity structure, the amount of cantilever support dependent on the lean of the cells, and the supporting value of the soil (both under and on the sides of the cells at the base).

Cellular Cofferdams on Deep Sand Strata.—Professor Terzaghi states (see "Part II. Design of Cellular Cofferdams") that a review of current methods of designing cofferdams reveals an "amazing situation," inferring that the seepage of water, possible boils in the bottom, and loss of stability of the foundation soil inside a cofferdam have not received consideration. The writer does not know of any phase in the design of cofferdams which has received more attention from designers and contractors. In 1935, the writer presented a discussion (29) of this hazard. This article offered some rule-of-thumb ratios between the hydrostatic head and depth of penetration necessary for the sheet piling in single-wall cofferdams when driven into various types of soil. These ratios were based on long observation of successful practice in preventing bottoms from boiling seriously or "blowing up." The ratio given for water-bearing sand was a penetration of 30% to 40% of the unbalanced hydrostatic head, provided the cofferdam is properly pumped, as against the 67% mentioned in the paper.

Also, the author recommends a penetration of $\frac{2}{3}$ H into sand as being necessary to prevent possible settlement at the toe of the cofferdam, due to vertical load on the sheet piles. It is commonly known that sand is probably the soil most resistant to the penetration of sheet piling and, under most conditions encountered in practice, the writer doubts if sheet piling could be forced into the depth of sand, indicated as necessary in the paper, without jetting, without rupturing interlocks, or without encountering absolute refusal. The writer has test results before him giving safe bearing loads of sheet piles, which show that a single pile tested to 47 tons when driven 25 ft into sand and when interlocked with two other sheet piles tested to 120 tons. When one considers that for even a 60-ft height of cofferdam the load on the sheet piles at the toe could hardly exceed 7 tons per foot width of sheet pile, $\frac{2}{3}$ H, or about 40 ft of penetration, seems at wide variance with the actual need.

In the discussion of filters and gravel toes for taking care of seepage, the author has omitted to mention the usual methods of stabilizing the soil inside cofferdams by pumping from sumps and the remarkable achievements of the so-called well-point systems in this respect.

The discussion of breakwaters founded on sand includes a recommendation that the sand should be compacted to a depth of at least 1.5 H in some situations. Under the conditions in Fig. 9(*f*), showing water going over the top of the breakwater, the critical consideration for stability is the fact that the turbulent water scours the bottom on the harbor side until the breakwater fails, unless protected by a stone berm. Several articles on breakwaters published between 1932 and 1934 (30)(31)(32)(33) are enlightening with respect to the author's treatment.

Conclusion.—In general, the author deserves commendation for attempting to place the design of cellular cofferdams on a more precise mathematical basis. He has demonstrated that few problems have been overlooked in the past by the engineers and contractors who have had experience with the practical considerations necessary to design and build such structures properly and who have tried to reduce some of the intangible factors to some semblance of a precise basis for analysis. The paper is largely confined to a mathematical analysis of a cellular bulkhead of hypothetical size and weight of fill under a condition that is not common in practice. The attempt to apply the analysis, however, serves to indicate a wide variance between theory and practice. Dismissal of the old "middle third" method of approximating the proper width of a bulkhead under the wide variety of conditions met in practice by the substitution of the "average," "acceptable," or "usual" ratio of width equal to 0.85 H is not only erroneous but dangerous.

In estimating the interlock tension, a conversion factor of 0.4 for the computation of the lateral pressure in a sand fill would be too high under some conditions and dangerous in others. No method is proposed whereby the critical interlock tension can be determined or the maximum size of cells established to meet the wide variety of conditions encountered in practice. The conclusion that consideration of the shear value of the soil in cellular cofferdams is more critical than the determination of the proper width and maximum size of cells is fallacious.

Dean P. Tsagaris,[6] M. Am. Soc. C. E.—Comparatively little has been written or published on the rational design procedure and the behavior exhibited by this type of cellular cofferdam construction. Therefore, assumptions, analyses, and final judgment must be based on actual experience and observation. The paper constitutes a valuable and significant contribution to the engineering profession on this subject. As the author states, tests should be made, but results should be used with discretion, since they have often proved inconclusive.

The following comments and discussion are confined to cofferdams in which piling is driven to rock through an overburden varying from several feet to 50 ft in depth. Experience is largely drawn from the many cofferdams designed and built by the Tennessee Valley Authority (TVA) for the purpose of enclosing construction operations.

The inherent economic advantages in using circular cells with connecting arcs are due primarily to simplicity of construction and re-use on subsequent stages and projects. Furthermore, cells can be filled independently without interruption, and possible interlock failure will be localized in one cell. As a general rule, if a cofferdam does not exceed 50 ft in height and is carefully designed for sliding and interlock, allowing for saturation of fill within the cells, the resulting construction will be satisfactory and safe.

Designing on an "equivalent width" basis (and a length of unity) was found to be sufficiently accurate after a comparison was made with the results obtained from using a typical cell as a unit. This expedient obviously simplified calculations greatly.

Because of the great height of the Kentucky cofferdam (100 ft above rock) and of the magnitude of this undertaking as a whole, very careful consideration was given to the following factors: (*a*) Saturation of fill material within the cells; (*b*) interlock tension; and (*c*) internal resistance to shear. In view of this concern, the writer cannot agree with the statements made on the subject of internal shear, which read (see second paragraph following Eq. 8): "* * * before this failure [by overturning] occurs, the cofferdam is likely to fail from another cause which has never received any attention" and (see second paragraph preceding Eq. 28*a*) "* * * a potential source of failure by shear along vertical planes (Eq. 19*b*) which has been ignored in the past.* * *."

(*a*) *Saturation of Fill Material Within the Cells.*—On all cofferdams built by TVA, a mixture of sand and gravel with little silt content was used to obtain as much free drainage as possible. Filling was done by the hydraulic process, except for a few cells built in the dry, such as tie-ins. When the first cofferdams were constructed, the need for dependable information on saturation was realized. For purposes of study, several rows of pipes were provided within the cells, and observations were taken, after unwatering, on the level of water resulting from both a rising and receding river.

---

[6] Structural Engr., Constr. Dept., TVA, Knoxville, Tenn.

In general, results disclosed a rather flat gradient across the cells, beginning from a point somewhat below the outside river elevation. No complete drainage was evidenced in spite of the customary weep holes on the dry side. In any case, much depends on the care exercised in the field and the extent of the provisions made to ameliorate saturation.

A saturation line with an approximate slope of 1 on 2 starting from the outside water elevation was considered satisfactory, and slopes as steep as 1 on 1 were adopted where special care was taken to keep cells well drained. Hence, all calculations were made accordingly on subsequent jobs, using 110 lb per cu ft for material above the saturation line, and 65 lb per cu ft for material below the saturation line. As a result, all cofferdams required a berm on the dry side to satisfy the aforementioned requirements. This does not necessarily mean that cells cannot be made wide enough to avoid berms, provided they check in every other respect and are economical. A horizontal line, at an elevation so chosen as to represent the average expected condition of saturation, should serve just as well and at the same time simplify computations.

(*b*) *Interlock Tension.*—This is one of the most important features in cellular cofferdam design and should be kept within safe limits. The practice of computing pressures on a straight-line variation all the way to rock is fallacious since cells almost invariably exhibit a characteristic bulge about one quarter to one third of the way up from the base. Driving apparently forces the steel sheet piling into rock sufficiently to prevent any appreciable movement at this point. When berms are used a similar condition exists, except that the overburden or the berms serve to restrain the piling. In the light of this phenomenon, the writer believes that pressures from which interlock tension is computed should be considered maximum at three quarters of the way down from the top in cases without berms. If berms are used, however, maximum pressures will occur at a somewhat higher position.

With the improvement of piling and the ability of the manufacturers to guarantee higher strengths, interlock failures have been very few and are due primarily to construction operations such as difficult driving. In such instances "brooming" and opening of interlocks have resulted near the bottom, but repairs can be made easily, especially in cases where no berms are used. All possible conditions should be investigated to determine maximum interlock tension, particularly during filling operations when the river elevation is low, because this condition most often controls.

The author does not mention the amount of tension contributed by the connecting arcs to the existing main cell tension. This has been found considerable, and should be neither neglected nor computed as a free force acting on the main cell through the tees or wyes. The neglect cannot be excused, and computation as a free force does not consider the passive resistance of the fill within the connecting arcs, which resists a large percentage of the tension before it can find its way into the main cell.

(c) *Internal Resistance to Shear.*—The possibility of shear failure has been recognized by TVA engineers concerned with cofferdam design, and investigations in this connection have been thorough. No rigorous mathematical analysis is justified, however, when friction coefficients for fill material, the actual pressure against the inside of the piling, and the resistance offered by interlocks are so variable. Very ably, Professor Terzaghi explains the implications involved in computing actual shear and evaluating the resistance to this shear along a selected critical plane.

Relatively small horizontal deflections are capable of mobilizing high pressures within the fill, especially against the inside surface of the piling, with equally large resistances. This tendency will continue as the lateral load increases provided the cofferdam is still safe against interlock failure, sliding, and overturning. Furthermore, if slippage occurs between sand and gravel particles, the new configuration of material may conceivably offer a greater resistance to shear than the results of computations indicate. Readjustment in each case is associated with planes of weakness, but other contact surfaces not so highly stressed will come into play to relieve the situation until horizontal movement due to slippage stops. This behavior transcends the realm of hypothesis; otherwise the paradox of nonfailure for cases with factors of safety less than unity cannot be explained. Since all cofferdams built by TVA were temporary, a factor of safety of 1.25 for shear, sliding, and interlock tension was considered quite adequate.

Briefly, the method used to compute total shear in any vertical plane, and the resistance, followed the general procedure described by the author, except that it was recognized that active pressure within the material was augmented by the effect of external horizontal forces tending to compact the fill confined in the cells. A friction coefficient of 0.55 was used. To the foregoing, the resistance against interlock slippage was added, using a coefficient of friction of 0.3, which gave the total effective resistance to shear. Under the most unfavorable conditions, the smallest factor of safety was 1.2. It is felt, however, that the coefficients of friction for both internal shear and slipping of interlock were quite conservative.

Recommendations.—To summarize, the writer would like to offer six recommendations, as follows:

1. Circular or clover-leaf type cells with connecting arcs should be used;
2. Selected free draining fill material, such as sand and gravel, will be found best;
3. Computations should be based on saturated fill below a line with an approximate slope of two horizontal to one vertical (for simplicity a horizontal line may be adopted at an elevation which represents average conditions);
4. Shear resistance should be considered and computed on a logical and rational basis;
5. Interlock tension must be kept within safe limits and the modifying effects of the characteristic bulge in sheet piling should be recognized; and
6. Grouting of the foundation rock will result in a tighter and safer cofferdam.

R. T. Colburn,[7] M. Am. Soc. C. E.—It is gratifying to find that the subject of the design of cellular cofferdams is being given the consideration it deserves. This paper is a welcome and comprehensive addition to the data previously existing on this subject, and points the way to possible future developments through field observations on actual structures. The Tennessee Valley Authority (TVA) has designed and built fourteen sheet-pile cofferdams since 1936, and the paper would have been extremely useful in this connection had it been published at an earlier date.

The TVA cofferdams were all constructed of standard 15-in. straight-web piling, with $\frac{3}{8}$-in. web thickness and weighing 38.8 lb per ft. They were driven through varying depths of overburden to solid rock and the cells were of either the clover-leaf type or the circular type with connecting arcs. About 90% of the cells were filled by the hydraulic method and in all cases the material was sand and gravel. Where the rock foundation was unsound grouting was used to consolidate it, to prevent undermining, and to reduce the flow of water under the cells and stop "boils."

The twelve cofferdams used at Pickwick, Guntersville, Chickamauga, Watts Bar, and Fort Loudoun dams, vary in height from 30 ft to 55 ft. The diaphragm or cross-wall type of cell was not used by TVA. The reasons for the selection of the circular and clover-leaf type cells deserve consideration. The designers found by analysis that the saving in amount of piling by use of the diaphragm type decreases as the height increases, and for heights of 40 or 50 ft no appreciable saving results. For the circular cell type of cofferdam for any given length, the amount of piling is practically constant regardless of the diameter of the cell. The circular and clover-leaf cells have a distinct advantage over the diaphragm type if they are filled hydraulically as was the case at TVA. In the diaphragm type the fill in one cell cannot be more than 5 ft or 10 ft higher than the fill in the adjoining cell without distorting the cells. This is especially inconvenient when the cells are filled with a hydraulic dredge. The principal reason for deciding on this type of cell, however, was that any failure due to a split interlock or other cause could be localized in the cell in which the failure occurred. Every cell is self-supporting. In the diaphragm type a serious failure in one cell will cause partial or progressive failure in several adjacent ones.

Both stages of the cofferdams built at Kentucky Dam were 100 ft high and presented a problem of a magnitude on which practically no data existed. Whereas the other twelve cofferdams built by TVA were designed in accordance with the usual current practice for (*a*) bursting of the cells, (*b*) sliding, and (*c*) overturning, it was at once discovered that the factor of vertical shear became extremely important on this high cofferdam. This fourth factor was carefully checked in the Kentucky Dam design and, in fact, it determined the height of the berms inside the cofferdam. The writer agrees with Professor Terzaghi that shear is a factor that should be considered.

To give the greatest interlock strength possible the piling at Kentucky Dam was specified to have a guaranteed ultimate strength of at least 16,000 lb per in. instead of the standard 12,000 lb per in. The increase in value was obtained by more careful inspection and selection of piling being rolled and no change was made in the standard piling section. The cells were driven to solid rock through 40 ft or 50 ft of overburden, which consisted of sand and gravel containing only a small amount of silt and fines and no boulders. The connecting arcs were made with fabricated 30° Y-connections instead of the standard tees and with a longer more flexible arc. This gave much more flexibility and allowed for deviations and inaccuracies in driving the main cells through the heavy overburden. If the usual T-connections had been used the arcs would have been shorter, and this important feature would not exist and undoubtedly many more interlocks in the connecting arc would have been split in driving. It was also felt that by using a 30° Y instead of the standard T-connection the increase in interlock stress in the adjacent piles in the main cell would be less.

---

[7] Constr. Plant Engr., TVA, Knoxville, Tenn.

Many extensive laboratory tests were made on the fill material to determine the basic characteristics and provide a basis for determination of the design coefficients and assumptions. TVA engineers can readily testify to the accuracy of the author's statement that laboratory tests are inadequate. Several series of tests were made, the best of these showing ranges of 24° to 35° for the angle of internal friction and 0.45 to 0.70 for the coefficient of internal friction. Some tests showed these values to be even higher. The assumed value of this coefficient makes a great difference in the design, especially in the vertical shear strength. The values assumed at Kentucky Dam were 28° 50′ for the angle of internal friction with a corresponding coefficient of 0.55, which are extremely conservative; but in the absence of more conclusive tests a higher design value did not seem justified. The actual design assumptions for the Kentucky cofferdam were as follows:

No.	Description	Quantity
1	Fill material: Sand and gravel, with a very small quantity of silt	...
2	Overburden: Sand and gravel—in some places a layer of cemented gravel and in one place a 20-ft layer of blue clay	...

The plan and section of the Kentucky cofferdam is shown in Fig. 13. The design assumed the cell, with its fill material, to act as a homogeneous mass similar to an earth dam except that its shape was restricted and held in position by the sheet piling. The resistance to sliding, overturning moments, and shear stresses were calculated on this basis, taking into account the effect of the berms, overburden, and the shear resistance of the fill and the interlocks. On this basis the limiting factor in some cases was found to be vertical shear of the material in the center of the cell or at the inside face of the cofferdam. The stress in the sheet piling was calculated from the internal pressure or bursting effect of the material as it was restricted by the sheet piling, plus the stress introduced by the connecting arcs through the Y-pile connections. The effect of complete saturation during the hydraulic filling was considered. On this basis a cell 60 ft in diameter is about the maximum size that can be built without overstressing the interlocks. This was the determining factor in fixing the size of the cells. Obviously, this was too small to take care of the required 100-ft head. The additional support necessary was then provided by a berm of sufficient height and slope to back up the cells with 100-ft head of water on the outside. It can be seen that the overburden itself provided the major part of the berm which was undisturbed material and this section was used in locations where there was sufficient room for a berm. On the outstream arm, however, the berm on the inside had to be removed for construction reasons. This left a 100-ft-high cofferdam with no berm or overburden on the inside resting on a fairly flat rock surface, or in the second stage on the spillway apron. This is the section where the clover-leaf cell was used which provided a total width of approximately 100 ft. It might be mentioned here that even with this type it was felt necessary to stipulate that the berm could only be removed if the height of the water was 25 ft or more below the top of the cofferdam during the months that the berm was removed. This was done in the dry season and the water remained at a low level so that no harmful results were experienced.

The TVA has had an opportunity to make various tests on their cofferdams and has made several which are of value in that they give actual results under field conditions.

Saturation tests were made at Pickwick and are summarized in Fig. 14. As stated by Professor Terzaghi, the saturation line is almost horizontal except on the outstream third which rises sharply to within a few feet of the water level. Subsequent tests made at Guntersville and Kentucky dams con-

(b) CLOVERLEAF TYPE CELL

Fig 13.—Plan and Elevation of TVA Kentucky Cofferdam

firm these Pickwick tests and indicate the fallacy of assuming that a cell will ever become nonsaturated. It also shows the extreme importance of proper drainage. All TVA cofferdams were drained by weep holes on the inside face.

At Kentucky Dam 4-in. pipes were inserted in the cofferdam and driven several feet into the cells. Perforations in the pipe provided drainage and the pipes drained into a flume on top of the berm or to a system of corrugated pipe headers laid on the original river bed to keep the water from seeping into the berm itself.

At Chickamauga Dam an attempt was made to determine the stress in the piling by use of a strain gage. It so happened that several cells were built in the dry and filled before they received a water load on one side. Gage points were established at regular intervals on two cells and their connecting arcs and at points about 12 ft apart vertically. Careful readings were taken as the cell was filled and before and after the outside was flooded. The readings were so inconsistent and erratic, however, that no curves could be plotted and no conclusions could be made. Inadequate testing methods might account for this, but the actual conditions in the cells are probably the main reason. For example, it is probable that the piling does not interlock evenly over its full length, and the tension across the face of the piling might easily vary on this account. In fact, if the interlock contact was poor on a certain length of the pile, the tension across the face might be very low at that point with corresponding higher stresses adjacent to it. The only value of this test is that it indicates the very uncertain nature of the stresses in this type of structure and the danger of relying too heavily on a theoretical design.

The TVA also conducted some tension tests on interlock strength of piling which had already been used twice and a third use contemplated. The purpose of the test was to determine how much loss in interlock strength was to be expected after use. The sections of piling were interlocked at 3° and 22° angles. The specimens were tested to destruction and the results are not very conclusive; but they indicate that, with a certain amount of inspection, piling could be used several times. On TVA construction piling has been used as many as six times.

Deflection measurements were taken at Kentucky cofferdam. The water never came within 25 ft of the top of the first stage and therefore no full height test was available. The measurements taken, however, show so slight a deflection within the range of change in water level of the river as to be impossible to plot with any uniformity. As a matter of fact, one cell for some unexplainable reason showed a slight deflection outward with rising river.

In the second stage cofferdam, however, somewhat better although not conclusive measurements were made. This cofferdam was subjected to water pressure to within a few feet of the top of the cofferdam during the winter and was flooded in April, 1944. The flooding started on March 31, and the following day the water pressure inside the cofferdam equalized the tailwater pressure. On April 2 the upstream arm was overtopped. The maximum river elevation was reached on April 6 when it was several feet above the upstream cofferdam arm. Unwatering started on April 12 and continued through the month. Readings were taken on every other cell between November 6, 1943, and

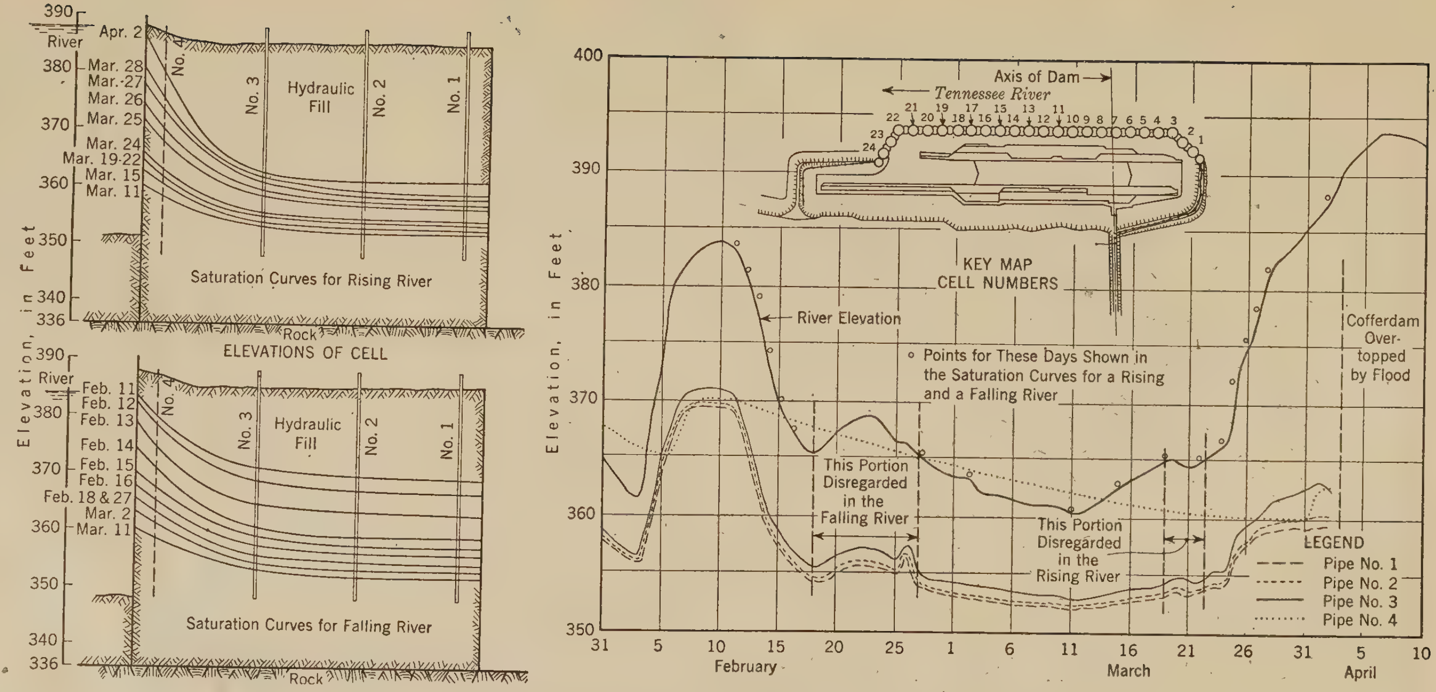

FIG. 14.—SATURATION TESTS; PICKWICK COFFERDAM

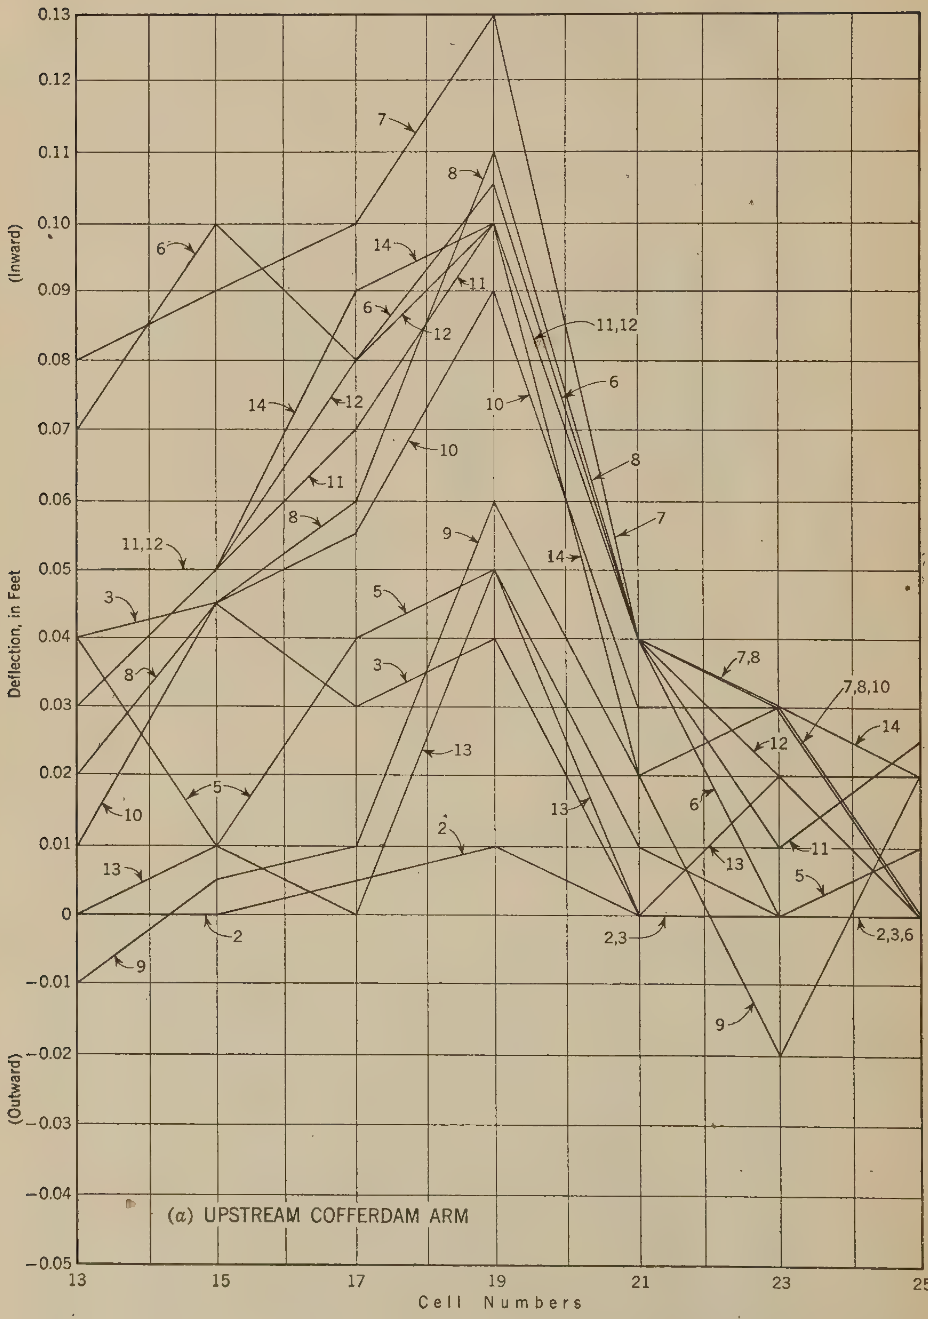

FIG. 15.—HORIZONTAL MOVEMEN

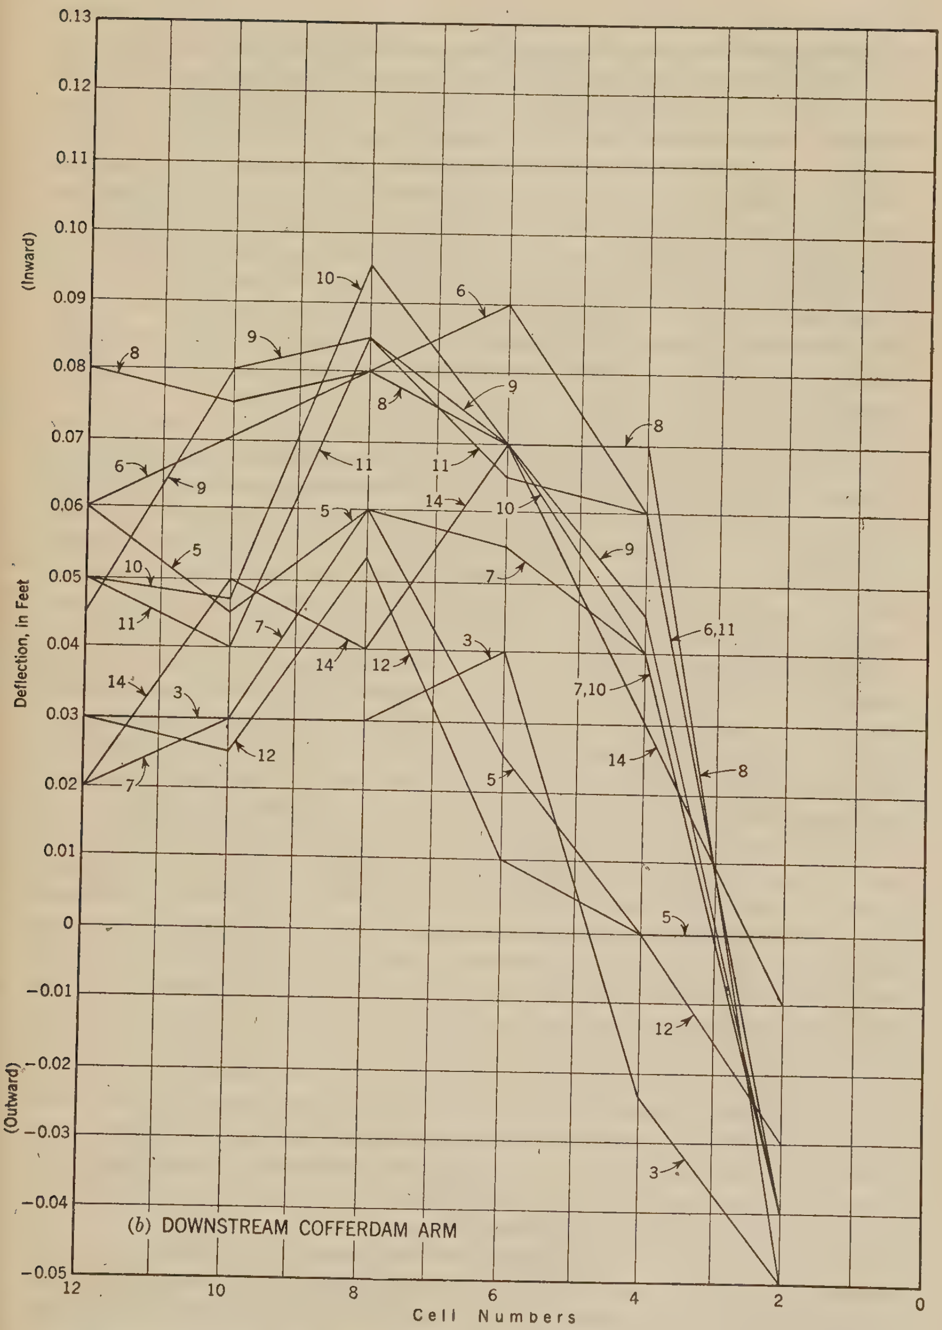

of Cells, Kentucky Cofferdam

April 24, 1944, to determine the horizontal movement of the top of the cells at various river stages. These readings indicated that the cofferdam cells deflected slightly inward with a rising river, the maximum being near the center of each arm of the cofferdam. The maximum amounted to only 0.13 ft on the upstream arm and 0.095 on the downstream arm. In general, the deflection was less near the shore where the overburden was highest. On the downstream arm the cell nearest the shore deflected outward. Fig. 15 shows the horizontal deflection of the cells in the upstream and downstream cofferdam arms plotted for each cell measured. The deflections decreased after the flooding of the cofferdam, as evidenced by comparing curves Nos. 11 and 12. When, later, the tailwater had dropped below the water inside the cofferdam the cells in the downstream arm deflected outward as indicated by curve No. 13. After most of the water within the cofferdam had been pumped out the cells again deflected inward, as shown in curve No. 14.

The best full-load test on TVA cofferdams occurred on the first one that was built at Pickwick Landing Dam. This was a cofferdam with cells 60 ft in diameter, 55 ft high, and with no berm. It withstood a head of a full 55 ft without any visible signs of distress. At this time the fill was completely saturated, as evidenced by the discharge from weep holes near the top. The only plausible reason why this cofferdam did not fail by vertical shear is that (*a*) the actual coefficient of friction of the material is much higher than laboratory tests indicate, and (*b*) the internal pressure is much higher than active earth pressure, as mentioned by Professor Terzaghi. During filling a certain interlock tension is developed in the piling. It is quite likely that this tension may be maintained by the development of reactive pressure in the cell fill. If the cells are filled by hydraulic dredge when the river level is low the piling tension may be quite large and consequently the reactive pressure quite large, which is a definite advantage in favor of hydraulic filling.

In the design of the Kentucky cofferdam the shear resistance in the fill was computed on this basis rather than by using the active earth pressure.

In computing the maximum interlock stress—that is, the interlock stress in the circular cell plus the additional stress due to the connecting arc—it was assumed that the maximum interlock stress which occurred during filling remained even after the cell fill above the saturation line is drained out. In computing the interlock resistance to shear, however, active pressure was used.

Several of the clover-leaf type cells were built in the dry. They constitute the tie-in connection for the second-stage cofferdam and were built inside the first-stage cofferdam and rested on the flat concrete apron. No hard driving was necessary and each pile was seated in a recess left in the apron to act as a key. This is an ideal condition and did not exist for most of the cells which required hard driving.

In some locations at Kentucky Dam the piling was driven through a stratum of cemented sand and gravel. This together with the 50-ft depth produced conditions which caused the interlocks to split in several cases. When the berm was removed these failures were exposed and reinforced with heavy steel bars as the berm was removed.

This interlock failure due to hard driving is the only type of failure experienced on any TVA cofferdam and is easily repaired. This leads to the conclusion that the driving conditions and interlock strength are the danger points in a properly designed cellular cofferdam.

The following general conclusions are possible in connection with steel sheet-pile cofferdam design based on TVA experience:

(1) Experience at Kentucky Dam indicates that driving through 40 or 50 ft of overburden produces excessive stresses in the interlock of a nature which cannot be calculated and that broken interlocks must be expected under such conditions. Dredging to reduce the amount of driving is recommended. To take care of conditions of deep driving, such as at Kentucky Dam, a suggestion is offered to piling manufacturers to design a pile with additional weight and strength in the interlock. It is not enough under these conditions for it to equal the strength of the web in tension. It should be considerably higher in interlock strength to take care of unpredictable stresses encountered in driving into heavy material.

(2) Proper provision for draining the cells should be made and a degree of saturation coinciding with actual tests should be used in the design. Cells are actually saturated to a much greater extent than usually assumed.

(3) Determination of the coefficient of internal friction and other coefficients of friction of the material should be carefully made by tests if there is doubt concerning its suitability. Actual field tests as suggested by Professor Terzaghi are preferable to laboratory tests. If, as in most cases, only laboratory tests are available, they should be used with judgment and conservatism.

The greatest difficulty in the path of a more exact design procedure is the lack of sufficient field test data. This lack is due in some degree to the fact that it is almost impossible to obtain a series of tests or measurements which show any degree of uniformity. It is to be hoped that better and more extensive testing methods can be made on future installations.

The writer wishes to acknowledge the valuable assistance of A. F. Hedman engineer, TVA, in the preparation of this discussion.

A. F. Hedman,[8] Esq.—It is with the greatest interest that the engineers of the Tennessee Valley Authority (TVA), who have been connected with the planning and the design of fourteen steel sheet-pile cofferdams on the Tennessee River, have read Professor Terzaghi's logical interpretation of cofferdam behavior. The importance of the paper is not so much that it develops new formulas, as that it endeavors to explain what is happening in a cofferdam, and thus gives the designer a better conception of the factors that will affect the design.

The writer agrees with the explanation of cofferdam behavior, in general, but takes exception to the author's statement about what has and has not been done in the past when designing cofferdams.

Experiences with Cellular Cofferdams.—Admittedly, cellular cofferdams are as reliable as other types and in the writer's opinion are even more reliable.

---

[8] Engr., Constr. Plant Div., TVA, Knoxville, Tenn.

None of the cells in the TVA cofferdams has ever burst or has ever shown any sign of being near failure. With the exception of the cofferdams at Kentucky Dam, no apparent weakness has been discovered in the interlocks even though some piling was used as many as five and six times. At Kentucky Dam steel sheet piling was driven through 50 ft of overburden consisting of sand, gravel, and, under some of the cells, a 10-ft to 20-ft layer of blue clay. After the cofferdam had been unwatered, the overburden was excavated completely to rock at some of the cells, and it was discovered that some of the piling had been driven out of interlock. The failures all occurred near the bottom of the cell and were repaired by tying the piling together, welding heavy steel straps across the break. Where the overburden remained and acted as a berm, such a failure should not be serious because the interlock stress due to pressure from cell fill should be very small or nonexistent.

Deflection of Cellular Cofferdams.—Practically all cells in the TVA steel sheet-pile cofferdams were filled by pumping sand and gravel from the overburden or from near-by deposits in the river. In no case was any appreciable deflection noticed. No doubt this was partly due to the method of filling the cells which caused compaction of the fill material, thus changing the elastic properties. The hydraulic fill also caused higher interlock stresses and therefore greater interlock resistance, which, as the author states, should stiffen the structure. An attempt was made at Kentucky Dam to measure the horizontal deflection for various heights of water pressure after the cofferdam had been unwatered. The deflections were very small, the maximum deflection being only 0.14 ft. In contrast to the cofferdams described by the author, the crest of the cofferdams at Kentucky Dam did not assume the W-shape after unwatering. This was possibly due to the capability of the ends to deflect.

Permeability of Cellular Cofferdams and of Their Sheet-Pile Enclosures.—As stated by the author, observations were made at Pickwick Dam to determine the saturation line in the cell fill. The TVA has collected some data on the location of the saturation line in several of the cofferdams constructed. Pipes were installed in the cells to serve as observation wells, and frequent readings were taken during rising and falling stages of the river. To provide drainage, weep holes 1.5 in. in diameter were burned on 3-ft centers in every third or fifth pile of the inside row of piling. At Kentucky Dam two rows of nine holes, 4 in. in diameter, were burned in each cell, including the connecting cell, one row at the river bed and one at the top of the berm.

Observation wells in one cell of the lock cofferdam at Pickwick Landing Dam indicated that the saturation line was practically horizontal across the cell. The height of the saturation line above the base varied with the rise and fall of the river. The highest observed level of the saturation line, when the river was almost up to the top of the cofferdam, was approximately 0.71 times the height of river above base of cell. This ratio decreased later, possibly due to either cleaning or adding weep holes.

At Guntersville Dam where seven of the lock cofferdam cells were observed, the saturation line was nearly level across the cells (but only a few feet above the base of the cells), and there was very little fluctuation in this saturation line for variations in the river elevation.

Neither the Pickwick cofferdams nor the lock cofferdam at Guntersville Dam had a berm. The cells in these cofferdams were filled with hydraulic fill consisting of sand and gravel with only a small percentage of silt. In leakage through the cofferdam a comparatively large loss of head occurred at the outside piling. Only a small head was required for flow through the sand and gravel fill. A further loss of head occurred at the inner piling wall. This was quite large in the case of the cell at Pickwick Landing Dam and was probably due to the flow carrying what silt there was in the fill across the cell and depositing it near the weep holes, thus reducing the discharge. At Guntersville Dam there may have been less silt in the fill or the weep holes may have been kept functioning better, possibly by driving rods into them to prevent plugging.

At Chickamauga Dam auger holes were drilled in the third-stage cofferdam cells along the inner piling wall. The saturation line was near the top of the berm used in this cofferdam to back up the cells.

An elaborate drainage system was devised at Kentucky Dam. The cell fill around the 4-in. weep holes was removed and replaced with 3-in. gravel, and the weep holes were then connected by short pipes, welded to the piling, to a flume at the top of the berm and to a system of corrugated pipes at the level of the river bed. Great care was taken to keep all pipes discharging. Observation wells were placed in all cells and the saturation line remained very constant at an elevation of from about 4 or 5 ft below the top of the berm (which was 10 ft above the original river bed), although there was a 32-ft variation in the river level.

All these observations seem to show that it is possible to keep the saturation line quite low, but that it should not be so assumed for design purposes unless great care will be taken to insure that the cell-drainage system functions properly. Where a berm is used, the saturation line should not be assumed to be below the top of the berm. The tighter the interlocks, the less the leakage will be. Therefore, leakage will be affected by the method of filling the cells and by whether piling is new or used.

The author's statement (see heading, "Part I. Practical Considerations: Permeability of Cellular Cofferdams and of Their Sheet-Pile Enclosures"), "The seepage across a cofferdam with such a foundation merely affects the tension in the locks," is contradictory to his subsequent statements that the amount of saturation affects the sliding resistance of a cell.

Cellular Cofferdams on Rock; Sliding Resistance.—The average width of TVA cofferdams has been 1.60 r. The lower value is due to the use of smaller connecting cells. As stated by Professor Terzaghi, the sliding resistance at the base of the cell should be found by taking into account the saturated state of the fill. He implies, however, that this should be done only where the rock is smooth. The writer does not agree that the unit weight of the fill in a moist state should be used in Eq. 3. The weight per cubic foot of saturated fill at Kentucky Dam was approximately 18 lb more than that for the same volume of moist fill. Where H_s is large, a considerably higher value for F_{bs} will result if the weight of saturated fill is used. As correctly stated by Professor Terzaghi, the saturated state of the fill was not considered at Pickwick Dam when investigating for sliding. On subsequent jobs saturation was taken into account and a berm added on the inside not only to obtain sufficient resistance to sliding, but also to keep the resultant within the middle third. At Pickwick Dam the rock surface was fairly smooth, and considerable resistance against sliding was apparently obtained by the steel sheet piling being driven into rock.

Cellular Cofferdams on Rock; Resistance Against Internal Shear.—Contrary to the author's assumption, the possible failure of a cofferdam due to excessive vertical shear through the fill and the piling has been considered by others. Lengthy discussions on this and other related subjects have taken place among TVA engineers especially before the final design of the Kentucky cofferdam was begun. The writer feels that a summary of the methods used by TVA engineers when designing the cofferdams at Kentucky Dam will show that:

1. Uplift was considered to be based upon an assumed saturation line;
2. Vertical shear was computed and resistance to vertical shear was calculated by assuming an internal pressure as stated later (the interlock resistance was taken into account); and
3. The interlock stresses were computed first by considering the pressure that existed during hydraulic filling, and second, after unwatering, by including the water pressure within the cell corresponding to the height of the saturation line.

The Kentucky cofferdam which consisted of both circular and clover-leaf type cells has been described fully elsewhere (34)(35). A brief summary of the design assumptions used, and the design procedure follows.

Fig. 16 shows a typical cross section through the upstream or the downstream arm of the cofferdam. Circular cells with diameters of 58 ft 10 in. were selected. Piling was driven to rock and the cells were filled hydraulically. Before unwatering, the overburden was dredged to leave a berm as indicated, and an additional 10 ft of fill was added to bring the top of the final berm within 38 ft of the top of cofferdam. An equivalent cofferdam width was assumed equal to the combined areas of one circular cell and one connecting cell, divided by the distance between main cells. The saturation line for two conditions of berm drainage is shown in Fig. 16. Other design assumptions were:

No.	Description	Quantity
1	Water pressure, in feet, assumed acting on the full height of the entire structure	98
	Weight of Material, in Pounds per Cubic Foot—	
2	Dry or drained	110
3	Submerged	65
	Coefficients of Friction—	
4	Gravel on rock	0.5
5	Gravel on steel (corresponding to $\delta = 21° 50'$)	0.4
6	Steel on steel	0.3
7	Coefficient of internal friction, tan ϕ, for dry or saturated material ($\phi = 28° 50'$)	0.55

No.	Description	Quantity
	Allowable Stresses in Sheet Piles—	
8	Interlock tension, in pounds per linear inch	12,000
9	Web tension, in pounds per square inch	32,000
10	Section modulus (feet^3) based on the average width of cell	391
11	Factor of safety against interlock failure, sliding, and vertical shear (factor of safety against overturning not computed)	1.25

The active earth pressure was computed by the Coulomb formula,

$$P_{e,a} = \frac{C_1 \gamma H^2}{2} \qquad (40)$$

For level surfaces, $\phi = 28° 50'$; $\delta = 21° 50'$; and $C_1 = 0.29$. The pressure distribution for active earth pressure is triangular, the resultant acting at a point distant $H/3$ above the base.

The reactive earth pressure, for broken surfaces, was computed graphically. The pressure distribution is parabolic, with the resultant acting at a point distant $H/2$ above the base.

Computation of Interlock Stresses.—Maximum stress occurred during filling by hydraulic dredge when the fill was saturated to the top of the cell. Tension was computed at the top of the overburden on the basis of triangular distribution of pressure. Actually, maximum tension will occur at a higher elevation due to the restraint of the overburden. The increase in interlock stress due to the connecting arc was considered (discussed subsequently).

Stability of Cells.—The following cases were analyzed:

1. Circular cells: (*a*) Berm saturated; and (*b*) berm completely drained.
2. Clover-leaf cells: (*a*) Berm saturated; (*b*) berm completely drained; (*c*) berm removed; (*d*) clay seam at the base with berm saturated; and (*e*) clay seam at the base with berm removed.

Résumé of Procedure for Determining Interlock Stresses.—Only the design of the circular cells with the berm saturated or completely drained will be discussed in this résumé. When investigating the interlock stresses that might occur during filling, it was assumed that the river would not be lower than El. 305 (see Fig. 17). During filling, the pressure adjacent to steel sheet piling at El. 290 (in pounds per square foot) would be from:

Water pressure within the cell	$62.5 \times 48 =$	3,000
Submerged fill in the cell	$0.29 \times 65 \times 48 =$	904
		3,904
Outside water pressure	$-62.5 \times 15 =$	-937
		2,967

In the main cell alone the interlock stress will be $\frac{2{,}967}{12} \times 29.44 = 7{,}280$ lb per lin in.; and in the connecting cell it will be $\frac{2{,}967}{12} \times 9.57 = 2{,}365$ lb per lin in.

(a) COMPLETELY DRAINED BERM

(b) SATURATED BERM

FIG. 16.—DESIGN ANALYSIS, KENTUCKY COFFERDAM

The pressure of the water and the submerged cell fill, of course, changed the shape of the cells into the familiar barrel form. As the water drained out of the cell fill, the cell probably maintained most of its changed shape, the reactive earth pressure being substituted for the water pressure as the cell tended to contract. For this reason it was felt that the interlock tension would not be reduced appreciably as the cell fill drained. Therefore, when computing the maximum interlock tension, the value obtained in the main cell alone was used, to which was added the effect of the connecting arc. To reduce this effect a 30° wye was used instead of the more common 90° tee.

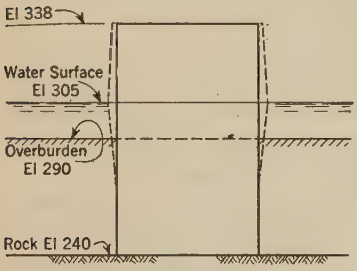

Fig. 17.—Section Through Cell During Filling

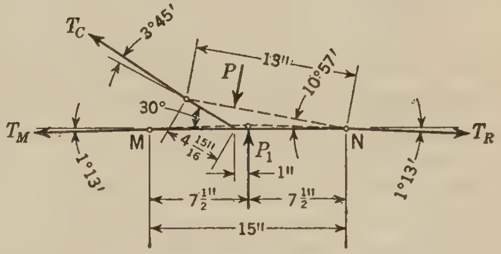

Fig. 18.—Detail Data for a 30° Wye

The forces acting upon the wye are shown in Fig. 18. Considering a section of piling, 1 in. high, the following forces were known: $T_c = 2{,}365$ lb; $T_m = 7{,}280$ lb; and $P_1 = 1.25 \times 2{,}967 \times \frac{1}{12} = 309$ lb.

By projecting the forces on line MN, Fig. 18, and on a line perpendicular to line MN, it was found that $P = 1{,}292 \text{ lb} > \frac{2{,}967}{12} 1.08$, indicating that reactive pressure was developed. Knowing P, it was then possible to find the maximum interlock stress T_r. This stress was found to be equal to 9,500 lb—more than 50% higher than would have been the case if the author's suggested empirical formula, Eq. 28*f*, had been used. The method of filling the cell and the river level at time of filling should definitely affect the interlock tension, making it impossible to establish and use Eq. 28*f* as suggested by Professor Terzaghi. The interlock stress on all TVA steel sheet piling cofferdams (including the ones at Pickwick Landing Dam) was computed by assuming water pressure and saturated fill within the cell—for the full height of the cell—counteracted by the water pressure (low river) acting on the outside of the cell. The factor C (the ratio between horizontal and vertical pressure) in most cases was close to 0.7.

The interlock tension was also computed for the condition after unwatering, and was found to be smaller than the foregoing value.

The average width for the aforementioned cofferdams was approximately 0.89 H for the first ones designed (cells assumed drained and no berm used) and varied between 0.50 H and 0.79 H for those with berms (saturation and vertical shear considered).

Professor Terzaghi states, in the second paragraph following Eq. 21, that

> "If the inner side of a cellular cofferdam is supported by a berm whose height is almost equal to the height of the dam, both the cross-walls and the inner row of sheet piles are acted upon by equal earth pressures from both sides. This condition practically eliminates the tension in the locks, but it also eliminates the lock friction."

This statement is true if the cofferdam is filled while the river is near the top of the cells, which apparently was the case for the cofferdams in New York, mentioned by the author. However, if the cells are driven and filled hydraulically with the river at a low level (which is generally the case where dams are constructed), a large pressure is created in the cell fill, resulting in a high interlock stress. This pressure and the corresponding interlock tension are likely to be maintained by the reactive pressure induced in the cell fill by any tendency of the piling to contract. A berm added afterward on the inside of the cofferdam will exert a pressure far smaller than the pressure within the cell. With rising river the berm may develop reactive pressure, and it is possible that the interlock tension may be somewhat reduced.

Résumé of Procedure for Determining the Stability of Cells.—A saturation line was selected extending from the top of the cell on the river side and sloping down to the top of the berm on the dry side. Perhaps it might have been just as well to select a horizontal saturation line about 20 ft below the top of cell. Observations made after the cofferdam was completed indicated that the saturation line at the inner piling wall was actually below the top of the berm (see also "Part I. Practical Considerations: Permeability of Cellular Cofferdams and of Their Sheet-Pile Enclosures"). Not knowing where the saturation line in the berm might be, the TVA engineers decided to investigate the cell with the berm being either saturated or completely drained.

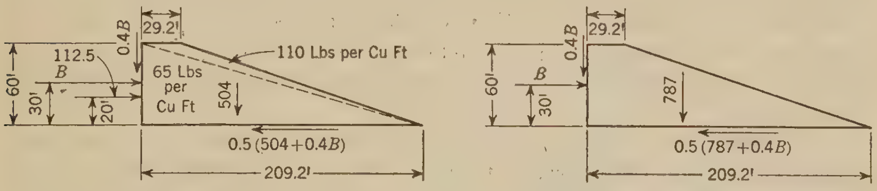
The weight of the cell and the berm, as well as the forces acting on the cell, was then determined. When computing the weight of the cell and the berm, uplift, as measured by the distance from the assumed saturation line down to rock, was taken into account by using the submerged weight of fill. The following results for a 1-ft length of cofferdam were obtained:

No.	Description	Quantity
	Weight of Material, W, in Thousands of Pounds, or Kips—	
1	Cell fill (piling not included), W_c	349.7
2	Saturated berm, W_b	504.0
3	Completely drained berm, W_b	787.0
4	Center of gravity of the cell fill (distance in feet from the center line of the cell)	0.95
	Forces, in Kips, Acting on the River Side of the Cell—	
5	Water pressure on the full height of the cell ($P_1 = 0.5 \times 0.0625 \times 98^2$)	300.0
6	Pressure from overburden; saturated ($P_{e,a} = 0.5 \times 0.065 \times 0.29 \times 50^2$)	23.5
7	Vertical friction on the cell; downward ($F_1 = 23.5 \times 0.4$)	9.4

No.	Description	Quantity
	Forces, in Kips, Acting on the Dry Side of the Cell; Saturated Berm—	
8	Water pressure ($P_2 = 0.5 \times 0.0625 \times 60^2$)	112.5
9	Maximum sliding resistance of berm; see Fig. 19(*a*) [$F_b = 0.5\ (504 + 0.4\ F_b)$]	286.5
10	Reactive pressure by graphical construction	362.0
11	Maximum vertical friction on the cell ($F_2 = 0.4\ F_b = 0.4 \times 174$)	69.6
	Forces, in Kips, Acting on the Dry Side of the Cell; Drained Berm—	
12	Water pressure	0
13	Sliding resistance of berm; see Fig. 19(*b*) [$F_b = 0.5\ (787 + 0.4\ F_b)$]	492.0
14	Reactive pressure by graphical construction	561.0
15	Maximum vertical friction on the cell ($F_2 = 0.4\ F_b = 0.4 \times 492$)	196.8

The maximum reactive pressure of the berm was found, by graphical solution, to be greater than the sliding resistance of the berm. The latter, therefore, became the controlling factor, and was the maximum resisting force that could be developed if necessary. The horizontal forces, water pressure, and overburden pressure, which act on the river side of the cell will be resisted by the friction between the cell and the rock and by the berm. In the case of a saturated berm, water pressure between the cell and the berm will help to counteract any movement or deflection of the cell.

Next, it was assumed that full friction was developed under the cell, and that the berm then had only to develop a resistance equal to the difference between the horizontal forces on the river side and the friction F_c under the cell, where $F_c = 0.5\ (W_c + F_1 - F_2)$. This resistance was found to be considerably smaller than the sliding resistance F_b of the berm. The resistance, B (Figs. 16 and 19), was applied at one half the height of the berm. The vertical force $F_2 = 0.4\ B$ was computed, and, by taking moments of all the forces about point O at the toe of the cell, the pressure at the base of the cell was calculated. This pressure was assumed to vary as a straight line. Next, the vertical shear in the cell was determined. On any vertical plane in the cell this shear would



(*a*) SATURATED BERM (*b*) COMPLETELY DRAINED BERM

FIG. 19.—FORCES ACTING ON THE BERM

be equal to the resultant of all vertical forces to the left or the right of the plane considered—that is, the sum of F_1 plus the weight of cell fill W_c (partly dry and partly saturated) less the pressure on the base. In the computation of the shear resistance of the cell fill, the pressure within the fill was assumed to vary as a straight line between the pressure of water and overburden, $P_1 + P_{e,a}$, on the river side to the resistance from berm and water, $B + P_2$, on the dry side. By multiplying the pressure by 0.55, the assumed coefficient of internal friction, the resistance to vertical shear was obtained. The resistance to failure in vertical shear which exists in the piling interlock was added to the shear resistance of the cell fill. Although it was felt that the high interlock stress, which occurred during the hydraulic filling of the cells during low water in the river, would remain after unwatering and subsequent draining of the cell fill regardless of variations in river elevations, it was decided to be conservative because there was no proof that such an assumption had been made before. The resistance of the steel sheet piling to vertical shear was consequently based on the interlock stress produced by active pressure. Another reason for doing this was the possibility that, with maximum water pressure on the river side and the corresponding resistance from the berm, the cell fill would possibly be squeezed together somewhat and thus would reduce the initial interlock stress obtained during hydraulic filling. The resistance of the piling to shear was determined by multiplying the interlock stress by the coefficient of friction in the interlocks. By combining the resistance in the cell fill and the resistance in the piling interlock, the total resistance for the cell was obtained.

If this resistance is less than the shear in any vertical plane a-b through the cell (see Fig. 16), the cell will fail in vertical shear and will deflect farther toward the berm. This movement will increase the resistance of the berm until equilibrium is obtained and the horizontal movement is stopped. The increased berm pressure will decrease the vertical shear and increase the resistance to vertical shear as indicated by the curves in Fig. 16. The resistance B created in the berm cannot be greater than the sliding resistance F_b of the berm. It cannot be greater than the sum of the horizontal forces acting on the river side; nor can it be expected to be so great that the heel pressure is greater than the toe pressure.

For the cofferdam at Kentucky Dam the minimum resistance of the berm, required to prevent sliding, was not sufficient to prevent failure in vertical shear, if the berm should be saturated. The maximum resistance $B = 174.0$ kips (plus 112.5 kips of water pressure) for the saturated berm and a resistance $B = 259$ kips for the drained berm (which gave uniform pressure at the base of the cell) both proved to produce sufficient resistance to failure in vertical shear. Smaller berm resistances—203 kips for the drained berm and 142 kips (plus 112.5 kips of water pressure) for the saturated berm—were required to give zero heel pressure.

A similar procedure followed when designing the clover-leaf cells is not discussed herein.

Cellular Cofferdam on Rock; Without Overburden and Without Berm.—To form an idea of the stability of a cofferdam built on rock, where no overburden exists and no berm is used to support the cells, the writer investigated the possibility of a cell in such a cofferdam failing by sliding on the rock or in vertical shear. The following assumptions were made:

(*a*) The cell would be filled hydraulically with sand and gravel, water being present outside the cell not higher than halfway up the cell;

(*b*) The pressure produced inside the cell would remain, due to the tendency of the cell to contract and create reactive pressure, and no additional increase would occur after the water on the outside had risen to the top of the cell (after unwatering of cofferdam);

(*c*) The interlock tension during filling would remain after unwatering and subsequent draining of the cell, regardless of outside water pressure;

(*d*) The saturation line after unwatering would not be higher than halfway up the cell; and

(*e*) The coefficient of friction against sliding on rock and the coefficient of internal friction would be 0.50 and 0.55, respectively (both values conservative). The coefficient of friction in the interlock was assumed to be 0.3.

The following safety factors were found for various dimensions of cells:

Width of cell	Against failure by sliding	Against failure in vertical shear
0.85 H	1.19	1.29
1.00 H	1.40	1.79

If the cells are filled during a period when the water level is lower than that for the foregoing assumption, the cofferdam should be still safer. The opposite would be true if the water level were higher.

Had the cells in the cofferdam been filled with dry material, the internal pressure during filling would have been considerably smaller. After completion of the cofferdam and unwatering, the outside pressure would possibly increase the internal pressure somewhat and thus the resistance to shear, but a cell built in this manner would always be weaker than one filled hydraulically.

As stated by Professor Terzaghi, the internal pressure in the cell is not known definitely. Several assumptions are possible. Whether the cell is filled hydraulically or with dry fill, the horizontal pressure on the inner and the outer walls can be determined. If, next, the pressures on the base and at various other levels above the base, due to overturning moments, were computed, another horizontal pressure diagram could be determined. Should the greater value found by these methods be used when investigating vertical planes on either side of the center of the cell? Does the external water pressure increase the pressure in the fill at the outer wall as assumed in the Kentucky cofferdam design? Answers to these questions would do much to clarify the designer's problems.

The writer is grateful to R. S. Blomfield, associate civil engineer, Construction Plant Division, TVA, for his valuable assistance in the preparation of this discussion.

ADOLPH J. ACKERMAN,[9] M. AM. SOC. C. E.—This paper represents an important milestone in the history of retaining wall structures composed of sheet piling cells filled with sand and gravel. According to past practice, it has been customary to regard such structures as gravity walls which were designed under two very elementary considerations. First, the width of the wall should be approximately equal to from 0.83 to 1.0 times the head of water, in feet, which the wall is to support; and second, the cylindrical or hoop stress in the cells and in the interlocks should not exceed a designated acceptable value. Many sheet-pile cellular cofferdams have been constructed under these principles, and experience has demonstrated that such cellular structures, when filled with sand and gravel, are reasonably successful for cofferdams and other temporary types of construction.

---

[9] Director of Eng., Dravo Corp., Neville Island, Pittsburgh, Pa.

In spite of the fact that the foregoing statements provided sufficient criteria for the design of sheet-pile cellular walls, there was, nevertheless, in practically every case, a large amount of scientific-appearing computation work performed to make it seem that the structure had the benefit of a careful design analysis. In many cases, however, the assumptions, under which the mathematical analyses were developed, were at complete variance with the actual conditions surrounding the structure. The reassuring thing with respect to past practice has been the fact that, in the end, if the width was approximately equal to from 0.83 to 1.0 times the height of the wall, if the structure stood on a suitable foundation, and if it was filled with a stable granular material, the wall could be considered safe and the computations a success.

Professor Terzaghi's paper summarizes the following significant points:

1. It is incorrect to assume for design purposes that a sheet-pile cellular wall acts like a solid gravity wall;
2. The cellular wall is a composite construction of two different materials—steel and soil (the stresses in each material and the interaction of the two materials are analyzed);
3. The distribution of the stresses in the cell fill material is clarified in terms of basic principles of soil mechanics;
4. The frictional stress of the earth fill on the inside of the steel cell is defined;
5. The principal stability of the structure is obtained from the cell fill, with the steel shell acting as an important stiffening influence;
6. High frictional resistance in the interlocks is desirable;
7. In some cases the vertical shear in the cell fill may be a point of critical weakness (in the past, this generally has been ignored in the design);
8. Percolation under cellular walls resting on soil foundations requires close attention;
9. The permeability in sheet-pile cellular walls is clarified; and
10. It is a fallacy to assume that cells with weep holes in the back-wall drain to the bottom of the weep holes. (This assumption in the past has been intended to assure reduced interlock stresses, and maximum weight of cell fill for stability.) The buoyancy effect which results when cells are not adequately drained reduces the stability of the cells.

Professor Terzaghi states that a cellular cofferdam consists of two very different materials—steel and soil—and that its elastic properties can be compared to those of a composite construction material such as reinforced concrete. Although the composite construction can be described readily in this manner, it appears preferable to identify the sheet-pile cellular wall as a "plastic structure," to which the usual laws of elastic structures do not apply except in special instances where a cementing action in the cell fill material might result in the development of typical characteristics of elasticity. For example, when the writer was studying means for increasing the stiffness of a cellular wall which started to deflect excessively, he considered the possibility of welding together all the interlocks in a zone about 10 ft high in the upper part of the diaphragm cross-walls. However, in discussing this subject with the writer, Raymond P. Pennoyer, Assoc. M. Am. Soc. C. E., promptly showed that this would be a mistake because it would introduce a rigid section into a plastic structure. In the event of further deflection, the upper section of the diaphragm could not adjust itself with respect to the body of the structure, and there would be a localized building up of stresses in the welded area which might eventually result in sudden failure.

Professor Terzaghi has presented theories and formulas which are intended to be more rational than the methods of analysis which have been used. Fortunately, in the past, good judgment has prevailed sufficiently so that the mathematical analyses were not relied upon to an extent that might have been harmful. However, the paper is timely because the possibilities in connection with cellular structures are rapidly expanding and several recent installations in so-called permanent structures have opened up new fields for the utilization of sheet-pile cellular construction. For such structures, it is important to have more precise and dependable means of design.

A few engineers with considerable experience in this class of structure have advocated the use of the middle third theory of stability analysis. In the hands of these engineers this may be an acceptable check or yardstick, but it is a fair presumption that considerably more reliance probably is placed on judgment than on computation. The application of the middle third theory to plastic structures reminds one very much of the housewife who has learned to determine when a flatiron is hot enough for ironing by moistening the fingers and for an instant tapping the hot spot. With the requisite skill and judgment, such a test serves its purpose, but in less experienced hands it may lead to burning the fingers!

The chief objection to the arbitrary use of the middle third theory is that it tends to classify structures of the cellular cofferdam type with the rigid type of concrete structures, such as gravity dams. For most engineers the design of a cellular structure is an infrequent incident, and, when such an assignment develops, there is a natural tendency, particularly among the younger designers, to apply, automatically, their usual training in the theories of elasticity and gravity structures without developing a proper concept of the distribution of stresses as they actually occur in a cellular cofferdam. On a number of occasions the writer has inspected design computations for the stability of cellular structures which disclose this tendency of blissfully accepting the middle third theory for stability. In some cases design assumptions were set up for applying the middle third theory in a manner which indicated a complete lack of concept regarding the actual distribution of stresses. It may be that some of this faulty reasoning accounts for the fact that as recently as 1944 it is still possible to hear about a failure of a cellular sheet-pile structure.

Such failures, of course, will continue to persuade conservative engineers to regard cellular type of construction as useful purely for temporary purposes such as cofferdams. It will only be through such attempt as that presented in this paper, in developing a more rational concept of stress distribution in such structures, that broader acceptance will be accorded this type of construction for so-called permanent structures.

In view of the potentially larger use of steel sheet piling, once this type of construction wins proper acceptance for permanent structures, a paper such as this should be a sign of encouragement to the manufacturers of sheet piling. The author's painstaking effort to remove some of the mystery, and to develop a clear explanation of the principles of soil mechanics as they apply to this type of structure, deserves strong encouragement.

In the past, the best-known reservoirs of accumulated knowledge in this field have been with the manufacturers of sheet piling. Much valuable guidance and advice are available from such sources, but it seems only proper to point out that engineers and builders with limited experience in this field will find themselves in an untenable position, in the event of failure, if they assume

that the manufacturer accepts any responsibility for the design of the structure, or any obligations or liability beyond those covered by the manufacturer's guarantee in the fabrication of piling. Under the circumstances, any cellular sheet-pile structure of importance should have the benefit of the best obtainable professional engineering advice. This is particularly so for cases where there is the added factor of a difficult foundation condition.

The most elaborate design theories are of little use, however, if proper construction methods are ignored. Since a considerable portion of most cell structures is driven below ground or below water, where it cannot be seen, there is a serious possibility of wrecking even the best design during the process of construction and before the structure is put into service. Under the circumstances it seems in order to call attention to some of these factors which, in themselves, may influence the ultimate design.

Whenever cells are to be driven through a stratum of mud or soft clay, which is unsuitable for cell fill materials because of its low shearing resistance, it is advisable to excavate and remove such objectionable material before driving the cells. Where this is not feasible, the mud inside of the cells must be replaced by sand and gravel by a carefully controlled process of displacement to avoid collapsing the cells due to external pressures.

Sheet-pile cellular walls should be treated as living structures. It is always

Some unusual experiences were encountered in driving piles at Madden Dam (in the Isthmus of Panama) through a gravel formation containing many boulders which were not disclosed in the original exploratory borings. This pointed to the advisability of driving a test cell on large projects, ahead of the main undertaking of cofferdam construction; such a cell can be excavated to rock and the conditions of the interlock observed as well as the penetration into the rock. If such a procedure is followed with a careful recording of the type of hammer and energy required to drive the piling, formation through which driving occurs, amount of ground water encountered, and similar data, the cost of such a test cell is quickly recovered in the better procedures that can be adopted for driving and subsequent pulling of the main cofferdams. Such a test cell was employed to advantage at Pickwick Landing Dam and others built subsequently.

Pile driving and construction procedures have a vital bearing on the successful application of a design in which sheet-pile cellular walls are used.

Often the driving of sheet piling is considered an ordinary operation, and the highly specialized techniques are frequently ignored. This results in typical "butchery" of the sheet piling, making it practically useless for re-driving or salvage. A sheet pile, deflected by a boulder, can curl underground in such a way that, if driving is continued, the entire pile may be dislocated. Furthermore, driving out of the interlock is a possibility which must be controlled properly. Where there is a well-developed understanding of the formation through which piles are to be driven and where there is competent and experienced pile driving supervision with proper recognition of the design objectives and limitations, a cellular wall structure of high structural capacity can be secured.

Pickwick Landing Dam was the first of the large projects on the Tennessee River requiring sheet-pile cellular cofferdams. In view of the fact that a number of important projects had previously been constructed with the diaphragm type of cofferdams, under heads corresponding to those encountered at Pickwick, the diaphragm type was adopted at the outset. This was also in accordance with general advice offered by sheet-pile manufacturers. This plan required the minimum tonnage of steel and presumably the manufacturers considered that they were acting in the best interests of the customer by saving steel. However, in the process of studying the construction procedures and other details more carefully, the writer decided to inspect three cofferdams, then in operation, in the eastern part of the United States, at Gallipolis Dam on the Ohio River Tygart Dam in West Virginia, and on the Fear River in South Carolina. He was impressed with the fact that in each case the circular cell type of cofferdam had been used and certain practical construction advantages were evident. This experience led him to abandon the original plans for Pickwick and to adopt the circular construction, which was used subsequently on all the other Tennessee River projects. A comparison of the two types of cells is shown in Table 1.

The good fortune of this decision was emphasized later when the job forces perfected a portable type of template which could be lifted out of a completed cell and set up alongside for assembly of the next cell. This in itself was a major contribution toward reducing the cost of constructing this type of cofferdam. With a diaphragm type of construction, it has often been necessary to drive timber piling and introduce internal bracing to hold the diaphragm straight while the filling is carefully placed on each side of the diaphragm, with only a slight difference in elevation of the fill from the full cell down to the empty cell, ranging in steps over eight or ten cells. With circular cells, it is feasible to fill each cell to the top. Furthermore, in the event of damage to, or failure of, a circular cell, the trouble remains localized and can be repaired more readily. The use of the diaphragm type of cellular wall is justified in special cases where there is no problem of filling the cells, or holding the empty cells in place until they can be filled. The simplest way to fill circular cells is by means of a suction dredge and here again, if there is an objectionable percentage of fines in the materials, the suction dredge tends to churn up the material and throw the fines into suspension so they can be drained off, as the heavier and sounder materials settle into the cells.

It is of interest to note in Table 1 that, for cofferdams higher than 35 ft, there is little difference in the sheet-pile tonnage in the circular cell or the diaphragm type cell, but there are great savings in the cost of constructing the circular type of cofferdam where it is possible to employ a cheaper method of filling the cells.

No doubt the art of design in the type of structure discussed herein would be advanced considerably if a precise record of stress measurements could be made on a full-sized structure to determine actual stress distribution in the steel cell, as well as in the fill and in the supporting foundation. It would appear that the promotion of such a research project deserves further consideration.

Savile Packshaw,[10] M. Am. Soc. C. E.—The design of cellular cofferdams is treated as a problem in soil mechanics in this paper, and the author has made an analysis of the forces and stresses acting on the dam. As a result, most of the obscurities existing until now have been swept away; where uncertainties remain the author has indicated the boundaries within which they are confined.

Among the previously neglected aspects is the investigation of stability with respect to shear along a plane through the center of the dam. The author shows that the horizontal earth pressure within the fill near the center of the dam must be considerably greater than the active Rankine pressure. Otherwise there would be no explanation for the stability of cellular dams that have been built from time to time, and for the fact that the corresponding factor of safety then decreases with increasing values of ϕ—the opposite of what one would visualize. On the other hand, the pressure in the vicinity of the inner wall, which has to withstand the greatest lock tension, is not much in excess of the active Rankine pressure, as confirmed by the author's recommendation that, with sand or gravel filling, an empirical pressure coefficient of 0.4 should be used.

---

[10] With The British Steel Piling Co., Ltd., London, England.

The variation in the state of stress within the filling is even more marked in double-wall cofferdams than in cellular cofferdams, as the sheet piling in the former is subjected mainly to bending stresses and to horizontal deformations. Although there is a good deal of difference between the two types, a brief description of the methods commonly employed in the design of double-wall dams may be useful for purposes of comparison. The basic principles can be summarized by stating that the inner and outer walls of the dam are treated as a retaining wall and an anchor wall, respectively; the problem therefore resolves itself mainly into evaluating the forces, pressures, and resistances which the two walls must withstand or from which they derive their stability.

In this type of dam the two longitudinal walls of sheet piling are driven along straight lines and not in a series of circular arcs, and are connected together by one or sometimes two sets of tie rods near the top. The inner wall thus acts as a vertical beam spanning between the tie rods at the top and the reaction from the ground at the bottom. It behaves like an ordinary sheet-pile bulkhead and must withstand the bending stresses caused by the pressure of the filling. Therefore, a high section modulus is desirable. On the other hand, interlock strength against axial tension is of no importance. The same criterion applies to the outer wall, although the forces and pressures acting on it are more complex. The frequent cross-walls which form an essential part of a cellular cofferdam are not necessary in a double-wall dam, although occasional cross-walls at intervals of from 150 to 200 ft might be provided to facilitate placing the filling and for convenience in construction. Fig. 20.—Earth Pressure and Resistance in Double-Wall Cofferdams

walls do not add much to the stability, as the deep-arch or Z-sections which are necessary for this type of dam have little strength against tension or compression in the plane of the sheeting. The author shows that in a cellular dam the cross-walls add something like 50% to the stability of the dam. However, this is obtained at the expense of approximately the same amount of additional sheet piling.

The design of the inner wall, Fig. 20, is quite straightforward when the level and shape of the saturation line have been estimated in accordance with the author's suggestions (see "Part I. Practical Considerations: Permeability of Cellular Cofferdams and of Their Sheet-Pile Enclosures"). The earth pressure is derived from the formation of the unstable wedge A′RB, the failure line A′R being assumed to be straight even if wall friction is taken into account. The point A′ would be at A for a dam fixed in a rock trench and at C for a wall freely supported by the soil; if the sheeting acts as a beam fixed in the ground A′ is likely to be at about the point where the deflection line crosses the axis of the wall, so that $\overline{AA'}$ is approximately $0.75\,\overline{AC}$. After allowing for the reduction in soil density due to the subsoil water within the dam, the pressure on the inner wall can be obtained from a triangle of forces consisting of the weight W of the wedge, the earth pressure P_e, and the reaction Q along the plane of rupture. The earth pressure is equal to the active Rankine pressure when δ is assumed to be zero. The error caused by neglecting wall friction is small and adds to the factor of safety. As a rule the width of the dam is sufficient to permit the formation of the complete pressure wedge. The approximate distribution of pressure and the resistance for a dam on cohesionless soil are shown in Fig. 21, although the sharp changes in pressure or resistance, of course, are hypothetical. The diagram as drawn does not indicate the probable redistribution of pressure on a flexible wall, leading to a reduction of bending moment in the sheeting. The design of the sheet piling and the determination of the tie-rod load T follow the usual practice and call for no comment.

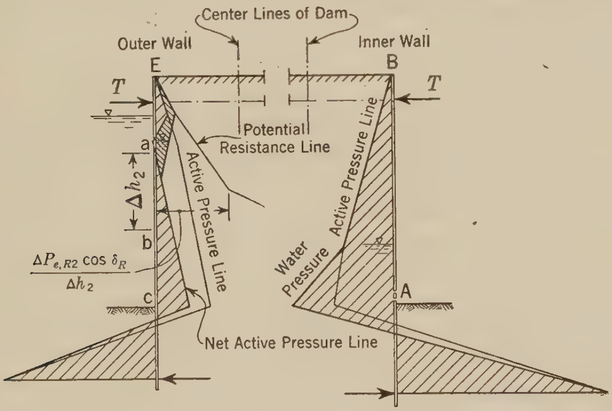

FIG. 21.—PRESSURE AND RESISTANCE DIAGRAMS

The outer wall must withstand an inward pressure due to the difference in water levels outside and inside the dam and is also subjected to the tie-rod load T imposed on it by the inner wall. To balance these forces earth resistance is developed by the soil mass A′DER, Fig. 20. The magnitude and distribution of this resistance are obtained from the assumption that the unstable soil wedge A′RB does not affect the resistance, except for the effect of the force Q, which is similar to that of a super-load applied to the plane of rupture A′R. This also implies that there is a sharp division between the expanding soil in the pressure wedge to the right of A′R and the contracting soil to the left. Actually there would have to be an intermediate zone of soil at rest.

It has been shown (36) that for any point such as point a or point b on the outer wall the least resistance will be developed by failure along a plane coinciding nearly enough with aA′ or bA′. It is permissible, therefore, to divide the area A′DER into a series of wedges radiating from point A′. Then the equilibrium of the first wedge, aA′RE, is governed by its weight W_1, the force Q from the pressure wedge, the reaction Q_1 along aA′ acting at an angle ϕ from the normal to aA′, and the reaction or earth resistance $P_{e,R1}$ along aE. The first two forces are known in magnitude and direction, the remaining two in direction only; $P_{e,R1}$ acts at the angle of wall friction δ_R to the normal to aE, provided the sheet piling is held by the soil and therefore is able to resist uplift. A polygon of forces can be drawn to determine $P_{e,R1}$, therefore, and the construction can be repeated for successive wedges so as to obtain the resistance due to each. For the sake of clearness, only four wedges have been shown. The potential resistance line, which shows the resistance that the soil can develop at various depths, is indicated in Fig. 21. It can be drawn by taking the resistance that can be derived from, say, an element ab of the wall and dividing it by the length of the element, Δh_2. This gives the average resistance along ab, assumed to occur midway between points a and b.

The resistance line starts from the ground level at point E or from the intersection of the failure line with the outer wall when the dam is rather narrow. It is usually found that, with the normal width of dam equal to about 2/3 H or 3/4 H, there is little resistance developed in the top quarter of the wall. Below that it increases rapidly and as a rule only a portion needs to be called into action. The least pressure on the sheeting, however, is the active earth pressure of the filling, with due allowance for the reduction in weight due to the buoyancy of the soil below the internal water level. This may be partly balanced, or even more than balanced, by the inward water pressure caused by the difference in water levels inside and outside the dam; but, if the net diagram obtained in this manner is taken as the basis for the design of the wall, it will be found that the reaction at the upper support—that is, the tie-rod load—does not exactly correspond to the pull T from the inner wall. Most probably the reaction at the outer wall will be smaller than T, so that the effect of the excess tie-rod load will be to draw the wall in toward the filling and thus mobilize some of the potential resistance until the necessary increase in pressure behind the wall has been obtained. For design purposes the extra pressure area would correspond roughly to that shown by the close-hatched area in Fig. 21. It would tend to concentrate as much as possible in the vicinity of the tie rods and one or two trials may have to be made before satisfactory agreement with the tie-rod load T is obtained. The fundamental conditions of equilibrium—

that the algebraic sums of forces and of moments must be equal to zero—are taken into account by the usual methods of bulkhead design.

The development of cellular cofferdams in the United States can be ascribed partly to the production of straight-web sections of steel sheet piling with a high interlock strength. On the other hand, these sections have a relatively low moment of resistance to bending. In Europe the emphasis since the beginning of the century has been mainly on the production of deep-arch sections with a good strength-to-weight ratio and a high section modulus. These encouraged the development of double-wall dams but precluded the construction of cellular dams owing to their very low interlock strength. A comparison of the technical and economic merits of cellular and double-wall cofferdams seems to be outside the scope of this discussion. It might be suggested, however, that, since Z-sections and other types with a high strength modulus have now been available in the United States for some time, double-wall dams may find occasional application in the future.

Martin W. Lautz,[11] Assoc. M. Am. Soc. C. E.—Before 1910, the subject of this paper began to interest engineers. Since that time many cellular cofferdams and bulkhead walls have been constructed. The proportions of a few of them were based on experience only; but most of the cofferdams were subjected to design analysis. Resistance against overturning, sliding on the base, and tension in the interlocks were determined, and in later years the shearing resistance of the confined earth was recognized as a most important factor. The added stability afforded by the cross-walls, including the resistance of the sheet-pile interlocks against sliding, was also stressed; in fact, consideration was given to increasing this resistance by welding.

The paper has outlined an approach to the subject of cellular cofferdams. The author's exposition of methods for determining the vertical shear, shearing resistance in the earth fill, and the sliding resistance of the piling interlocks is of great interest, and should prove a most important basis for further discussion and consequent increased knowledge.

In regard to the shearing resistance of the fill on a central vertical plane, the writer believes that the normal pressure on the plane is increased substantially beyond the active Rankine pressure by the horizontal load imposed on the outside of the structure. How much external load is exerted on this plane is problematical—perhaps as much as 50%. This theory merits discussion and may account for the high resistance against shear present in actual installations mentioned by the author.

The following three examples of cellular sheet-pile structures are presented because they have features that are somewhat different from those found in most installations.

Example 1. Cellular Dock Wall at an Eastern Shipyard.—Fig. 22 is an example of a permanent cellular type sheet-pile wall constructed in 1941 at an eastern shipyard. The following reasons for the selection of this type of dock wall are significant.

FIG. 22.—CELLULAR SHEET-PILE DOCK WALL AT AN EASTERN SHIPYARD

The location of the left-hand face of the dock was determined by plant layout considerations. Buildings on the right-hand side were on adjacent property and could not be disturbed by the dock-wall construction. Thus, only a strip of ground not more than 48 ft wide could be used for the proposed construction. A platform type of marginal wharf with a sheet-pile wall along the inner edge was eliminated by the fact that brace piles could not be driven where desired due to interference from the adjacent buildings which were about 30 ft high. A straight-wall bulkhead, consisting of a row of sheet piles at the left-hand face tied back to an anchorage, was also rejected because it would have been necessary to place the anchorage at least 60 ft back of the sheet piling—well into the adjacent property under the adjoining buildings.

A cellular type sheet-pile structure did not have any of the foregoing disadvantages, and its cost compared favorably with the two other designs considered. A disturbing factor, however, was the unstable character of the earth down to about 24 ft below water level as is indicated on the test boring record shown in Fig. 22(*c*), which was typical of others made within the area to be occupied by the proposed structure. Dredging this poor material and replacing it by sand fill would have cost a prohibitive amount because of the necessity of maintaining the adjacent buildings. The dock wall was built as shown in Fig. 22(*b*), leaving the original ground in place and driving the sheet piling well into the firm underlying strata. The average width of the cells as built was about 39 ft as compared with a height above dredged bottom of about 35 ft —a ratio of 1.15:1. Vertical loads on the top of the dock wall, including a movable tower crane, were supported on a concrete platform resting on steel H-piles driven to practical refusal at about El. +50. There was no connection between this structure and the sheet piling. The sheet-pile cross-walls, which were driven with their tops at El. +4.5, were notched away by flame-cutting to allow the reinforced concrete beams to extend through without contact with the sheet piling. It was considered undesirable for any vertical loads to be carried by the sheet piling.

An indication of the stability of the soil below El. −28 was the fact that as many as 400 blows per foot from a single-acting steam hammer (capacity, 15,000 ft-lb) were required to obtain penetration of the sheet piling to the elevations shown in section A–A, Fig. 22(*b*). (The numbers in the right-hand column of Fig. 22(*c*) indicate the number of blows required to drive a sample pipe 1 ft, using a 140-lb weight with a drop of 30 in.)

After installation of the sheet piling and concrete platform with bearing pile supports, the slip along the left-hand face was dredged to El. −30. At that time a slight outward movement of the piling on the water side was noted. This resulted from the unbalanced earth load, which caused take-up in the piling interlocks. After 3.5 years of service, there were no visual signs of further movement. The crane rails on the dock wall have maintained alinement throughout their length.

To summarize—this structure owes its stability to: (*a*) A large ratio between width and height; (*b*) the penetration of sheet piling into firm material; and (*c*) an unyielding base. These conditions have increased the safety factor sufficiently to overcome the weakness inherent in the unstable soil confined within the piling walls.

Example 2. Cellular Cofferdam, Hastings, Minn.—The cellular type cofferdam shown in Fig. 23 was used in the construction of a lock and dam in the Mississippi River in 1929. This cofferdam formed part of the enclosure around an area of 775 ft by 220 ft and consisted of eighty-six circular cells, each having a diameter of 12 ft 4 in., connected in the usual manner by short piling walls. The cells were filled with sand dredged out in making the excavation for the proposed structure. The section of the cofferdam in Fig. 23 is interesting because it shows the average width to be less than half the height and yet this structure served its purpose without failing.

One explanation of the stability of this wall could be that it acted in part as a cantilever fixed at the bottom by the passive resistance of the soil into which the sheet piling was driven. This favorable factor has not received sufficient attention in design analyses, but may be worthy of further consideration in cases where the sheet piling penetrates firm, resistant soil below the base of the cofferdam.

Example 3. Cellular Cofferdam for Intake System, Detroit, Mich.—The cofferdam shown in Fig. 24 was built in 1929 to enable the construction of two shafts and an intake structure in the Detroit River near Detroit. The ground material was plastic clay of the same general character as that found in the Detroit area—decidedly not an ideal kind of ground material on which to build a cellular cofferdam.

The lower part of the soil enclosed within the cell walls was clay in its original position, with clay fill above (see Fig. 24(*d*)). The inner sheet piling was longer than the outer walls and diaphragms to provide resistance against

settlement at the toe, penetration below the general excavation level being almost equal to the height of the cofferdam. The average width, if taken as 90% of 30.58 ft, would be about 27.5 ft, or 89% of 31 ft—the height of the dam.

After construction was begun, it was believed that excessive deflections might occur and that additional stability should be provided. Therefore, the tieback system shown in Fig. 24(*a*) was installed to afford a greater factor of safety. At the semicircular ends it was considered that arch action would make the tiebacks unnecessary. The sheet piling used was a 15-in. web section, now obsolete, having a minimum ultimate interlock strength of 9,500 lb per in.

No excessive movement of the cells occurred after inside excavation and unwatering were completed. This result probably would not have been obtained if the tiebacks had been omitted.

J. S. MILLER,[12] ESQ.—Professor Terzaghi stated in his paper that the most important criterion for determining the proper width of a cellular cofferdam structure has grown out of past experience. Under the circumstances it seems proper to discuss some of the practical applications of steel sheet piling and cellular structures as employed on projects with which the writer has been familiar.

Credit for the circular cell type of cofferdam must be given to Maj.-Gen. Harley B. Ferguson, M. Am. Soc. C. E., Corps of Engineers, U. S. Army (Retired), and to the late C. S. Boardman, M. Am. Soc. C. E. General (then Captain) Ferguson used the circular steel cell method in the raising of the battleship *Maine* in Havana harbor in 1910 and 1911, and this application stimulated much interest in the use of cellular cofferdams for other projects.

There are several advantages in the circular cell type of cofferdam for dam construction. The most important advantage concerns the very common situation in which the upper arm of the cofferdam must be extended across the river against the current. The current, of course, becomes more rapid as the structure is extended and the channel becomes correspondingly constricted. Furthermore, there is always the danger of freshets; therefore, it is distinctly advantageous to fill and make each main cell safe as soon as it is in place. Another advantage of circular cells is that the connecting arcs can be omitted until all the main cells are driven, thus providing partial relief of hydrostatic head while the main cells are being installed.

The cells should be filled with sand, or preferably sand and gravel, as these materials compact almost as soon as placed, especially if they are well saturated and if the cells must resist distortion and provide the greatest frictional resistance to sliding. Generally, it pays to dredge the area on which the cofferdam is to be built to within 10 ft, or better still to within 4 ft or 5 ft, of rock before driving piles. Thus, the chance of the sheets encountering boulders and injuring the interlocking joints is reduced.

Most frequently, the diaphragm-wall type of cofferdam is used in protected areas (in this case, parallel with the current and relatively close to the protected shore), whereas the circular cell type is used when fighting currents such as are encountered on dam construction. Care must be taken in placing the filling in this single connecting-wall type of cofferdam. The filling must be stepped down from cell to cell to avoid distortion of the cross-walls. After being completely filled, however, the resulting cofferdam is very satisfactory in every respect.

---

[12] Senior Vice-Pres., Dravo Corp., Pittsburgh, Pa.

The decision as to whether a circular cell or single connecting-wall cellular type of coffer be used also depends on the depth and character of the material through which the steel piles are driven. The single connecting-wall coffer should not be used where the sheets are driven through boulders as the sheets may drive out of the interlock. It is difficult to repair this type of coffer because of the necessity of removing and replacing a large amount of fill. Furthermore, the damaged sheets may be in the cross-wall where the break, of course, is concealed. In the case of driving through boulders, it is preferable to use circular cells as the filling of one cell can be removed for necessary repairs without affecting the adjoining cells, and with less expense and delay.

The single connecting-wall type of coffer, however, has the advantage of stiffening the coffer against deflection, especially in cases where the sheet piles are not on rock and are driven below the excavation line. The decision as to which of these two types should be used is largely a matter of judgment. It is important that the sheets be long enough to permit driving into firm material to practical refusal.

The writer's firm has conformed very closely to a width of cofferdam approximately equal to the height. If the walls were parallel, the width should be approximately 83% of the height. However, because of the loss of width due to curvature of the cells, an over-all width has been fixed arbitrarily that is equal to their height for cellular construction. A 6-in. concrete cap is customarily placed on top of the cells, on which are mounted the whirler cranes for the permanent construction work. In spite of the concrete cap, some damage to the concrete, and a small amount of washing out of the filling material, may occur during floods, and requires careful watching and prompt replacement.

In many cases the sheet-pile interlock would probably have sufficient strength to allow full hydrostatic head to the top of the sheets on the inner side of the cofferdam. Nevertheless, the writer and his associates do not like to take this chance, and consider it very good insurance to burn holes through the webs of enough sheet piles on the inner side of the cofferdam to insure the drainage of each cell to within at least 5 ft of the bottom of the excavation. This is one point that is insisted on because the writer has known of one or two instances where a cellular cofferdam failed with river stages just about to the top. Probably, the cell first filled with water and one or more of the interlocking joints were not sufficiently strong to withstand this hydrostatic head, with the result that the inner wall failed first; and, of course, the outer wall also failed after the rupture of the inner wall permitted the coffer filling to become displaced. The draining of the cells on the inside does not ordinarily result in an increased leakage because the outer row of sheeting should exclude the water from the cofferdam area.

The writer takes exception to the statement (see heading, "Part I. Practical Considerations: Permeability of Cellular Cofferdams and of Their Sheet-Pile

Enclosures") that "As a consequence, the water percolates through the dam as if the outer row [of sheet piles] were nonexistent." Admittedly, a certain quantity of seepage escapes through a sheet-pile wall—either through the interlocking joints or under the sheets—but the leakage through the interlocking joints is practically nonexistent except in coarse material. One of the reasons for using long sheeting is to prevent water from descending on the outside, passing under and coming up on the inside of a sheet-pile wall, and thus tending to loosen the material into which the sheet piles are driven, resulting in danger of settlement or loss of bearing power on the inner sheet-pile wall.

The author has made the further statement (see heading, "Part III. Conclusions") that "The assumption that the weep holes in the inner wall of cells filled with sand suffice to drain the cells is not necessarily justified." Wherever possible, in the writer's experience, sand and gravel are used for filling cellular cofferdams. As the cofferdam is unwatered, holes are burned in the inner row of a certain number of sheet piles in each cell and the progress of dewatering the cofferdam is limited by the progress of draining the individual cells. When the cells do not drain fast enough, the dewatering of the cofferdam is retarded.

It is easy to determine whether a cell is draining because, if the cell is not draining properly, moisture will appear at the joints in the sheet pile; and, if this moisture line is too high, additional holes need to be burned in the cell or the previously placed drain holes have become clogged. The important thing is to eliminate hydrostatic pressure against the inner row of sheet piles.

Although it is obvious that the water in the fill material on the back side of the cells is doubtless standing at a higher elevation than the water on the inner side, a certain length of time is required to lower the water table in the cells; hence, the cofferdam should be unwatered slowly enough to prevent undue hydrostatic head. In the design of cellular cofferdams, the writer and his associates usually provide a safe resistance against bursting of the cell for full hydrostatic head to an elevation one third of the height from the bottom to which the cofferdam will be unwatered.

The author's reference to boils on the inner side of cofferdams is most emphatically commended. Unless they come from a deep porous stratum, these boils can usually be greatly reduced by the use of long sheet piles and careful drainage of the inside walls of the cellular structure. Drainage is exceedingly important for the simple reason that it usually tends to reduce the hydrostatic head on any boils that may develop on the inside of the cofferdam.

To prevent boils inside the cofferdam, it is sometimes advisable to place a berm or blanket on the outside of the cofferdam; thus water cannot descend and pass under the outer row of sheet piles. Fundamentally, the outer row of sheet piles is the line of defense at which water should be stopped and held. The inner wall of the cofferdam should be considered as the stability side of the structure, and for this reason the same length of piles should be used on the inside as on the outside. In case of trouble due to boils, a berm should be provided on the outside because it usually results in reducing or eliminating the boils.

From many tests of the strength of interlock of the various types of steel piling the writer has found that sections M-107, M-108, M-112, and M-113 of the Carnegie piling, and their counterparts which are manufactured under other designations by Bethlehem, Inland, Weirton, and other steel companies, are the sections best adapted for cellular construction. In general, the strength of these sections lies in the interlocking joint; and, as a general rule, a closely fitting interlock is stronger than an interlock with wide grooves and narrow tongues. In addition, one can predict the strength of an interlock almost exactly by measuring the difference between the widths of the tongues and the widths of the grooves of the individual sheets involved. Obviously, the stronger the interlocked joint is, the better (even if the sheet pile may fail in the web rather than in the interlock), for the very simple reason that the interlock is liable to be injured during driving; and the heavier the interlocked joint is made, the less likelihood there is of damage during driving.

Another danger is the occurrence of too much carbon in the steel. There should never be more than 0.35% carbon, and preferably the carbon content should be just as close to 0.30% as possible, except that, in the case of sections that have to be bent, the carbon content should be very little more than 0.25%. In one case, three cells of a cofferdam split open from top to bottom right through the web of the sheet due to the fact that there was too much carbon in the steel, and large ice cakes pounding over the top of the cofferdam caused failure.

On a few occasions, trouble has been experienced due to lamination in the web, and even in the steel-pile interlock, in spite of careful inspection both at the mill and at the site of the work. Such failures, although quite disconcerting, are very rare and do not warrant condemnation of the use of steel piling in cellular construction. Extreme care should always be taken, however, with the interlock to insure that it is properly rolled and that there are no laminated sheets.

As yet, much is to be learned about the uses that can be made of steel piling. There is ample room for improvement in the design, and also in manufacture and installation, of cellular steel-pile structures. Progress in this field since 1925 has been most gratifying and there is every reason to believe that it will continue at a rapid pace.

ROBERT F. LEGGET,[13] M. AM. SOC. C. E.—The use of steel sheet piling has increased so rapidly in the past twenty years, for both temporary and permanent civil engineering works, that the written records of the profession still contain all too few discussions of the many complex factors that must be considered in the design of structures consisting of this versatile rolled steel section. Professor Terzaghi's paper, therefore, has a double value: (*a*) It assembles much useful information on actual experience with cellular cofferdams in connection with a very thorough design study; and (*b*) it inevitably mentions some of the general characteristics affecting the use of steel sheet piling for other types of structures. Although discussion of these wider implications of the paper is not in order at this time, it is to be hoped that critical study of the paper will direct increased attention to these other points and thus lead, even if indirectly, to improvement of the art.

---

[13] Associate Prof., Civ. Eng., Dept. of Civ. Eng., Univ. of Toronto, Torónto, Ont., Canada.

Professor Terzaghi is unusually forthright in condemning the application of the results of laboratory soil tests to the design of cellular steel pile structures, and he emphasizes the corresponding importance of observations on actual structures. The soundness of this empirical approach, especially in view of the many variable factors, will not be questioned at this stage in the development of steel piling design. However, some simple laboratory soil testing may provide useful and practical design information—such as how to determine the type of fill material and the degree of its conformity with the assumptions as to its properties made by Professor Terzaghi, as well as how to determine the friction between fill material and the surface of the steel piling.

Since this friction (admittedly an important factor in design) is a variable, the statement (see heading, "Part I. Practical Considerations: Deflection of Cellular Cofferdams") that the "* * * elastic properties [of a cellular cofferdam] can be compared to those of a composite construction material such as reinforced concrete" is somewhat puzzling. Possibly, the author intended such a comparison to demonstrate the differences between the two combinations of materials. Some elaboration of the statement would be welcome.

Another frictional force, that developed in the interlocks of the steel sheet piling, is clearly one of the most important factors involved in the stability of cellular structures. It cannot be calculated on the basis of any theory in view of the many practical variables—the type of lock, the limits of clearance between the jaws of locks in contact, the nature of the material (if any) plugging the locks, and the relative position of "mating" locks (as determined by the way they are held by either the soil or the rock into which they have been driven). In view of the emphasis given in the paper to lock friction (see conclusion 3), it would be of great interest to know whether any experimentally determined values of lock friction have been developed for any type of steel pile or, alternatively, whether the author believes that such values could be obtained.

Lock friction is even more important than this paper would suggest; for, in the case of straight walls of deep-arch, steel sheet piling which retain lateral loading, the degree to which lock friction is developed determines whether the piles must be considered acting as individual units or, alternatively, whether the wall can be regarded as made of "interlocked units"—the lock friction exceeding the shear stress developed longitudinally in the lock. In some countries other than the United States, deep-arch piles have been developed which do give an "interlocked section modulus." In consequence, double-wall cofferdams have been used generally there instead of the cellular type of structure, which appears to be confined almost exclusively to American practice. Although it is probably outside the province of the paper, an economic comparison of the two types of piles would be of interest.

In view of this wider significance of lock friction, the author's condemnation of the practice of lubricating the interlocks of steel sheet piling will be most heartening to all who have had to argue about this matter with enthusiastic pile driving foremen. Unfortunately, his reasoned arguments will provide little useful "ammunition" for such on-the-job discussions; but they should go far toward clarifying not only this point but also many others in the minds of all those responsible for the design of structures of steel sheet piling.

D. P. KRYNINE,[14] M. AM. SOC. C. E.—Few formulas are as accurate as the Rankine formula as applied to cohesionless masses, such as cohesionless sand or gravel. If there are claims that actual pressures in a cohesionless mass are not in accordance with the Rankine formula, such claims possibly may be based on the fact that the formula in question has been used incorrectly. In particular, the value of C given by Eq. 20 is the ratio between the minor and the major principal stresses at a point of a cohesionless mass just immediately preceding the failure of that mass by shear, but, in a general case, the value of C given by Eq. 20 is not the ratio between the horizontal and the vertical pressure at the point in question.

Internal Shear in the Fill of a Cofferdam on Rock.—If the shear failure is expected to occur along a vertical plane, such as plane gh in Fig. 7(*b*), this direction is not a principal one because, by definition, there are no shears along principal axes. Hence, to compute the horizontal pressure on the plane of expected failure such as section gh in Fig. 7(*b*), Eq. 20 cannot be applied.

The well-known Mohr's circle can be applied for finding the ratio C between the horizontal and vertical pressures at a point on plane gh (Fig. 7(*b*)) at a depth Z from the top of the fill, just immediately prior to failure by shear. Simply draw a horizontal line and a circle of arbitrary radius with its center O on that horizontal line (Fig. 25). Draw a line tangent to a circle that will describe an angle ϕ intersecting the horizontal at point E, as shown in Fig. 25. Furthermore, draw both the diameter through the point of tangency B and the vertical line AEC. Then the ratio of the distances EF and EG is the ratio of the principal stresses at the given point as determined by Eq. 20. Distance AB is proportional to the normal pressure on the plane of failure (section gh in the given case, Fig. 7(*b*)), and distance CD is proportional to the pressure on the plane perpendicular to that plane of failure—that is, in the given case, the horizontal plane. Hence, the ratio of both distances AB and CD multiplied by γZ (which is the vertical pressure at the given point), is the horizontal pressure on plane gh at the given point. Simple algebra shows that the value of C for the plane of expected failure gh is

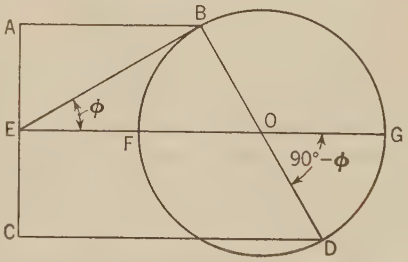

FIG. 25.—RANKINE FORMULA REPRESENTED GRAPHICALLY

$$C = \frac{\cos^2 \phi}{2 - \cos^2 \phi} \qquad (41)$$

If the angle of friction equals 30°, the value of C given by the Rankine formula, if correctly interpreted, is 0.6, and not $(0.577)^2 = 0.33$, as determined by Eq. 20.

---

[14] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

Recomputation of the Selected Example.—The factor of safety with respect to shear in the example immediately following Eq. 20 is $G_s = 0.87$. In the numerical formula for this factor of safety the value of $(0.577)^2$ must be replaced by 0.6, as explained in the preceding paragraph, which furnishes a corrected value of the factor of safety $G_s = 1.59$. Neglecting the friction in the locks—that is, dropping the value of 0.3 in the numerical formula in question—the factor of safety would be $G_s = 1$.

Perfect Safety of Plane gh *(Fig. 7(b)) with Respect to Shear.*—It will be assumed that Eq. 19*b* for the factor of safety G_s, with respect to shear, is correct except for the value of C which should be computed by Eq. 41. Consider a fill material weighing $\gamma = 110$ lb per cu ft with the angle of friction ϕ varying from 30° to 40°. Let $\gamma_w = 62.5$ lb per cu ft and $f = 0.3$. Then for $\phi = 30°$:

$$G_s = 2 \times \frac{110}{62.5} \times \frac{b}{H} \times 0.6 \times (0.577 + 0.3) = 1.85 \frac{b}{H} \quad \ldots\ldots (42a)$$

Similarly, for $\phi = 40°$,

$$G_s = 1.65 \frac{b}{H} \quad \ldots\ldots (42b)$$

Since Eq. 42*b* is less favorable than Eq. 42*a*, compute the values of the safety factor for $\phi = 40°$, as follows:

Ratio $\frac{b}{H}$	Safety factor G_s
0.85	1.4
1.00	1.65

Hence, under the given assumptions, plane gh is always safe with respect to shear. It is no miracle and no paradox, therefore, that many cofferdams wide enough, but with factors of safety of 0.6 or 0.7 incorrectly calculated, stand safely. Their true factor of safety with respect to shear certainly is greater than 1.

These considerations do not mean, however, that a shear failure cannot occur in a cellular cofferdam. They mean simply that under the given assumptions shear cannot occur along plane gh (Fig. 7(*b*)).

FIG. 26.—INTERNAL SHEAR IN A CELLULAR COFFERDAM

Phenomenon of Internal Shear in a Cofferdam on Rock.—In 1935, R. P. Pennoyer, Assoc. M. Am. Soc. C. E. (10*c*), called the attention of the profession to the possibility of internal shear along the vertical plane gh (Fig. 7(*b*)).

Professor Terzaghi also considers this plane dangerous with respect to shear. The writer, however, visualizes the possibility that internal shear can occur in a still different way. When the cofferdam begins to tip, it comes from the initial position ABCD into some other position AB′C′D (Fig. 26(*a*)). As the tipping of the cofferdam progresses, the density within the compressed zone I (and perhaps the size of this zone) increases until a certain critical density has been reached. Zone I then bursts and pushes zone II upward. To bring this picture back to the Rankine formula, it should be remembered that at any point O of a mass (Fig. 26(*b*)) there are actually two directions of maximum shear—not one. Each of these makes an angle $45° - \frac{\phi}{2}$ with the direction of the major principal stress. It follows that, if point O (Fig. 26(*b*)) is located in plane gh, there is, at that point, another possibility of shear along plane AOM making an angle ϕ with the horizon. The hydrostatic pressure pushes the mass up along a plane AM making an angle ϕ at point O (Fig. 26(*b*)) with the horizon, to meet the inside wall of the cofferdam, MC. The actual failure probably occurs as shown in Fig. 26(*c*). An observer standing at the top of the cofferdam possibly would report that, in the case of shear failure, all sand grains and all rocks and pebbles of the mass were moving. In reality there is probably a zone of quiet marked III in Fig. 26(*a*) and 26(*c*). A simple inspection of Fig. 26(*c*) shows that, to offer due resistance, the failure line must be sufficiently long. In other words, a guarantee against possible shear failure is the widening of the cofferdam.

Overturning of the Cofferdam on Rock.—Unless a shear failure in the fill occurs, the cofferdam is exceedingly stable with respect to overturning. If there is no water outside the cofferdam the fill material is pressed against the outside wall by the active pressure $\frac{1}{2}\gamma C H^2$, the value of C being smaller than that at the plane gh (Fig. 7(*b*)). To be conservative, it will be assumed that C may be computed using Eq. 20. If there is water outside the cofferdam, the pressure of the fill material, in addition to active pressure, is applied against the outside wall by the full hydrostatic pressure due to flexibility of the sheet piles. To start overturning, friction between the fill material and the outside wall must be overcome. The situation is very similar to that of a man who wants to lean to the right but cannot do so because his left leg is deep in a sticky swamp; the first thing for him to do is to pull his leg out of that swamp. In the case of the cofferdam, the friction is tantamount to a vertical force acting downward at the outside wall. Neglecting the weight of the cofferdam entirely, the factor of safety with respect to overturning would be:

$$G_s = \frac{(\frac{1}{2}\gamma C H^2 + \frac{1}{2}\gamma_w H^2)\, b \tan\delta}{\frac{1}{6}\gamma_w H^3} \ldots\ldots\ldots\ldots\ldots (43a)$$

in which the term $\tan\delta$ denotes the coefficient of friction between fill and sheet-pile enclosure. Assuming, furthermore, that the width b is some fraction of the height H, such as $b = a\,H$, and the value of $\tan\delta = 0.4$, Eq. 43*a* may be rewritten thus:

$$G_s = 1.2\, a \left(\frac{\gamma C}{\gamma_w} + 1\right) \ldots\ldots\ldots\ldots\ldots\ldots (43b)$$

For current values of a, C, γ, and γ_w, this safety factor is always greater than 1.4. It should be recalled that Eqs. 43 were developed neglecting the weight of the fill inside the cofferdam completely, so that at least a value of 1.4 should be added to the value of the factor of safety computed as recommended in the paper. In the example selected to illustrate this procedure a total of $2 + 1.4 = 3.4$ should be computed, which is very close to 3.8 as determined by the usual gravity wall method.

Sliding of the Cofferdam on Rock.—Fig. 7(a) is of rather academic interest and perhaps should have been omitted. It is questionable whether the boundary corrections should be introduced in this diagram since discontinuity of stresses (but not of strains) is acceptable. Corrected as it is, the area shown in Fig. 7(a) is less than the value of F as given by Eq. 1. This fact implies the necessity of correcting the ordinates at the middle of the diagram and thus changing the given value of the angle of friction. Finally, boundary corrections, if any, should be extended through the diagram to meet somewhere at the middle of the curve and not be connected to the curve at some arbitrary points. What is important, however, is not the diagram but that "There seems to be no record of a failure by sliding" as Professor Terzaghi states (see heading, "Part II. Design of Cellular Cofferdams: General Considerations"), and this apparently settles the question of sliding.

Conclusion.—The designer of a cellular cofferdam on rock must ensure close cooperation between the sheet-pile enclosure and the inside fill, making them work together and preventing their possible separation by internal shear. Attention should be paid to: (a) A good packing of the gravel and sand fill inside the cofferdam in order to increase the horizontal pressure and (b) a good interlock arrangement. The size of sheet pile should be selected properly and the cofferdam should be given ample width, the latter item being of extreme importance. To design and analyze such structures good engineering judgment and vast experience in the given field combined with clear understanding of statics are needed. A great number of cellular cofferdams have been constructed successfully in the United States—incomparably more than in other countries. It is obvious therefore that American engineers have demonstrated fully their ability to design and to build these structures, both permanent and temporary.

J. J. POLIVKA,[15] M. AM. SOC. C. E.—In the field of cellular cofferdams this excellent paper is a valuable contribution to engineering knowledge. In July, 1944, the writer had the opportunity to make some preliminary studies on cellular cofferdams in the Kaiser Shipyards at Richmond, Calif. These cofferdams had been constructed in February–March, 1945, for the U. S. Maritime Commission, preliminary to deepening the existing concrete-lined basins. In many respects the basins resembled graving docks, 100 ft by 590 ft in plan, and originally were built behind the protection of a cofferdam made with part of the rock excavation (37).

Semicircular walls were built consisting of a series of cellular cofferdams, each 40 ft in diameter and 51 ft in average depth, connected by short arcs of

---

[15] Lecturer, Univ. of California, Cons. Engr., Kaiser Co., Berkeley, Calif.

9-ft radius (Figs. 27 and 28). Since the cofferdams rest on a rock foundation, a fill approximately 10 ft deep was placed before driving sheet piles (Fig. 29).

Studies and tests were made to determine:

(a) Relation Between the Overturning Moment and the Weight of the Fill for Different Ratios H/r.—The results of the investigations under item (*a*) are in good agreement with the author's shear theory of the cofferdam presented in this paper. Fig. 30 shows some of the test installations. The standard formula for the pressure on a solid retaining wall, assuming that the full weight of the fill is acting, cannot be applied to a cofferdam consisting of a steel shell and containing more or less cohesive, plastic fill, with a variable degree of water saturation. This fact can be demonstrated by simple and inexpensive tests on small specimens made of thin sheet metal, thus simulating the cofferdam by a continuous smooth shell without irregularities of interlock. The minimum interlock strength of the sheet piles in the prototype is from 8,000 lb per lin in. to 12,000 lb per lin in. which, in the case of a $\frac{3}{8}$-in. web, is equal to from 21,333 lb per sq in. to 32,000 lb per sq in. In practical cases the stress ordinarily does not reach 50% of the latter values so that the effect of the interlock can be neglected. In the writer's investigations, the specimens simulating the cofferdams were made of plain sheet metal, 0.004 in. thick (see Fig. 30).

TABLE 2.—Relation Between the Overturning Moment and the Weight of the Fill for Different Ratios *H/r*

Specimen No.	Radius *r* (in.)	Ratio *H/r*	Weight *W* (lb)	Overturning moment *M* (lb-in.)	*M/W*	Overturning moment[a]	*V* (lb)
1	3.5	1.72	12.0	17.7	1.5	17.5	3.2
2	3.0	2.00	8.8	12.5	1.4	12.6	2.7
3	2.5	2.40	6.1	8.1	1.3	8.2	2.1
4	2.0	3.00	3.9	5.0	1.3	4.9	1.5
5	1.5	4.00	2.2	2.6	1.2	2.6	1.1
6[b]	1.5	4.00	2.4	3.1	1.3	3.2	1.4

[a] Computed by Eqs. 5 and 6. [b] Special shape; see text.

With height (*H*) equal to 6 in. and with radii varying from 1.5 in. to 3.5 in., most of the ratio values of *H/r* occurring in practice were represented. The greater stiffness of the shell can possibly affect the result of test to a certain extent. A very fine sand was used as fill, for which, approximately, $\phi = 26.5°$ and $\gamma = 90$ lb per cu ft.

Table 2 shows the values of the weight and overturning moment of individual specimens as determined by measurements. It also shows the overturning moments computed from the total average shearing resistance exerted by the fill on the shell.

The shear resistance against overturning can be computed from the frictional resistance obtained by measuring the vertical force, V, necessary to overcome the friction between the fill and the inner surface of the cylindrical shell. The shear or sliding force acting upon the inner surface of the cylindrical shell can also be computed on the basis of a theory of arching as presented by the author in 1943 (17*a*). Applying this theory (which was originally developed for the yielding of a rectangular base) to a segment of a circle, representing the base of a circular cofferdam, the vertical stress σ_v on a horizontal section at the depth z below the surface of the fill is

$$\sigma_v = \frac{\frac{r}{2}\left(\gamma - \frac{2\,c}{r}\right)}{K \tan \phi}\,(1 - e^{-n}) + q\,e^{-n} \ldots\ldots\ldots\ldots\ldots (44)$$

in which

$$n = \frac{z}{r} K \tan \phi \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45)$$

and, in addition to the notation of the paper: K is a coefficient $= \sigma_h/\sigma_v = 1$; q is the additional unit load upon the fill; e is the base of Napierian logarithms; and c is cohesion in Coulomb's equation. The horizontal pressure exerted by the fill upon the unit length of the cofferdam is

$$\sum\nolimits_h = \int_0^H \sigma_h \, dz \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (46)$$

and the force, v, which it is necessary to apply in a vertical direction to overcome the friction between the fill and the inner surface of the circular cofferdam, per unit length of the circumference, is

$$v = \sum\nolimits_h \times \tan \delta \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (47)$$

in which δ is the angle of the wall friction. The total force V is then

$$V = 2\,\pi\,r\,v \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (48)$$

It has been found that the vertical force V computed from Eqs. 44, 46, and 47 agrees with the results of tests. For sand as fill material, the cohesion, c, is equal to zero, and Eq. 46 has the simplified form

$$\sum\nolimits_h = \sum\nolimits_v = r\,\gamma \int (1 - e^{-z/(2r)})\, dz \approx r\,\gamma\,A \ldots\ldots\ldots\ldots (49)$$

assuming that $K \tan \phi = \frac{1}{2}$.

The term A can be computed by Simpson's rule or by substituting the irregular area with the base $b = (1 - e^{H/(2r)})$ and the height H by a triangle and a parabolic segment:

$$A = \frac{b\,H}{2} + \frac{2}{3} H\,b_0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (50)$$

in which $b_0 = b' - \frac{b}{2}$, the dimension b' being the value of b for $z = \frac{H}{2}$.

This method of determining the value of V will be demonstrated for a case in which the ratio H/r is equal to 1.72 (Table 2). Assuming further that the fill material is cohesionless ($c = 0$), the angle of internal friction $\phi = 26.5°$ ($\tan \phi = 0.5$), the wall friction (friction between the fill and the sheet piles of the cofferdam) $\tan \delta = 0.4$, the unit weight of the fill $\gamma = 0.052$ lb per cu in., and no additional load upon the fill ($q = 0$), the following values are obtained: $b = 0.57876$; $b' = 0.34929$; and $b_0 = 0.34929 - 0.28938 = 0.05991$. The term $A = \frac{5.665 \times 0.1 \times 6}{1.72} = 1.976$, or, from the simplified Eq. 50, $A = 0.57876 \times \frac{6}{2} + 4 \times 0.05991 = 1.976$. The exponential values can be arranged as shown in Table 3.

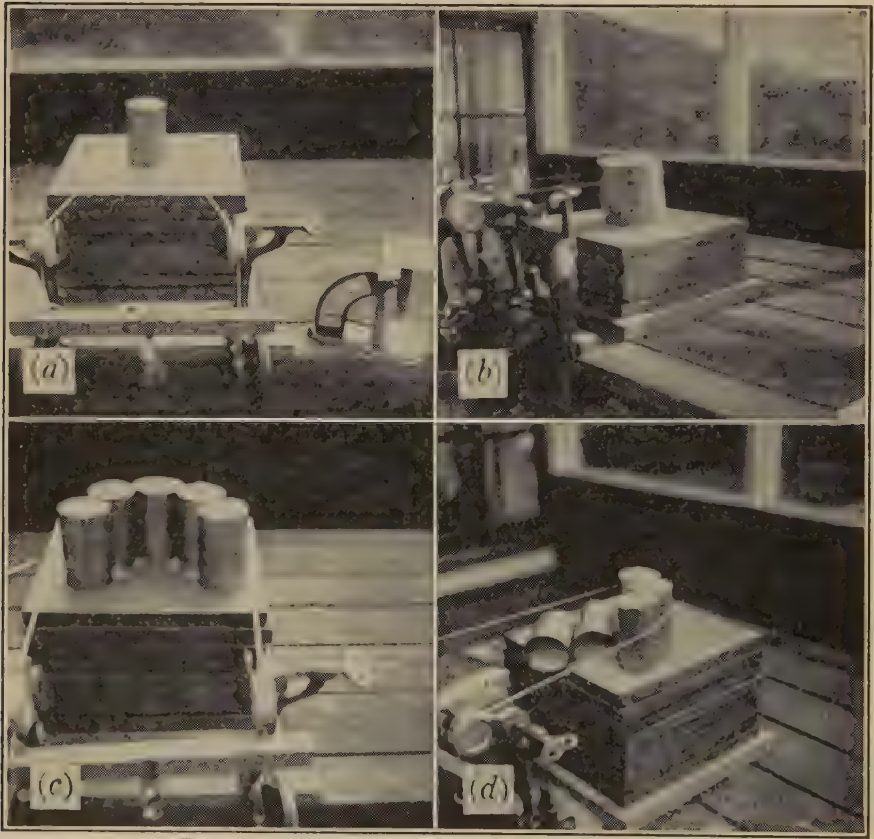

Fig. 30.—Laboratory Devices for Studying Cellular Cofferdams

The total horizontal pressure of the fill on the linear unit of the circumference of the cofferdam, by Eq. 49, is $\Sigma_h = 3.5 \times 0.052 \times 1.976 = 0.3596$ lb; the elemental vertical force (Eq. 47) is $v = 0.3596 \times 0.4 = 0.1438$ lb; and the total vertical force is $V = 2 \times 3.1416 \times 3.5 \times 0.1438 = 3.16$ lb. The measured value was 3.2 lb, so that the agreement with the test is good. The values of V for other specimens were computed similarly (see Table 2).

TABLE 3.—Computations for Arching Effect in the Fill

z/r	n (Eq. 45)	e^{-n}	$e^{-n} z$	$1 - e^{-n}$	$(1 - e^{-n}) z$	A (Eq. 50)

0.1	0.05	....	....	....	....	....
0.5	0.25	0.77880	3.925	0.22120	0.575	....
1.0	0.50	0.60653	7.371	0.39347	2.129	2.111
1.5	0.75	0.47237	10.053	0.52763	4.447	....
2.0	1.00	0.36788	12.143	0.63212	7.357	7.353
2.5	1.25	0.28650	13.771	0.71350	10.729	....
3.0	1.50	0.22313	15.039	0.77687	14.461	14.437
3.5	1.75	0.17377	16.026	0.82623	18.474	....
4.0	2.00	0.13534	16.795	0.86466	22.705	22.521

The small differences between the computed and measured values may be explained as follows:

(1) Inaccuracy in the measuring devices;

(2) A slightly higher value of the coefficient of friction between the fill and the wall ($\tan \delta = 0.41 - 0.43$) as introduced in the analysis (0.4);

(3) Variable value of the coefficient K, assumed in the analysis to be equal to 1, but increasing to $K = 1.5$ for higher elevations (38).

If an external couple created by external hydrostatic pressure tends to overturn the circular cell, this external couple will be resisted by the skin friction (friction between the fill and the shell). At the critical instant the internal couple of the force V in the formula

$$M_i = V d_0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (51)$$

will balance the external couple; that is, $M_e = M_i$. Thus the overturning moment of a cellular cofferdam can be determined readily if the values V and d_0 are known. The value V is given by Eqs. 47, 48, and 49, and the lever arm d_0 of the internal forces V can be determined under the assumption that the intensity of the friction between fill and shell follows a straight line, as shown in Fig. 31. In that case,

$$d_0 = r \frac{\int_0^{\pi} \sin^2 \phi \, d\phi}{\int_0^{\pi} \sin \phi \, d\phi} = \frac{\pi r}{2} = 1.57 \, r \ldots\ldots\ldots\ldots\ldots (52)$$

The values of the overturning moment computed by Eqs. 51 and 52 differ only slightly from the measured values (see Table 2). Table 2 contains also a specimen with folded shell (Fig. 32) which was included in the tests in order to determine the effect of the increased surface (circumference) of the shell upon the overturning moment. Such a case occurs when sheet piles with arched webs are used. The base of specimen No. 6, Table 2, was 7.6 sq in., and its circumference was 10.5 in.—12.5% greater than that of specimen No. 5.

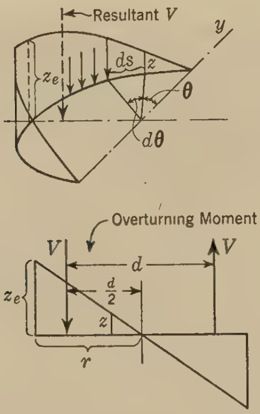

FIG. 31

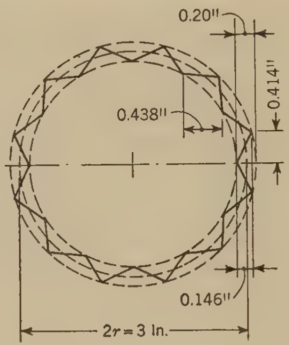

FIG. 32.—FOLDED SHELL TYPE OF COFFERDAM

It might be of interest to compare the values of overturning moment which resulted from the tests with those obtained by applying Eq. 17 to a continuous shell. Such a continuous shell simulates a sheet-pile wall without any slippage in the interlock joints. The use of Eq. 17 for this special case may be questioned, because it is necessary to substitute $f = 1$ in Eq. 17 in order to express the condition of unyielding interlocks of the cofferdam. Eq. 17 becomes then

$$S = \tfrac{1}{2} \gamma \, C \, H^2 (\tan \phi + 1) \ldots\ldots\ldots\ldots (53)$$

In accordance with Eq. 21, the coefficient of earth pressure, C, is greater than $\tan^2 (45° - \phi/2)$. Substituting the values of the tested specimens: $\gamma = 0.052$ lb per cu in., $\phi = 26.5°$, $H = 6$ in., and assuming $C > 0.383 = 0.4$, the average shearing resistance becomes $S = \frac{1}{2} \times 0.052 \times 0.4 \times 6^2 \times 1.5 = 0.562$ lb per inch of width of the neutral plane. According to the author, the critical overturning moment may be expressed as an internal couple of the shearing resistance S; that is:

$$M_e = S \, (2\, r) \, d'_0 \ldots\ldots\ldots\ldots (54)$$

The lever arm d'_0 will be smaller than $\frac{2}{3}\, b$ (Figs. 7(*b*) and 7(*d*)). Assuming that $d'_0 = \frac{4\, r}{\pi}$ (which is the distance of centroids of two semicircles), the overturning moment equals

$$M_e = \frac{8}{\pi} S \, r^2 = 1.43 \, r^2 \ldots\ldots\ldots\ldots (55)$$

Table 4 shows the values of overturning moment computed from Eq. 55 as compared with test results and values obtained from Eqs. 51 and 52. A better agreement between the measured overturning moments and their values calculated from Eq. 17 (Col. 3, Table 4) would be obtained by a variable coefficient of earth pressure, C, decreasing with an increasing ratio H/r, as shown in Col. 4, Table 4.

(*b*) *The Effect of Arch-Web Sheet Piles Upon the Safety of a Cellular Cofferdam.*—It should be emphasized that all investigations by the author regarding the shearing resistance on vertical sections through the fill in the cells and the lock friction are valid only for cellular cofferdams with straight-web sheet piles. If arch-web sheet piles are used, the total tension in a lock, expressed by Eq. 14*a*, will produce considerable deformation in the cofferdam shell. In the lower parts of the cofferdam the deformation may be beyond the elastic limit, resulting in an increase of 10 in. or more in the diameter of the cell. The bulge in such a case is quite noticeable. Any deformation of a structure beyond the elastic limit can be classified as failure, although several cofferdams of this type did not collapse, and served the purposes for which they were built. The total resistance against slippage in the lock will increase with bulging of the shell, since the total resistance against slippage increases with the increasing radius, as expressed by Eq. 14*b*.

TABLE 4.—COMPARISON OF OVERTURNING MOMENTS

Specimen No.	OVERTURNING MOMENT IN INCH-POUNDS, OBTAINED FROM:			C
	Tests (1)	Writer (2)	Author (3)	(4)
1	17.7	17.5	17.5	0.40
2	12.5	12.6	12.9	0.39
3	8.1	8.2	8.9	0.37
4	5.0	4.9	5.7	0.35
5	2.6	2.6	3.2	0.33

In the case of the cofferdam in the Kaiser Shipyards, the maximum tension in the locks, computed by Eq. 13, is $t_{\max} = r\,\gamma\,C\,H = 20 \times 110 \times 0.5 \times 41 = 45{,}100$ lb, or in sheet piles with $\frac{3}{8}$-in. web: $\frac{45{,}100}{0.375 \times 12} = 10{,}020$ lb per sq in. If arch-web sheet piles were used (for example, M112), the eccentricity of the interlock will produce bending of the sheet piles in a horizontal direction. The additional stress computed from the standard formula is so high $\left(\frac{45{,}100\,(1\frac{11}{32} - \frac{3}{16})}{0.28} = 185{,}531 \text{ lb per sq in.}\right)$ that the eccentricity ($1\frac{11}{32}$ in. $- \frac{3}{16}$ in.; see e in Fig. 33) will gradually decrease as the arch-web sheet piles stretch. In any case, the combined stress in the sheet piles will reach the yield point and cause permanent deformation as described previously.

The answer to the questions as to the approximateness of Eq. 13, and the nature of the two-dimensional stress conditions, can be attempted theoretically, considering the cellular cofferdam as a thin shell restrained at the bottom along its circumference. The results of any theoretical investigation of a problem, in which so many uncertain and indeterminate values are involved, must be approached with extreme caution. The analytical solution indicates deformation and stress distribution very similar to observations on actual cofferdams.

The horizontal force $P_s = Q_0$ (see Fig. 8) which is applied at the lower edge of the sheet piles in order to maintain equilibrium, and the restraining moment M_0 may be calculated (39) from the equations:

$$Q_0 = -\frac{\gamma\, r\, H\, h_2}{\sqrt{12\,(1-\nu^2)}}\left(2\,\beta - \frac{1}{H}\right) \qquad (56a)$$

and

$$M_0 = \frac{\gamma\, r\, H\, h_2}{\sqrt{12\,(1-\nu^2)}}\left(1 - \frac{1}{\beta\, H}\right) \qquad (56b)$$

FIG. 33

in which h_2 is a "theoretical thickness" of sheet piles derived from the section modulus S; thus,

$$h^2_2 = \sqrt{\frac{6\,S}{12}} = 0.7071\,\sqrt{S} \qquad (57)$$

In Eqs. 56, furthermore, ν is Poisson's ratio for steel $= 0.25$; and β is computed from

$$\beta^4 = \frac{3\,(1-\nu^2)\,h_1}{r^2\,h^3_2} \qquad (58)$$

In Eq. 58, h_1 is the actual web thickness of sheet piles. The values $N_{z'}$ and $M_{z'}$ for any depth $z' = H - z$ are expressed (39) by:

$$N_{z'} = -E\,\frac{h_1\,w}{r} = \gamma\, r\, H\left[1 - \frac{z'}{H} - \theta\,(\beta\, z') - \left(1 - \frac{1}{\beta\, H}\right)\zeta\,(\beta\, z')\right] \qquad (59a)$$

and

$$M_{z'} = -D\,\frac{d^2w}{dz^2} = \frac{\gamma\, r\, H\, h_2}{\sqrt{12\,(1-\nu^2)}}\left[-\zeta\,(\beta\, z') + \left(1 - \frac{1}{\beta\, H}\right)\theta\,(\beta\, z')\right] \qquad (59b)$$

in which

$$\theta\,(\beta\, z') = e^{-\beta z'}\cos\beta\, z' \qquad (60a)$$

and

$$\zeta\,(\beta\, z') = e^{-\beta z'}\sin\beta\, z' \qquad (60b)$$

The preceding values can be applied only for straight-web sections (see Table 5).

For arch-web sections, such as Carnegie Steel sections M112 and M113, or Inland sections (see Fig. 33) a modification of the formulas is necessary, expressing greater elastic displacements in circumferential direction due to bending of sheet piles. This effect can be attained theoretically by introducing an imaginary modulus of elasticity, E_1, for calculating elastic elongations in a circumferential direction, which is considerably smaller than the modulus of elasticity, E_2, expressing the stress-strain ratio in vertical direction of the sheet pile.

TABLE 5.—CHARACTERISTICS OF STRAIGHT-WEB SHEET PILES

No.	Section	Cross-section area A (sq in.)[a]	Section modulus S (in.^{3})[a]	Weight (lb)[a]	h_1 (in.)	h_2 (in.)	β (in.$^{-1}$)
A		9.1	3.0	31	0.375	1.225	0.0563
B		10.3	3.1	35	0.5	1.245	0.0598

[a] Per linear foot of wall.

The ratio $\frac{E_1}{E_2}$ $\left(\text{equal to } \frac{1}{100} \text{ approximately for section M112}\right)$ can be calculated under the assumption that the elastic displacement (expansion) of an arch-web sheet pile considered as an elastic bent is equal to the elongation of an imaginary straight-web sheet pile having a modulus of elasticity, E_1.

The computations confirm the fact that arch-web sheet piles must be avoided for cofferdams having a lateral (horizontal) tension (from two-dimentional stress condition). For cellular cofferdams only straight-web sheet piles should be used (see Table 5).

In all literature pertaining to cellular cofferdams to which the writer has had access, there was no statement to the effect that, for cellular cofferdams where a circumferential tension can occur, it is inadvisable and even dangerous to use arch-web sheet piles. Examination of the literature has shown that in very many cases the use of the arch-web sheet piles resulted in bulging or failure.

KARL TERZAGHI,[16] M. AM. SOC. C. E.—The discussion of this paper has been eminently constructive; any one who faces the problem of designing a cellular cofferdam will find in the discussions an inexhaustible source of information and guidance. Therefore, the profession as a whole is indebted to the discussers for the generosity with which they contributed from the store of their experience.

One of the principal theses of the paper is that the customary stability computations of cellular cofferdams based on the gravity concept need to be supplemented by an inquiry into the stress conditions in the fill constituting the body of the cofferdam. This conclusion was forced upon the writer by the results of observations made on a large cofferdam during 1941 and 1942. According to the gravity concept, the dam should have been stable; yet the observations left no doubt that the dam would be unable to stand the unbalanced horizontal pressures unless the shearing resistance of the earth in the cells was increased by artificial methods. These methods were adopted and their effect actually demonstrated the efficacy of the procedure.

---

[16] Cons. Engr. and Lecturer, Graduate School of Eng., Harvard Univ., Cambridge, Mass.

Some of the discussions revealed the fact that the engineers on the staff of the Tennessee Valley Authority (TVA) arrived at similar conclusions at an earlier date. The TVA engineers checked all their designs for what they called "internal shear," and for this purpose they used a method similar to the one proposed by the writer. This is more than a mere coincidence. It indicates that the time was ripe for this new development, and the writer acknowledges with pleasure that the credit for the corresponding modification of the design procedure belongs to the TVA engineers.

Mr. Greulich expresses the opinion that the inward deflection of a cellular cofferdam is associated with an important increase of the resistance against sliding in the interlocks of the cross-walls, equivalent to the introduction of stay rods from the inner top to the outer base of the cell. The lock friction as such, because of the hoop tension in the walls of the cells, has the mechanical effect of stay rods, because it counteracts the distortion of the cross-walls. However, it seems doubtful that the inward deflection of the cofferdam is associated with an increase of the lock friction. If such an increase occurs, it can scarcely be evaluated rationally.

Commenting on the depth to which the sheet piles for cofferdams on deep sand strata should be driven, Mr. Greulich contends that $H/2$ would be ample. His argument is that the sand in the cells can grip only one side of the sheet piles whereas when driven into the sand the piling is gripped on both sides. This argument can be accepted for the outer row, but it does not apply to the inner row. On the inner side of the inner row the water percolates through the sand in a vertical upward direction (see Fig. 9(*c*)). This process reduces the skin friction very considerably. An extreme possibility for this reduction was demonstrated by the following incident. An excavation was made by dredging in dense sand between sheet piles for a small dry dock in the vicinity of Hamburg, Germany. Prior to pumping, 1,500 wood piles were driven between 12 ft and 15 ft into the sand. No deeper penetration by driving could be obtained without breaking the piles. The pile cutoff was a short distance above grade. When the water level was lowered within the sheet-pile enclosure by about 8 ft, the piles began to rise one by one; yet the seepage pressure was not important enough to cause the sand to boil. It merely reduced the total skin friction of the pile to less than the hydrostatic uplift.

The total seepage pressure which acts on the sand adjoining the inner side of the inner row of sheet piles depends on details of stratification which are unknown. Hence, in some instances, a penetration of $H/2$ may be more than ample and in others not enough.

At the end of his discussion, Mr. Greulich requests an amplification of conclusion 2 of the paper and he also comments on conclusion 5. Conclusion 2 refers to the distribution of the soil pressure over the base of cellular cofferdams with conventional dimensions. According to the results of the analysis given in the paper, the application of an unbalanced horizontal force on such a cofferdam has very little, if any, effect on the distribution of the pressure on the base. In other words, the pressure distribution remains practically uniform. The entire overturning moment is transferred through skin friction on to that part of the sheet piles which is located below the base of the cofferdam. In conclusion 5 the writer implied that the ratio between the horizontal and the vertical pressure in the fill in the cells is greater than the Rankine value. Hence, the Rankine value is not on the conservative side as suggested by Mr. Greulich.

In several paragraphs of his discussion Colonel Pennoyer expresses the opinion that the paper involves an attempt to supersede the design method based on the gravity concept by proposing a standard ratio between width and height. Thus, he states:

> "* * * the writer feels that Professor Terzaghi has oversimplified the problem by assuming a cell width of 0.85 H and a conversion factor of 0.4 to develop the bursting pressures."

This, and many other similar passages in Colonel Pennoyer's discussion, indicate that the paper was not explicit enough to eliminate the possibility of misunderstandings in the minds of at least some readers. To clarify the issue, the following synopsis of the basic reasoning is submitted.

The stability and stiffness of cellular cofferdams depend on a great number of factors including the foundation conditions and the shearing resistance of the fill occupying the cells. Even under the simplest conditions, involving a cofferdam filled with sand and gravel resting on a solid foundation, theory alone cannot be relied upon because one of the most important factors—the ratio between horizontal and vertical pressure in the soil which occupies the cells—cannot be computed. This fact has been known ever since the first measurement of the side pressure in grain bins was made. Therefore, the designer depends to a certain extent on data derived from experience.

During the twenty years since 1925 a great number of cellular cofferdams have been built which have the following features in common: The sheet piles are driven through sand to bedrock; the cells are filled with sand or sand and gravel; the cofferdams are acted upon by one-sided water pressure; and the average (not the maximum) width of the cofferdams is roughly equal to 0.85 H. Since all these cofferdams gave satisfactory service, they constitute useful precedents and prototypes. To apply the experiences incorporated in the prototype to the design of cellular cofferdams to be built under different conditions of foundation and loading, the writer investigated the influence of several commonly encountered deviations from the prototype on stiffness and stability. If these influences are clearly recognized, the dimensions and proportions of the prototype can be changed in accordance with the findings. No claim is made that all the conceivable deviations from the prototype are covered, because such an attempt would obviously transcend the scope of a single paper. For the same reason, the discussions are limited strictly to cellular cofferdams filled with sand. As a matter of fact, cellular cofferdams filled with other soils are rather exceptional, as demonstrated by the construction record of the Dravo Corporation and the TVA.

Cellular cofferdams are commonly considered major structures and the uncertainties involved in their design are generally recognized. Hence, it goes without saying that no responsible engineer will consider the design of such cofferdams a routine problem under any except very simple conditions. Every scrap of available information should be utilized; and every known theoretical approach, including the stability computation based on the gravity concept, should be made before final decisions are reached. The design of the Kentucky cofferdam described by Messrs. Tsagaris, Colburn, and Hedman is an outstanding example. If two different approaches lead to different results, the more unfavorable one will be accepted.

Colonel Pennoyer comments on the writer's assumption that the soil fails along a vertical plane and calls the assumption fallacious. He further states:

> "What actually happens is that the entire mass of confined soil changes shape simultaneously. This action can best be described as a universal plastic flow, or distortion * * *."

The writer's concept of the process of failure is essentially identical with that described by Colonel Pennoyer, and the equations which were derived by the writer are merely mathematical expressions of the stress conditions required for producing this type of failure. Since the original explanation of the physical meaning of the equations was apparently not explicit enough to avoid a misunderstanding, the following discussion is presented in the hope of clarifying the issue. Fig. 34 is a vertical section through a mass of soil confined between two straight rows of sheet piles, not interconnected by cross-walls. The soil is assumed to adhere to the piles, and the resistance of the sheet piles against bending at ground level in the plane of the drawing is assumed negligible. As soon as a horizontal force P is applied at an elevation h above the ground surface, the outer row of sheet piles is pulled by a force $-S$, and the inner row is pushed down by the same force S. The force S is equal to the overturning moment $M = P\,h$ divided by the distance b between the two rows. The horizontal force P produces a change of shape as described by Colonel Pennoyer. As soon as the horizontal force exceeds a certain critical value, the distortion increases at a constant rate and the cofferdam fails by tilting forward more and more—whereby the cross section of the dam changes from a rectangle into a parallelogram with equal area. Since there are no cross-walls, the failure by plastic flow starts simultaneously at every point in the confined mass of soil. The failure occurs by shear along an infinite number of vertical planes. According to the theory of plastic materials, failure occurs

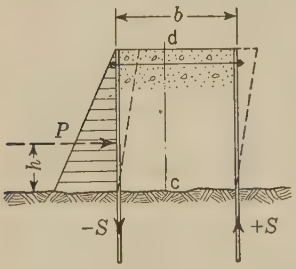

Fig. 34

as soon as the total shearing force on any vertical section such as cd becomes equal to the shearing resistance on this plane; and, according to the laws of mechanics, the shearing force is equal to S.

If the dam shown in Fig. 34 is reinforced by cross-walls consisting of sheet piles, the presence of these walls complicates the process of failure to some extent. Instead of starting at every point at the same time, the plastic-flow spreads from the neutral plane toward the walls. However, the laws that determine the conditions of failure are identical with those cited previously.

Colonel Pennoyer maintains that, if the coefficient of lock friction of 0.3

> "* * * was assumed analogous to the coefficient of friction of steel on steel, the statement would seem fallacious. Interlocks of sheet piling are designed * * * with emphasis on reducing the area of contact between surfaces to a minimum * * *. There is no relation between the frictional value of two pieces of steel in what amounts to line contact and the coefficient of friction of steel on steel times a tension force per unit of length, when no area of contact can be assumed."

The value of 0.3 assumed by the writer really is nothing more than the coefficient of friction of steel on steel. According to sources available to the writer (40), the coefficient of friction for metal on metal, dry, ranges from 0.15 to 0.20 and for metal on metal, wet, it is 0.30. To these values may be added the results of some tests performed by the writer who found that, for steel on smooth glass, dry, f equals from 0.20 to 0.22 and that, for steel on smooth glass, wet, f equals from 0.32 to 0.47 (16). In the walls of a cofferdam, the locks are wet or moist. Tests have shown that a trace of moisture is sufficient to produce the full "antilubricating" effect of water. Therefore, it seemed justified to assume $f = 0.3$.

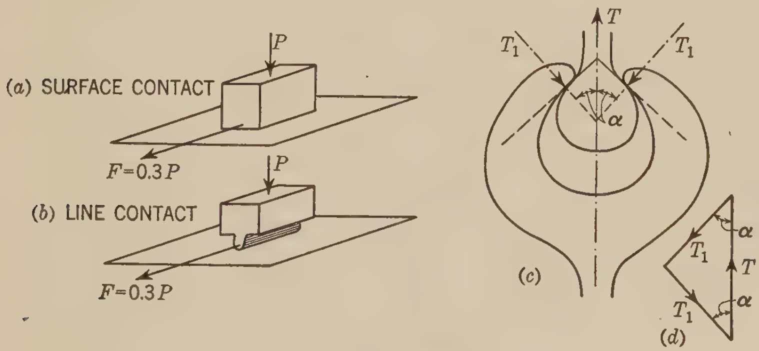

FIG. 35

Figs. 35(a) and 35(b) represent two different test arrangements for making a friction test. One involves a surface contact and the other what appears to the unaided eye as a line contact. Experience has shown that both test arrangements lead to the same result. Even if the two surfaces touch each other at what appears to be only a point, the result is no different. In other words, the coefficient of friction, $f = F/P$, is independent of the area of contact. This is quite generally regarded as one of the fundamental laws of physics.

Fig. 35(*c*) illustrates the influence of the shape of the lock on lock friction. It represents a section through a fictitious lock. If T is the lock tension per foot of length, the pressure on the two contact lines combined is equal to $\frac{T}{\cos \alpha}$, and the lock friction is $F = \frac{0.3\,T}{\cos \alpha}$ per foot of length. For $\alpha = 45°$, $F = 0.42\,T$. If $\alpha = 0°$, the lock friction assumes the smallest value that can be obtained without the aid of a lubricant—that is, $0.3\,T$. There seems to be no fallacy involved. The computation of the lock friction for the Kentucky cofferdam was made on the basis of a coefficient of friction of 0.3. Considering the customary shape of the locks, the value of 0.3 seems to be conservative.

Colonel Pennoyer describes an arching phenomenon which he observed in 1932 on a cellular cofferdam of the diaphragm type. After the sand was washed out under the fill of the cell, the fill was found to arch over the cavity. This observation led Colonel Pennoyer to conclude that arching may quite generally lead to the formation of a "bottom," or of "bottoms," in the cell, and he discusses the mechanical implications of the phenomena. Since the writer has noticed similar phenomena in grain and coal bins, he was interested in the mechanical prerequisites for such arch formation. Therefore, in 1918, he made several experiments involving the pressure conditions in bins filled with sand (41). The bottom of the bin was mounted on a platform scale. The side pressure of the sand on the walls of the bin was measured by horizontal friction tapes installed at different depths below the top. The tests were made with both dense and loose sand. The bin was filled while the bottom was held in its original position; and, after the bin was filled, both side and bottom pressures were measured. The next step was to lower the bottom of the bin by increments and to observe the effect of this operation on the pressures. The test results are illustrated by Fig. 36. The abscissas of the curve C_1 represent the unit pressure on the side-walls at different depths below the top of the bin. The unit pressure increased steadily from the top down. As soon as the bottom of the bin was allowed to descend, the pressure on the bottom and on the lower part of the side-walls decreased, whereas the pressure on the upper part of the side-walls remained unchanged. Finally, the pressure distribution on the side-walls became that shown by curve C_2. At this stage a slight amount of cohesion would have sufficed to keep the sand in the bin without any bottom support. This was the action that occurred in the cofferdam cells inspected by Colonel Pennoyer. The yield of the bin bottom in the experiment was produced in nature by the escape of the sand which originally occupied the space beneath the fill. However, under normal conditions the base of the fill remains intact; and, as a consequence, the distribution of the pressure on the walls of the cells is shown in Fig. 36 by curve C_1 and not by curve C_2.

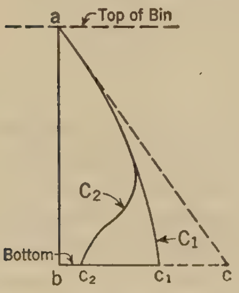

Fig. 36

Colonel Pennoyer remarks that he will continue to use the Rankine conversion factor until something better is available. Since the cells of a cellular cofferdam are essentially bins, the following data may be of interest. In 1920 the writer determined, by small-scale experiments, the ratio between the horizontal pressure in dense sand and the corresponding vertical pressure. In these tests the friction tape method was used and a value of 0.42 was obtained. The Rankine conversion factor for this sand was 0.22 (16). In 1929 direct measurement was made of the pressure exerted by loose sand on to the walls of a prismatic reinforced concrete container 7 ft high with a base 14 ft by 14 ft. The results of the observations furnished a value of 0.405 against a Rankine conversion factor of 0.31 (25) for the ratio between horizontal and vertical pressure. The lateral pressure exerted by completely submerged glacial till with an effective grain size of 0.019 mm was found equal to the sum of the full hydrostatic pressure of the water and the lateral pressure of the fill, computed on the basis of the submerged unit weight and a conversion factor of 0.38. The Rankine conversion factor for this material, computed on the basis of the results of friction tests, was 0.22 (42). These test results suggest that the value of 0.4 proposed by the writer may be much closer to the real ratio between the horizontal and the vertical pressure in sand enclosed in the cells of a cellular cofferdam than the Rankine conversion factor.

In discussing cofferdams on deep sand strata, Colonel Pennoyer refers to his own paper published in 1935 (29). Since this paper had escaped the writer's attention, he appreciated the reference and studied the paper with interest. The paper contains empirical values for the required sheet-pile penetration, together with other information. For water-bearing sand, the value is given as 30% to 40% of the unbalanced hydrostatic head. The writer has observed that the values in Colonel Pennoyer's paper are quite generally accepted in practice. However, he also noticed that blowouts are quite common, which induced him, about 1920, to make an inquiry into the causes.

The first step was to determine the hydraulic head required to produce a blowout under a straight row of sheet piles embedded in perfectly homogeneous sand. Both theory and experiment showed that the blowout does not occur until the hydraulic head approaches a value somewhat less than three times the depth of sheet-pile penetration. The grain-size characteristics of the sand are irrelevant (16); yet several instances have come to the writer's attention in which the sand began to boil on the inner side of single sheet-pile cofferdams at a head which ranged between 1½ and 2½ times the depth of sheet-pile penetration. Lazarus White, M. Am. Soc. C. E. (6), even describes a serious blowout in an open cut near the intersection between Canal Street and West Street in New York, N. Y. In this case the depth of sheet-pile penetration was equal to the full depth of the cut.

When several records of this nature were assembled, the reasons for the apparent incompatibility between test results and experience became quite plain. A blowout occurs as soon as the upward "drag" exerted by the water percolating through the sand along the inner face of the buried part of the sheet piles becomes equal to the submerged weight of the sand through which it percolates. The tests were made with perfectly homogeneous sand and the theory was developed for similar materials. However, in nature, sand strata are never even approximately homogeneous. By theory it can be shown that the drag depends to a large extent on the variations of the permeability of the sand in both horizontal and vertical directions, other factors being equal. By properly changing the permeability pattern for a sand adjoining a row of sheet piles, one can regulate the critical head within very wide limits. Hence, in nature too, the hydraulic head required to produce a blowout at a given sheet-pile penetration may vary between wide limits, and the real value cannot be ascertained by any practicable procedure before the sheet piles are driven and an unbalanced head is established.

A second factor that needs to be considered is the effect the seepage pressure or upward "drag" has on the bearing capacity of the inner row of sheet piles and on the resistance of the sand against a lateral displacement of the buried, lower part of the piles. Colonel Pennoyer mentions an instance in which a single sheet pile, driven 25 ft into sand, sustained a load of 47 tons. The piles previously mentioned in connection with Mr. Greulich's discussion would probably have sustained a load of 80 or 100 tons each because they were driven into hard sand. However, while the water level within the cofferdam was being lowered 8 ft by pumping, the sand loosened its grip on the piles to such an extent that the piles floated out of the sand. Hence, when evaluating the bearing capacity of the sheet piles of the inner row, the reducing effect of the "drag" on the skin friction must be considered. The results of load tests can be very misleading.

The mechanical effects of the "drag" must also be considered in the computation of the passive resistance of the sand adjoining the inner face of the buried part of the inner row of sheet piles. Lowering the water level adjoining the inner face of the cofferdam reduces this resistance very considerably as illustrated by Fig. 37, representing two vertical sections through a single-wall cofferdam. In Fig. 37(*a*), the water level is at the same elevation on both sides of the sheet-pile enclosure. On this assumption, the passive resistance of the sand on the right-hand side of the buried part of the sheet piles can be computed by Rankine's equation:

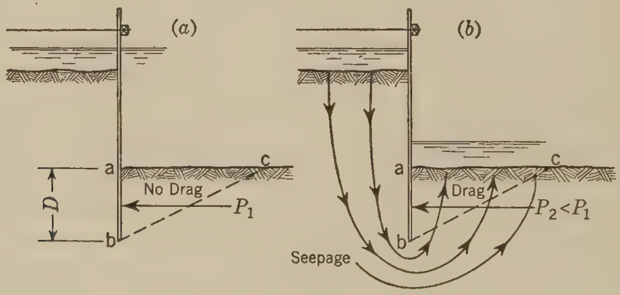

FIG. 37

$$P = \tfrac{1}{2} D \gamma' \tan^2 \left(45 + \frac{\phi}{2}\right) \qquad (61)$$

in which γ' is the submerged unit weight of the sand. If the water level within the cofferdam is lowered by pumping the water down to the level indicated in Fig. 37(*b*), the sand within the sliding wedge abc is acted upon not only by the simple hydrostatic uplift associated with submergence in still water but also by the seepage pressure or upward "drag" of the water which percolates through the wedge from below. This drag reduces the passive resistance of the sand considerably. The loss of resistance due to drag can be estimated by the flow-net method (17). In Colonel Pennoyer's computation of the passive resistance of the sand adjoining the inner face of a sheet-pile cofferdam (29), the drag has been disregarded. Therefore, the real passive resistance is smaller than the resistance indicated by Colonel Pennoyer's equations.

Considering all these facts and the inevitable uncertainties resulting from the unknown details of stratification of natural sand layers, the writer felt compelled to recommend a sheet-pile penetration of $2\,H/3$ instead of the customary $0.3\,H$ to $0.4\,H$.

In two places Colonel Pennoyer calls the reader's attention to various omissions in the writer's paragraphs on breakwaters. The design of cellular breakwaters has been treated so ably and comprehensibly in older publications that there was no incentive for discussing any aspect of this subject except the one that had not received any attention—the possibility of a base failure due to spontaneous liquefaction of underlying strata of loose sand. The writer's remarks on this subject were prompted by the spontaneous and complete subsidence of a breakwater on sand off the Atlantic coast of South America during a heavy storm. There are so many failures due to sponteneous liquefaction of masses of loose sand on record that this danger should not be ignored.

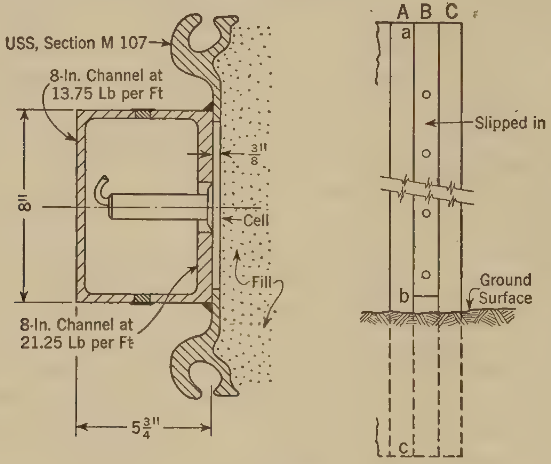
Mr. Tsagaris presents a brief review of the methods used in the design of the cellular cofferdams for the TVA. He points out that the possibility of a failure due to internal shear has received serious consideration, and comments on the writer's neglect of the tension contributed by the connecting arcs to the tension in the locks of the main cells. The reason for this omission will be given in the writer's comments on Mr. Hedman's discussion.

Mr. Colburn describes the Kentucky cofferdam, the highest cellular cofferdam which has ever been built. His account of the drainage provision on this and some of the other TVA cofferdams deserves special attention. An attempt to measure the tension in the sheet-pile enclosure of two of the cells of the Chickamauga cofferdam by strain gages was unsuccessful. The observations disclosed a very erratic distribution of the tensile stresses over the sheet piles.

More reliable information on the pressure acting on the walls of the cells can be obtained by pressure cells inserted into some of the sheet piles as shown in Fig. 38(*a*). A box composed of two channels is welded to a pile. The cells are $\frac{3}{8}$ in. thick and have a diameter of about 7 in. They fit into circular holes in the sheet piles and are seated on the outside of the web of the inner channel. The strain gage chambers project into the box and the cables are also installed in the box. The minimum requirement for obtaining fairly consistent results is the equipment of three sheet piles with five cells each.

These piles should be placed at the three-quarter points of the main arc on the inside of the cofferdam at the junction of the cofferdam with the connecting arcs.

Sheet piles to which cells are attached should not be driven because the impact of the hammer is likely to injure the cells. In order to incorporate a cell pile (unit B in Fig. 38(*b*)) into the sheet-pile enclosure of a cell, the pile is made of two pieces. First the lower part bc is driven to the required depth by means of a follower; then the next pile (unit C) is driven to full depth; the upper part of unit B is pulled; and finally the section containing the cells is slipped into place.



(*a*) (*b*)

FIG. 38

The cells register the sum of the earth and the water pressure which acts on the face of the cell. The water pressure alone is measured independently. If the fill consists of sand, reliable values can be obtained by means of observation wells with a small diameter.

Deflection observations on the Kentucky cofferdam showed that one of the cells deflected slightly outward with a rising river. This observation calls attention to the fact that the movement of every dam due to a change of the unbalanced head is equal to the difference between two movements in opposite directions. If the head increases, all the cells tilt inward with reference to their base on account of the increase in the overturning moment. At the same time, the base tilts outward due to the increase of the water load on the area outside the cofferdam. If the water is retained by a flexible cofferdam on a relatively unyielding foundation, the inward tilt prevails. On the other hand, a fairly rigid cofferdam on a yielding base must be expected to tilt outward. For similar reasons, the rise of the water level behind a relatively rigid storage dam on a less rigid foundation causes a tilt in an upstream direction. Such an upstream tilt was expected, and subsequently observed, on a concrete dam resting on a thick stratum of clay in northeastern Russia (43).

Before construction began, it was computed that filling the reservoir would cause a 0.75% tilt of the dam and powerhouse in an upstream direction. Since the turbine shafts had to be installed before the reservoir was filled, they were mounted with a 0.75% tilt toward the downstream side. While the reservoir was being filled for the first time, the shafts moved into an almost vertical position.

The Kentucky cofferdam rested on a limestone base. Hence, the outward tilt due to a rise of the river level undoubtedly was very small compared with the inward tilt of most of the cells; yet it might have been important enough to produce a measurable outward deflection of those cells which, for some reason, retained their original position with reference to the base.

Mr. Colburn expresses the opinion that the reactive pressure of the fill in the cells prevents a relaxation of the lock tension even though the bursting pressure may decrease. There is no doubt in the writer's mind that this assumption is justified.

Mr. Hedman gives a detailed account of the methods used in the design of the Kentucky cofferdam. He remarks that the writer's statement regarding the effect of seepage on the tension in the locks is contradictory to subsequent statements regarding the effect of seepage on sliding resistance. The apparent contradiction is due to the fact that the writer's first statement was inadequately qualified. Furthermore, Mr. Hedman does not agree "that the unit weight of the fill in a moist state should be used in Eq. 3." This objection is justified. The effect of the air content on the unit weight of a drained soil can be disregarded only if the effective grain size is equal to, or smaller than, about 0.05 mm.

Mr. Hedman presents a résumé of the procedure for determining the lock stresses:

> "This stress was found to be equal to 9,500 lb [per lin in.]—more than 50% higher than would have been the case if the author's suggested empirical formula, Eq. 28*f*, had been used."

The major part of the difference is due to the fact that the TVA computation was based on the assumption of complete saturation of the fill in the cells, whereas the writer's equation presupposes fairly complete drainage. The fill in the cells of most or of all the TVA cofferdams was deposited by the hydraulic method during a low-water stage. On this condition, Eq. 28*f* should be modified in such a way as to comply with the state of full saturation. The modified equation furnishes, for the interlock stress in the main cells, a value of about 8,120 lb per lin in. against the value of 7,280 lb per lin in. given by Mr. Hedman.

To the value of 7,280 lb per lin in. was added 2,220 lb per lin in. for the tension contributed by the connecting areas. This supplementary force was computed on the assumption that the sand pressure on the connecting arcs increased like a hydrostatic pressure in direct proportion to depth. However, considering the slenderness ratio of the columns of sand adjoining the connecting arches, the bin effect must be very important. In 1918 when the writer made his bin tests, he tried to destroy the bin effect by various means, such as pounding the sides of the container, but he did not succeed. He also poured the sand into water and afterward drained it through the perforated bottom of the bin; yet the bin effect persisted. Hence, it can be counted upon. If the bin action is taken into account, the contribution of the connecting arches to the tension in the main cells will probably be found to be rather unimportant and well within the range of error associated with the estimate of the bursting pressure exerted by the sand in the main cells. There is no doubt, however, that the junction between the main cells and the connecting arches is a delicate detail, and the attention which is received in the TVA design was fully justified.

Commenting on the effect of a berm on the lock tension in the cross-walls, Mr. Hedman points out correctly that the writer's statements concerning this effect require qualification. These statements are not valid unless the cells are filled while the water level in the river is fairly close to its highest position. The influence of the river stage when the cells are filled is strikingly demonstrated by the difference between the deflections of the Kentucky cofferdam which was filled at low water and those of the cofferdams on the west shore of the Hudson River in New York City which were filled while the water level was close to the high-water mark.

Considered as a whole, the procedure for designing the Kentucky cofferdam, as described by Mr. Hedman, is an outstanding example of sound engineering. This procedure discloses a thorough grasp of all the theoretical principles involved combined with mature judgment, and it deserves the attention of every engineer who faces the problem of designing a cellular cofferdam.

Mr. Ackerman presents a significant résumé of the practical considerations that enter into the selection of the type of cellular cofferdams under given conditions of foundation and exposure. Attention is called to his remarks on the benefits derived from the use of portable templates. The writer agrees with Mr. Ackerman that it might be preferable to refer to the cellular cofferdams as plastic and not as composite structures because the reactions of these cofferdams to external forces are decidedly those of plastic materials.

For comparison, Mr. Packshaw discusses the conditions required for the stability of double-wall sheet-pile cofferdams. The stability computation which he presents conveys a clear conception of the factors that determine the stability of these structures. Since, even in the United States, the double-wall type of cofferdam is far more frequently used than the cellular type, his contribution will be welcomed by many readers.

Mr. Lautz assumes that the excess of the normal pressure over the Rankine pressure on the vertical shear plane or planes is chiefly due to the horizontal load imposed upon the outside of the cofferdam. The bin tests which were described in the writer's comments on Colonel Pennoyer's discussion suggest that this excess is chiefly due to the fact that the fill is deposited within a laterally confined space. According to the results of bin tests, the normal pressure on every vertical section through the cells is much greater than the active Rankine pressure even before horizontal forces have been applied.

Example 1 in Mr. Lautz's discussion illustrates the application of the cellular cofferdam method to the construction of a dock-wall. The cells of this wall contain soft silt and clay in an undisturbed state. In this state clays and silty clays possess a remarkable degree of rigidity although their water content may be very high. Quite recently the writer examined a stratum of clay with a liquid limit of about 40% of the dry weight. The water content of the clay in its natural state was about 60%. Nevertheless, the clay contained hair cracks and was decidedly brittle. By kneading, it was transformed into a thick, viscous liquid. The rigidity of undisturbed clay, combined with an increase of the lock friction in the cross-walls and the low intensity of the unbalanced horizontal forces, accounts for the absence of noticeable deflections. The cells of the cofferdam for the intake system in Detroit, Mich. (Example 3), also chiefly contained soft clay in an undisturbed state. However, in contrast to the dock-wall, the cofferdam was acted upon by clay and water pressure combined. Hence, in spite of its ample dimensions, it required supplementary support.

Mr. Miller's discussion ranks among the most noteworthy contributions to this subject because it is based on extensive and varied experience in the design and construction of cellular cofferdams. Mr. Miller takes exception to the writer's statement concerning the influence of the outer row of sheet piles on the percolation of water through cells filled with clay or other soils with a low permeability. This influence has been the topic of several good-natured verbal controversies between Mr. Miller and the writer with the result that both parties remained utterly unconverted. The writer's arguments in favor of his thesis appear in "Part I. Practical Considerations" under the heading, "Permeability of Cellular Cofferdams and of Their Sheet-Pile Enclosures." Mr. Miller's confidence in the efficacy of weep holes is somewhat at variance with the results of the observations of the TVA engineers described in the discussions of Messrs. Tsagaris, Colburn, and Hedman.

Professor Legget comments on the writer's mildly skeptical remarks regarding the practical value of laboratory tests in connection with the design of cellular cofferdams. The principal benefit to be derived from these tests is that they give the engineer a firsthand knowledge of the character and the properties of the materials involved in the design. The benefits derived from such knowledge are important enough to justify a considerable amount of testing.

In the course of his discussion, Professor Legget requests an amplification of the writer's comparison of cellular cofferdams with structures made of composite materials. When making this comparison, the writer merely wished to emphasize that the distribution of the external forces acting on the two constituents of the dam—the steel and the soil—is governed by the stress-deformation characteristics of the two materials involved. The analogy cannot be extended further.

Commenting on lock friction, Professor Legget presents a list of all those variables which are likely to influence the friction value, and he raises the question as to whether or not reliable values could be obtained by experimental methods. In the writer's opinion, the lock friction can be resolved into two parts. One part is determined by the coefficient of friction of metal on metal and by the orientation of the surfaces of contact with reference to the direction of the pull. It has been referred to as the basic part of the friction. The second part is caused by the effect of one of several of the factors enumerated by Professor Legget. All these factors tend to increase the lock friction to some extent. Hence, the basic value determines the lower limit for the lock friction. The writer estimated that the basic value for the coefficient of lock friction is $\frac{0.3}{\cos \alpha}$ (see Fig. 35(*c*)). The data and considerations which led to this value are treated previously in the writer's comments on Colonel Pennoyer's discussion.

A more accurate basic value could be obtained by friction tests with specimens cut out of new steel sheet piles. Some information on the difference between the real and the basic values of the lock friction for the buried part of sheet-pile enclosures could be obtained by friction tests on specimens cut from sheet piles after they have been pulled. To preserve the state of contamination of the lock with soil particles, two sheet piles should be clamped together securely and pulled in a single operation. When cutting the test specimen from the pair, special precautions should be taken to prevent a slippage in the locks prior to the test.

Professor Legget also raises the question as to how much reliance can be placed on the lock friction in straight rows of sheet piles composed of deep arch sheet piling. In such rows, the tension in the locks is at least theoretically equal to zero. Hence, the basic value for the lock friction is also equal to zero and the resistance against slippage in the locks is entirely due to those factors which produce lock friction in excess of the basic value in the driven part of the sheet-pile enclosures of cellular cofferdams. Nevertheless, in Germany the manufacturers of deep arch sheet piling with locks in the neutral plane claimed that the weakening effects of the lock can be disregarded, and the moments of resistance contained in their catalogs were computed on the assumption that the locks do not exist. In design practice, it was customary to distinguish between the sheet piles driven into sand and those driven into clay. For sheet piles in sand, it was considered safe to ignore the presence of the locks, whereas the moment of resistance of sheet piles in clay was reduced by one third of the value obtained for jointless piling. The writer has never had much confidence in this procedure; yet it is conceivable that the mere process of driving sheet piles into the soil may create various sources of considerable friction. Hence, if in those parts of the steel skin of a cellular cofferdam which is located below the original ground surface or dredging line, the real lock friction may be greater than the basic value.

Professor Krynine furnishes convincing proof that shear failure on vertical planes is inevitably preceded by, and associated with, a considerable increase of the normal pressure on these planes. At the instant of failure the normal pressure is much higher than the value computed on the basis of the Rankine conversion factor $\tan^2\left(45 - \frac{\phi}{2}\right)$. This is a noteworthy contribution to the clarification of the theoretical issues involved in the cofferdam problem. The Mohr diagram which is used to support the argument serves its purpose to perfection.

Professor Krynine also calls attention to the possibility of a failure along shear planes other than vertical ones. However, the writer doubts whether these other planes can possibly be oriented as indicated in Fig. 26(*c*). A failure along such planes requires that the major principal stress be oriented as indicated in Fig. 26(*b*) and in Fig. 39(*a*). Such orientation of the major principal stress would be associated with a distortion of the body abcd in Fig. 39(*a*) into the shape a_1b_1cd. A deformation of this kind involves an outward tilt which is incompatible with the nature of the problem. To account for the inward tilt of the cells, it is necessary to assign the orientation indicated in Fig. 39(*b*) to the shear planes. One set of shear planes is vertical whereas the other slopes at an angle ϕ toward the inside of the cells. Failure occurs simultaneously on the vertical and the inclined planes. Hence, for estimating purposes, it seems justifiable to evaluate the factor of safety with respect to failure by internal shear on the basis of the stress conditions on vertical planes.

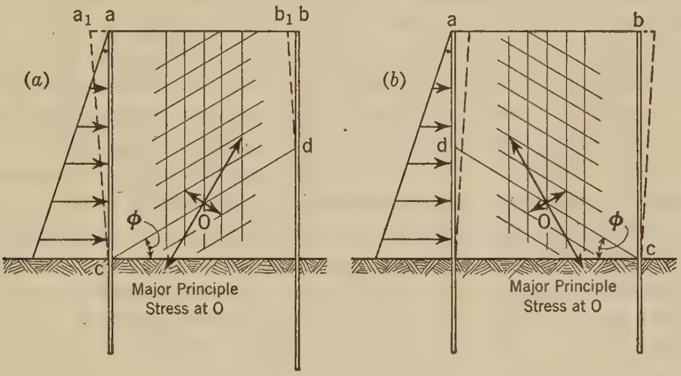


FIG. 39

Mr. Polivka describes the small-scale model tests made preliminary to the design of a cellular cofferdam in the Kaiser Shipyards at Richmond, Calif. The model cells were no more than 6 in. high. They consisted of cylinders made of plain sheet metal, 0.004 in. thick, filled with very fine sand. The results of tests on such cells cannot be correlated with the author's theory of internal shear, because the walls were incapable of distortion comparable to that in cells with walls containing locks. This difference is crucial.

In his mathematical interpretation of the test results on the basis of the general bin theory, Mr. Polivka assigned a value of 26° 30′ to the angle of internal friction ϕ of the sand and a value of $K = 1$ to the ratio between the horizontal and the vertical pressure in the sand. The value of ϕ appears to be rather low. Reliable values can be obtained only by an appropriate shear box apparatus or a triaxial compression device. The smallest value that was ever obtained by either one of these devices ranges from 27° to 28° 30′ (44)(45). The tests were made on Ottawa standard sand—a very uniform sand consisting of almost perfectly spherical quartz grains with a smooth surface. The normal values for loose sand range between 32° and 34°. The value $K = 1$ was derived from trap-door experiments and is not applicable to the case under consideration. The experimental values obtained from bin tests are mentioned previously in the writer's comments on Colonel Pennoyer's discussion. They are approximately equal to 0.4.

To establish an equation for the resistance of the model cells against shear along vertical sections, Mr. Polivka introduced a value of $f = 1$ into Eq. 17. This does not seem permissible, because the equation thus obtained applies to walls with locks, if the coefficient of lock friction is equal to unity. If the walls are continuous (such as is the case for model cells), Eq. 17 cannot be used.

In the last part of his discussion Mr. Polivka describes the practical implications of making the walls of cellular cofferdams of arch-web sheet piles such as the Carnegie M112 and M113 sheet piles and their equivalents. In cofferdams local stressing of the steel beyond the yield point can scarcely be considered a failure. However, the excessive increase of the diameter of the cells which results from the low value of the "equivalent modulus of elasticity," E, of arch-web sheet piles is a very undesirable feature. Since it involves an important lateral stretching of the fill in the cells, it is associated with an equally important decrease of the horizontal pressure in the fill, which in turn reduces the lock friction in the cross-walls and the resistance of the fill against deformation. Hence, the writer agrees with Mr. Polivka that the straight-web sections are preferable.

TRANSLATORY WAVES IN NATURAL CHANNELS

By J. H. Wilkinson,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Harold A. Weggel, W. M. Lansford, M. A. Churchill, and J. H. Wilkinson

Synopsis

The phenomena of translatory wave travel in natural channels have been studied for many years without entirely satisfactory results. Published studies have been largely theoretical, supplemented by laboratory tests in some instances, but with few observed data on waves in natural channels. Stream flow regulation by storage reservoirs in the Tennessee River Basin during the past few years has developed numerous translatory waves of various magnitudes. Under such conditions, waves can be selected for study which travel considerable distances without being appreciably affected by tributary inflows.

This paper presents data on natural channel translatory waves on the Clinch and the lower Tennessee rivers, and on Wheeler Reservoir in Alabama for a considerable range of flow in each type of channel. Theoretical velocities are computed for these waves by formulas and are compared with observed velocities. Results indicate that wave velocities on the Clinch River can be computed with reasonable accuracy, and that velocities for the rising face of a wave on the lower Tennessee River can be approximated. Computed velocities for waves in Wheeler Reservoir are in poor agreement with observed velocities.

Translatory Waves on the Clinch River

Regulated discharges at Norris Dam in Tennessee have developed a number of well-defined translatory waves which were not affected appreciably by tributary inflow in the reach of the Clinch River between Norris Dam and Wheat stream gage 65.3 miles downstream (see Fig. 1). The Clinch River at Norris Dam drains a mountainous area and has an average annual flow of 4,600 cu ft per sec. Below the dam the river drains a hilly country and has

an average slope of about 1.6 ft per mile in the reach from the dam to the Wheat gage.

Continuous stage recorders located at intervals throughout this reach provide records from which gage-height graphs in Fig. 2 are plotted. Norris and Wheat gages have been rated by the U. S. Geological Survey, and ratings for Clinton and Edgemoor gages are developed from these ratings. Discharge ratings and corresponding channel cross-section areas for these stations are given in Table 1. The gage-height relation between Wheat gage and Gallahers Ferry gage is also given. As discharge measurements for rating Wheat gage are made at Gallahers Ferry, data on the channel cross section at Wheat gage are not available. Pertinent data at these gages are given in Table 2.

FIG. 1.—CLINCH RIVER AND UPPER TENNESSEE RIVER

Velocity of a Translatory Wave.—To determine the velocity of a translatory wave from observed data, it is necessary to identify identical points on the wave at successive stations. In this study (1) the beginning-of-rise and (2) the midpoint-of-rise are used for this purpose on rising waves, and (3) the beginning-of-fall and (4) the midpoint-of-fall on falling waves. Velocities indicated by the points of fully developed rise and fully developed fall were investigated but were found to be unsatisfactory, partly because these points could not be identified accurately and partly because these points are modified considerably by other influences.

The following formulas[2] are used for computing theoretical velocities from channel characteristics:

$$c_1 = \frac{0.682\, dQ}{b\, dZ} \quad \ldots.(1a)$$

and

$$c_2 = \frac{0.682\,(Q_2 - Q_1)}{A_2 - A_1} \quad ..(1b)$$

in which c_1 is the velocity of a wave traveling on a stream at a given stage; c_2 is the average velocity of the wave, taking into account the channel discharge

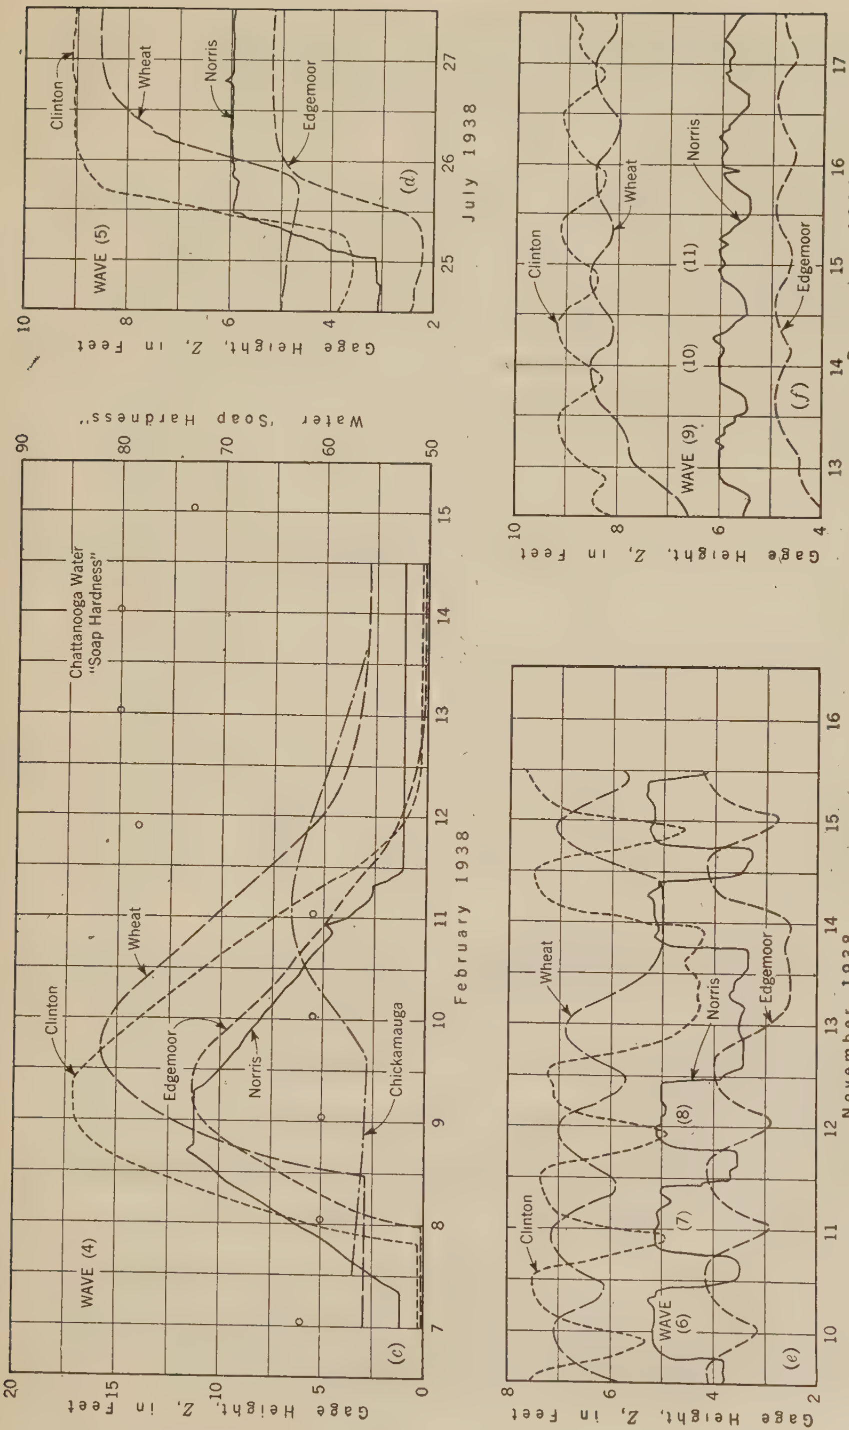

FIG. 2.—GAGE HEIGHTS, CLINCH RIVER WAVES

characteristics throughout the entire rise of the wave; Q_1 and Q_2 are the discharges corresponding to gage heights Z_1 and Z_2, respectively; dQ is an increment of discharge; dZ is a selected increment in a gage height Z; b is the width of the channel; and A_1 and A_2, respectively, are the cross-section areas below stages Z_1 and Z_2.

Eq. 1*a* is applicable only for determining the velocity of a wave traveling on a stream at a given stage. This becomes evident when the derivation of the equation is examined. Eq. 1*b* is applicable for determining the average velocity of the wave, as it takes into account the channel discharge characteristics throughout the entire rise of the wave. Results from both equations will be the same when the discharge characteristic of the channel, that is, $\frac{dQ}{b\,dZ}$, is constant throughout the range in stage covered by the wave. It will be noted that c_1 is a function of the slope of the rating curve at a given stage, whereas c_2 is a function of the slope of a secant to the rating curve between two stages, or the average slope of the rating curve. The constant 0.682 in Eqs. 1 is inserted to convert to miles per hour.

Using Eqs. 1, wave velocities are computed for the four identifiable points on each wave at each of the four stage recording stations. These computed velocities are assumed to exist half the distance to adjacent stations in determining the theoretical time required for the wave to traverse each of the three reaches between stage recording stations. The average velocity between Norris gage and Wheat gage is then computed from the total time required for the wave to traverse the three intermediate reaches.

Average c_1 (Norris to Wheat)					3.19	64.2	20.11

Col. 1.—Stations at which data on gage heights are available.
Col. 2.—The river stage at the beginning-of-rise, Z_1, is taken from the gage-height graph for each station in Fig. 2(*a*). As data on the channel at Wheat are not available, the stage at Gallahers corresponding to the observed stage is determined from the gage-height relation in Table 1 for computing the velocity at this station.
Col. 3.—Channel widths b at these stages are determined from the rate of change in channel cross-section area at stage Z_1 from Table 1.
Col. 4.—The rates of change in discharges, dQ, per 0.1 ft change in stage, at these stages are determined from the discharge rating curves in Table 1.
Col. 5.—0.1 ft change in stage.
Col. 6.—c_1 is computed by substituting values in Cols. 3, 4, and 5 in Eq. 1*a*.
Col. 7.—The reach length L in miles is the distance over which the computed velocity c_1 at each station is assumed to exist.
Col. 8.—The number of hours required for the wave to traverse this distance if traveling at a velocity c_1. The average velocity c_1, from Norris to Wheat, is then equal to 64.2 miles divided by the total number of hours required for the wave to traverse these four reaches.

The method of applying Eqs. 1 is illustrated in Tables 3 and 4, using data from Wave 1, October 6, 1937.

As the velocity c_1 in Eq. 1*a* at a given station is a function of the stage, curves for values of c_1 can be developed for each station as shown in Fig. 3. A curve for the average velocity c_1 for the Norris-to-Wheat reach can also be developed by determining stages at successive stations corresponding to a selected stage at Norris gage by mean gage-height relations and by computing the average velocity c_1. Such a curve indicates average values of c_1 plotted against Norris stages for the Norris-to-Wheat reach under average conditions of local inflow. It gives the same value of c_1 as computed in Table 3. This occurs only when average conditions of local inflow exist and the stages at all stations agree with the mean gage-height relation used for constructing this curve.

Col. 7.—Area A_1 corresponding to gage height Z_1.
Col. 8.—Q_2-Q_1 from Cols. 4 and 5.
Col. 9.—A_2-A_1 from Cols. 6 and 7.
Col. 10.—Wave velocity c_2 computed by substituting Cols. 8 and 9 in Eq. 1*b*.
Cols. 11 and 12.—c_2, L, and t (Cols. 10, 11, and 12) are determined in the same manner as corresponding values in Table 3.

For the purpose of comparison, a curve showing the water velocity in the Norris-to-Wheat reach is also shown in Fig. 3 (water velocity is the velocity indicated by a current meter). This curve is developed from the discharge rating and channel cross-section areas at each station for stages determined by gage-height relations, assuming that each station velocity exists halfway to adjacent stations. The water velocity is about half the wave velocity at ordinary stages and less than half at low stages.

In the computation of c_2 by Eq. 1*b*, in Table 4, an inconsistency in discharges Q_2 and Q_1 at successive stations will be noted. This can be caused by either an error in the station ratings, errors in observed stages, or irregularities in flow. It is believed that this inconsistency will not affect results materially as long as the area difference, $A_2 - A_1$, corresponds to the discharge difference, $Q_2 - Q_1$.

Theoretical velocities c_1 and c_2 for the beginning and midpoint of rising waves, and for the beginning and midpoint of falling waves shown in Fig. 2, together with the velocity c_o, corresponding to the observed time of travel from Norris to Wheat, are shown in Table 5.

Comparison of Observed and Computed Wave Velocities.—Fig. 4 shows velocities c_o, c_1, and c_2 plotted against the gage heights observed at Norris gage, with mean curves drawn for each. Mean curves of computed velocities for the midpoint-of-rise (Fig. 4(*b*)) and the midpoint-of-fall (Fig. 4(*d*)) agree very well with the mean curves for observed velocities. It will be noted that the range of gage heights covered by these data is small, and, the gage heights being midpoints, do not extend to either extremely low or high stages. Results for the beginning-of-rise (Fig. 4(*a*)) and the beginning-of-fall (Fig. 4(*c*)) do not agree nearly as well, computed velocities being smaller than the observed in both cases. In the latter plottings, velocities c_2 are computed from the total

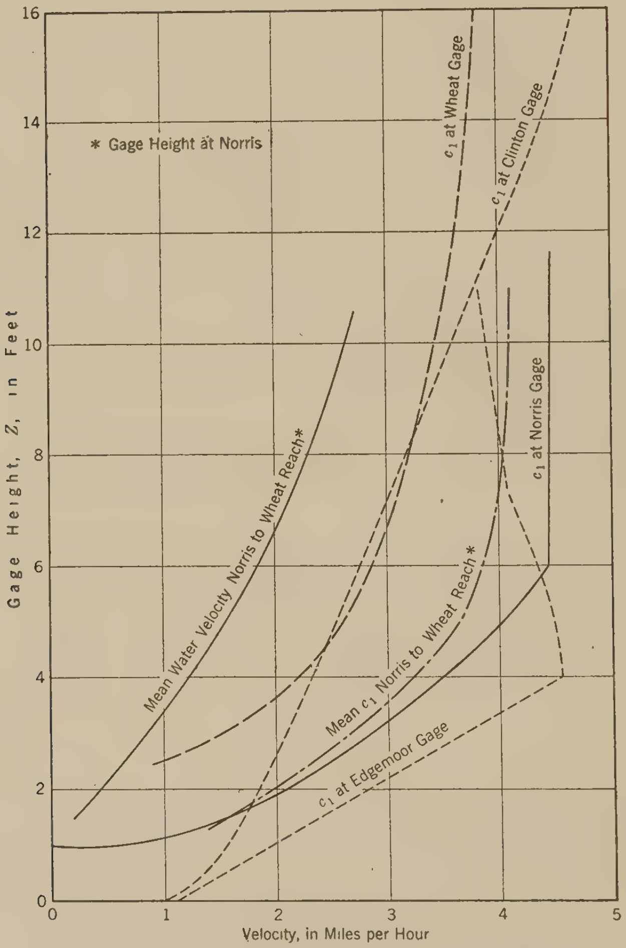

FIG. 3.—VELOCITY CURVES, NORRIS DAM TO WHEAT GAGE

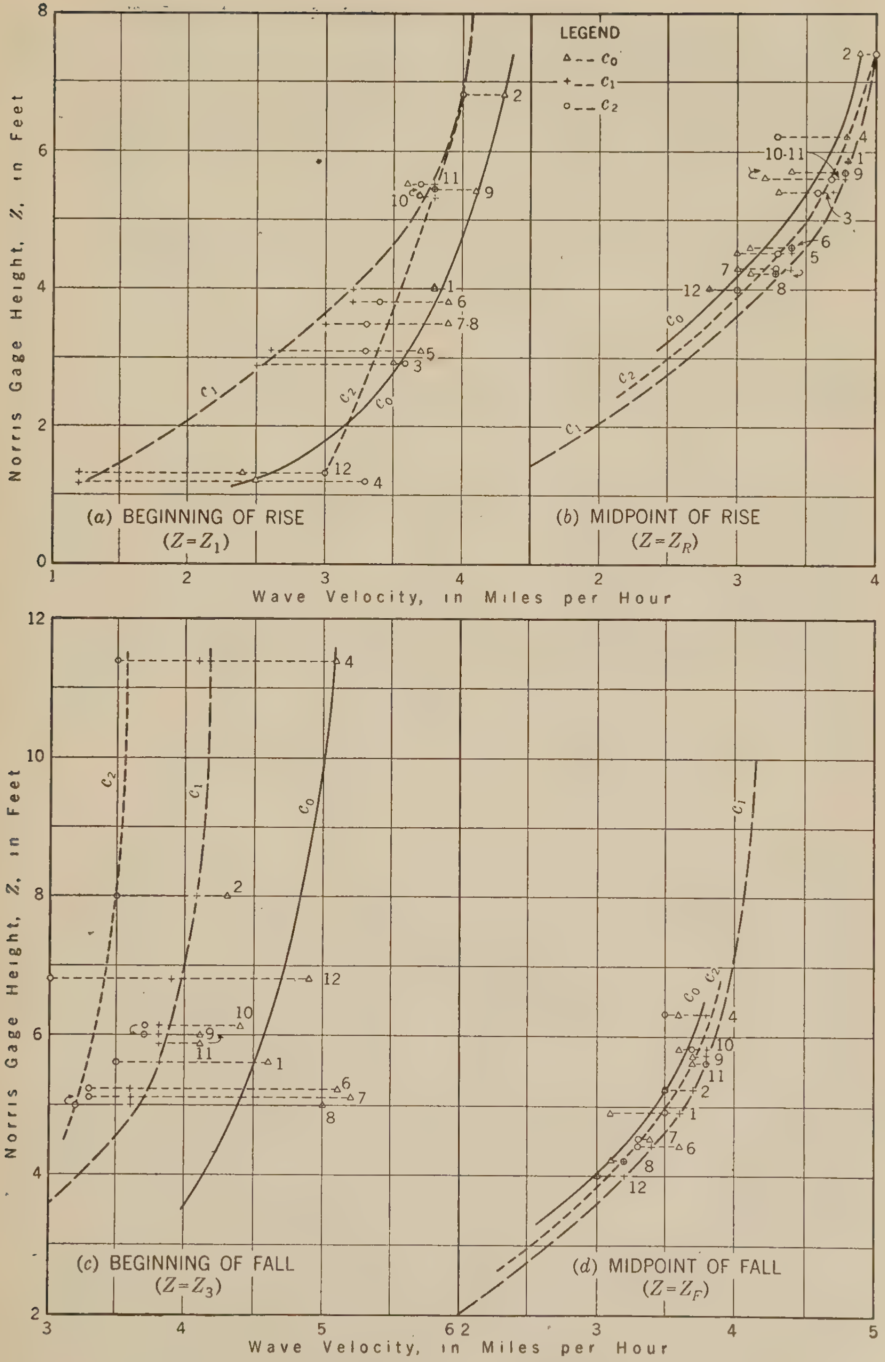

FIG. 4.—VELOCITY, CLINCH RIVER WAVES

rise or fall of the wave and are plotted against Z_1 or Z_2, respectively. Mean curves for observed velocities for both the beginning-of-rise and the beginning-of-fall are higher at a given stage than observed velocities for the midpoints.

Wave of February 7, 1938.—The wave of February 7, 1938 (Wave 4, Table 5), developed when the quantity released at Norris Dam was increased during a comparatively low and steady flow in the Clinch and upper Tennessee rivers.

[a] c_0 is the wave velocity corresponding to the observed time of travel.

The release was gradually increased from 30 cu ft per sec to 24,300 cu ft per sec in 33 hr, was held about steady for 14 hr, and then was gradually reduced to about the original release in 48 hr. Gage-height graphs of the resulting wave at Clinch River stations and at Chickamauga Dam site, near Chattanooga, Tenn., are shown in Fig. 2(*c*), together with the "soap hardness" of water samples from the Chattanooga City Pumping Plant intake. This intake is about six miles below Chickamauga Dam site and the water travels this distance in about 3 hr. Prior to the arrival of the wave from Norris Dam, soap-hardness tests at Chattanooga showed a fairly constant value of 60. However about 48 hr after the arrival of the wave the hardness increased to a value of 80 for a 2-day period. It has been found that the hardness of Norris Reservoir water is fairly constant at 95 ppm, whereas the hardness of Tennessee River water at Chattanooga averages about 65 ppm, Norris water being considerably harder than water from most of the tributaries above Chattanooga. There is a marked similarity between the pattern of the points for soap hardness and the shape of the Chickamauga Dam gage-height graph during the arrival of the wave from Norris Dam, the peak of hardness occurring about two days later than the peak flow. It is unfortunate that data are not available on the hardness of the water in the several tributaries coincident with the passage of the wave.

If the hardness peak indicates the arrival of actual water released from Norris Dam, it requires four days, corresponding to a velocity of about 2 miles per hr, for water to travel 183.3 miles from Norris Dam to Chattanooga, compared with 53 hr (3.5 miles per hr) for the wave. The flow in the river at Chattanooga before the arrival of the wave was 23,000 cu ft per sec. This would indicate that the actual water in the wave when it arrived at Chickamauga Dam site was in the river in front of the original wave developed at Norris Dam.

TRANSLATORY WAVES IN WHEELER RESERVOIR

Translatory waves in Wheeler Reservoir (Fig. 5) have quite different characteristics from those in tributary streams, such as the Clinch River. The channel has greater depth and width, together with a flatter water-surface slope. Even with abrupt changes of considerable magnitude in the rate of inflow, translatory waves are quickly smoothed out.

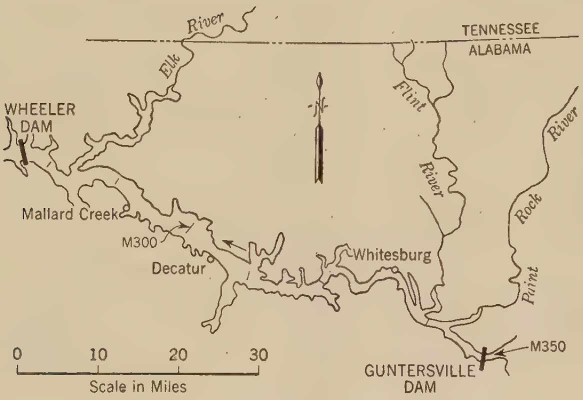

FIG. 5.—WHEELER RESERVOIR

Continuous stage recorders located in Alabama at Guntersville lower lock gage (mile 349.0), Whitesburg (mile 333.7), Decatur (mile 305.1), and Mallard Creek (mile 293.4), together with hourly observations at Wheeler Dam (mile 274.9), provide data from which elevation graphs in Figs. 6 and 7 were prepared. The accompanying hydrographs are prepared from computed discharges at Guntersville and Wheeler dams. The drainage area above Guntersville Dam is 24,450 sq miles with a mean annual discharge of 41,400 cu ft per sec, whereas the drainage area above Wheeler Dam is 29,590 sq miles with a mean annual discharge of 50,000 cu ft per sec.

Theoretical Formulas.—Changes in discharge at Guntersville Dam, which developed these waves, were made quickly enough to be considered as sudden for the purpose of analysis. H. W. King,[3] M. Am. Soc. C. E., has given a

---

[3] "Handbook of Hydraulics," by H. W. King, 3d Ed., 1939, pp. 420–421.

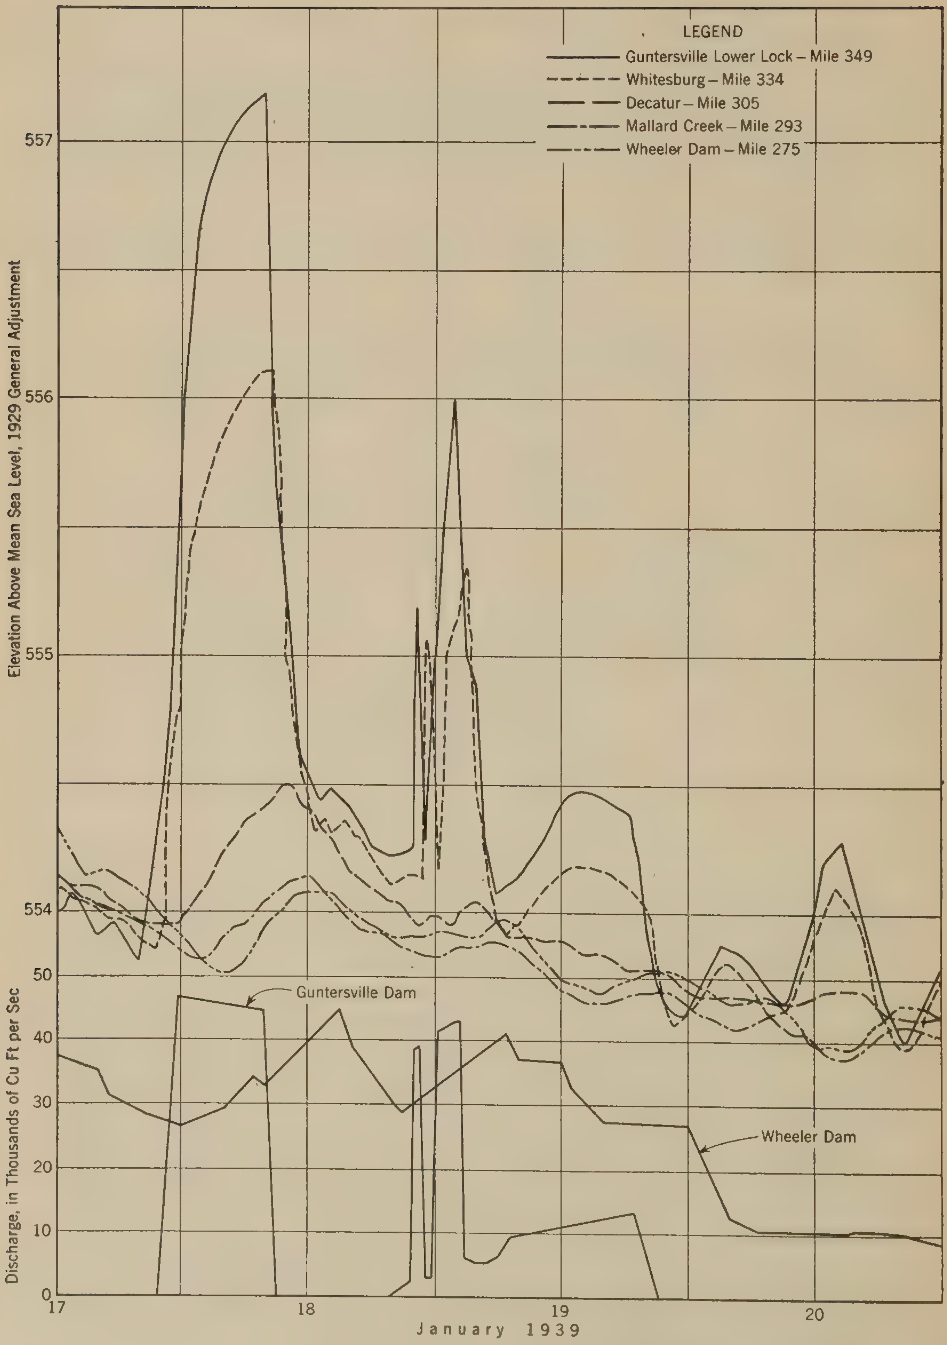

FIG. 6.—GAGE HEIGHTS AND DISCHARGE,

formula that is applicable for computing velocities of such waves:

$$c_3 = \left[V_1 + \sqrt{g \frac{A_2 \bar{y}_2 - A_1 \bar{y}_1}{A_1 \left(1 - \frac{A_1}{A_2}\right)}} \right] 0.682 \ldots\ldots\ldots\ldots (2a)$$

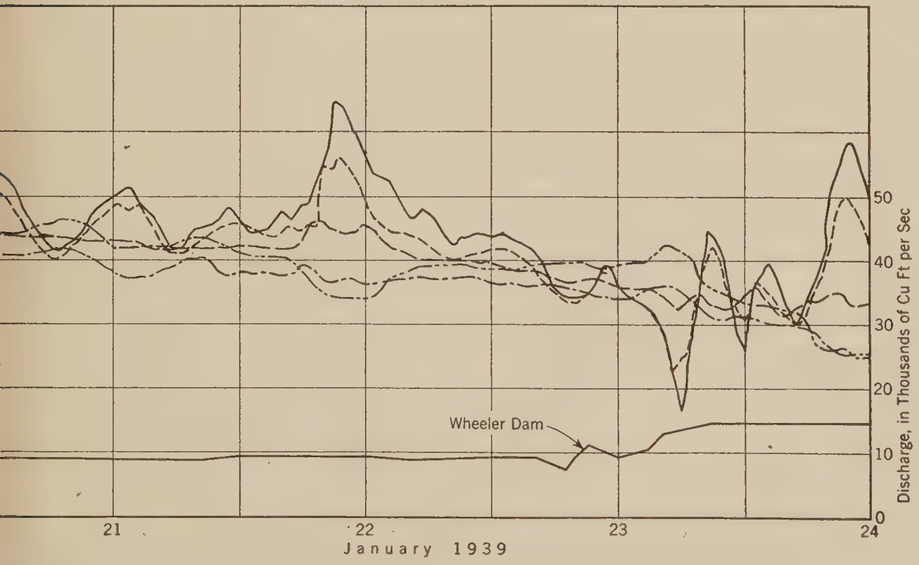
An approximation of this formula, based on the assumption that the difference between A_1 and A_2 is negligible, and also that the channel is of uniform cross section, is given by Professor King[3] as

$$c_4 = [V_1 + \sqrt{g\, y_m}]\, 0.682 \ldots\ldots\ldots\ldots\ldots\ldots (2b)$$

in which c_3 is the velocity of a wave created suddenly, the effect of the difference between A_1 and A_2 being taken into consideration; V_1 is initial water velocity; g is the acceleration of gravity; $\bar{y}_1$ and $\bar{y}_2$ are the depths to the center of pressure of A_1 and A_2, respectively; A_1 and A_2 are channel cross-section areas occupied by the wave at beginning and end, respectively; c_4 is the velocity of a wave created suddenly, the difference between A_1 and A_2 being considered negligible; and y_m is the mean depth of water. The constant 0.682 is inserted to convert to miles per hour.

The times of travel of observed translatory waves in reservoirs are determined from the beginning-of-rise in rising waves and the beginning-of-fall in falling waves. Observed velocities, c_o, and velocities c_3 and c_4, computed by Eqs. 2, are shown in Table 6 for each of four rising and four falling waves, for each of the four reaches between intermediate gages, and also for the overall reach between Guntersville and Wheeler dams.

Velocities of Translatory Waves in Wheeler Reservoir.—Velocities computed by Eqs. 2 (see Table 6) agree fairly well with the observed velocities in some



HEELER RESERVOIR WAVES IN JANUARY, 1939

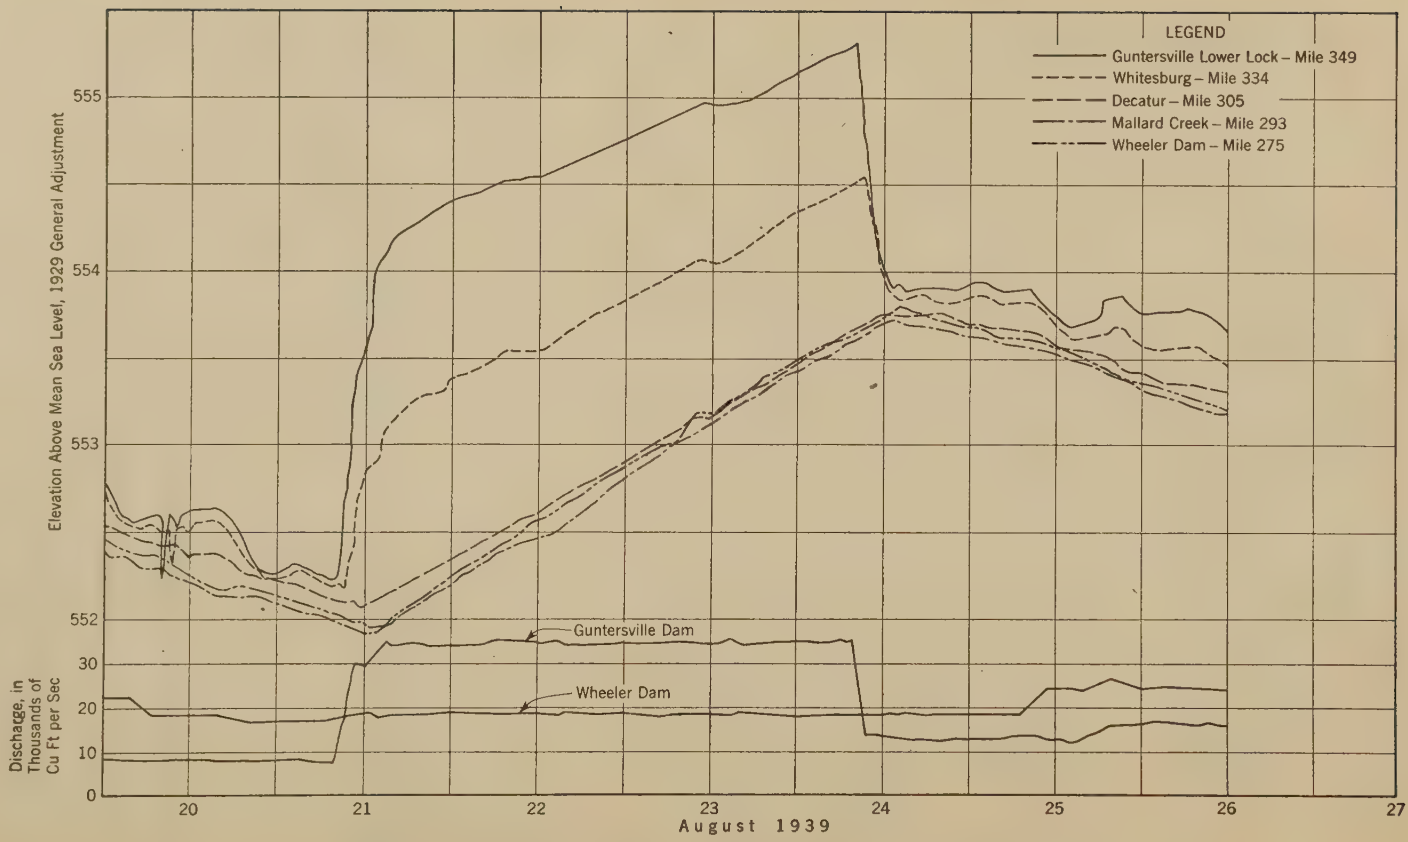


FIG. 7.—GAGE HEIGHTS AND DISCHARGE, WHEELER RESERVOIR WAVES IN AUGUST, 1939

cases and differ widely in others. For rising waves in the Guntersville Dam to Whitesburg reach, computed velocities by Eq. 2*a* and Eq. 2*b* both agree closely with the observed velocities except for the wave of January 17. Observed velocities for this wave are lower in all reaches than observed velocities for the other three waves. In this reach computed velocities c_3 and c_4 are practically the same for all waves.

Fig. 8.—Lower Tennessee River

For rising waves in the Whitesburg to Decatur reach, computed velocities c_4 are about the same as for the previous reach, whereas computed velocities c_3 are consistently lower. The average of velocities, c_3, is practically the same as the average of c_o. For rising waves in the Decatur to Mallard Creek reach, both computed velocities give about the same results, which are higher than observed velocities in all cases. The average of c_o is only a little more than half the observed velocity c_o for the previous reach. For rising waves in the Mallard Creek to Wheeler Dam reach, both computed velocities again give about the same results, but are about double the average of the observed velocities. In the over-all reach from Guntersville Dam to Wheeler Dam, rising wave computed velocities c_3 average slightly lower than computed velocities c_4, but are about one third larger than the observed velocity. Observed and computed velocities for falling waves are similar to those for rising waves.

Considerable difficulty is encountered in determining the effective average channel cross section for the application of Eqs. 2 in the Whitesburg-Decatur and the Decatur-Mallard Creek reaches. Channel cross sections

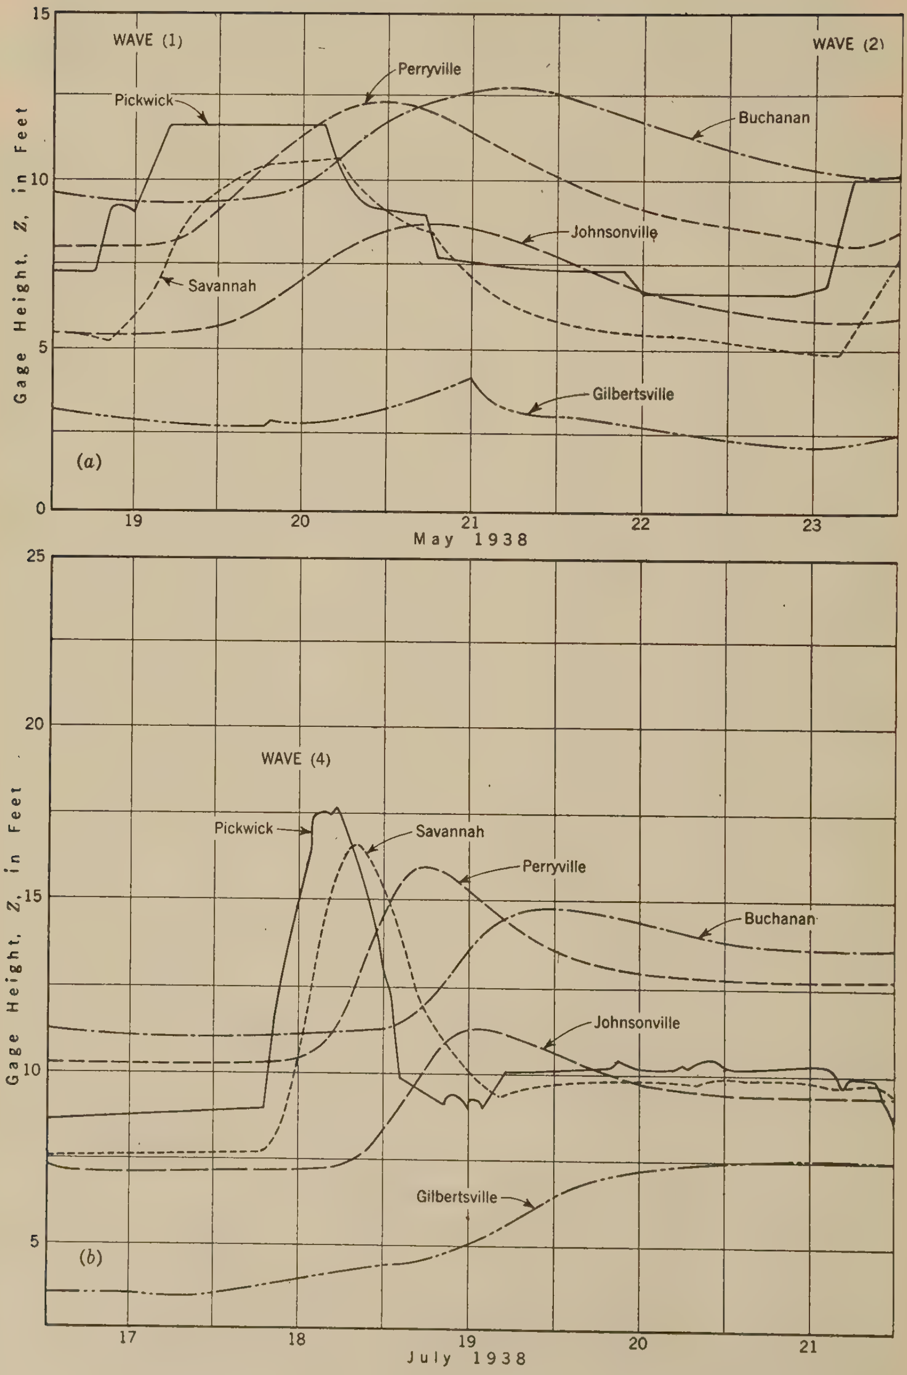

FIG. 9.—GAGE HEIGHTS,

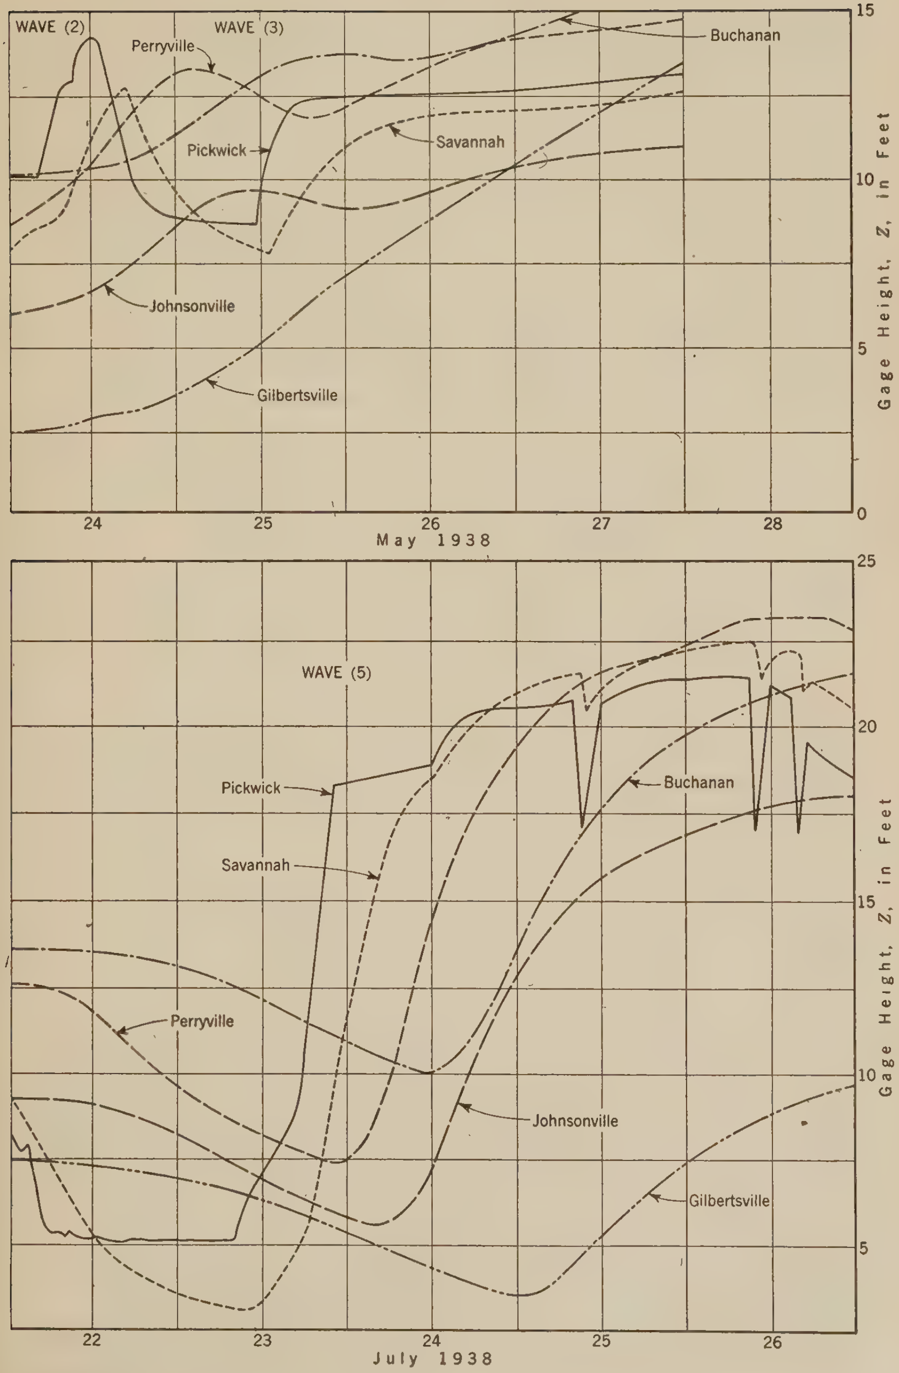

Tennessee River Waves

taken at about one-mile intervals are available throughout the length of Wheeler Reservoir. Upstream from Whitesburg the reservoir is largely within the old river channel and has fairly regular cross sections, while downstream from Mallard Creek the reservoir covers the entire river bottom. Between these two gages there is a gradual transition from river channel to river bottom sections. This may account in part for the wide discrepancy between observed and computed velocities in these two intermediate reaches, but would not account for the even wider discrepancy in the results for Mallard Creek to Wheeler Dam reach. It is probable that when the reservoir widens, the lateral spread of the wave reduces its downstream velocity. Another probable source of error is the inability to determine discharges at intermediate stations. Discharges at Guntersville and Wheeler dams are determined from gate settings and should be reasonably accurate. Discharges at intermediate stations are estimated from these discharges taking into account local inflow from tributaries.

In general, observed velocities in the reaches upstream from Decatur where the pool is largely within the original river channel are materially higher than in the reaches below Decatur where the pool submerges the original river banks. Two bridge embankments at Decatur restrict the flow to the original channel at these points. When a wave reaches the upstream embankment a portion of it rebounds to form an upstream wave that reduces the magnitude of the wave at downstream points.

Observed velocities determined from beginning-of-rise and beginning-of-fall points do not differ materially in a given reach, both being about 17 miles per hr upstream from Decatur and about 12 miles per hr downstream.

Surges in Wheeler Reservoir.—It will be noted in Fig. 6 that, when the release at Guntersville Dam was reduced suddenly and then held steady for a time, a series of surges occurred at fairly regular intervals of about 11 hr. This interval is about the time required for a wave to travel from Guntersville Dam to Wheeler Dam and return. Usually the peaks at Guntersville Dam coincide with valleys at Wheeler Dam. These surges have a much smaller magnitude at Decatur than at stations upstream or downstream. Water-surface profiles of the reservoir plotted for elevations observed at successive hours show that the reservoir water surface appears to pivot on Decatur. The water surface falls at upstream stations when it is rising at downstream stations.

TRANSLATORY WAVES ON THE TENNESSEE RIVER BELOW PICKWICK LANDING DAM

Translatory waves on the Tennessee River below Pickwick Landing Dam (see Fig. 8) are typical of waves developed by regulated releases in a natural river channel having a considerable discharge capacity and a comparatively flat slope. The mean annual discharge of this section of the river is about 60,000 cu ft per sec, and the fall is 65 ft in 207 miles, 0.3 ft per mile.

Waves for which gage-height graphs are shown in Fig. 9 are selected to cover a considerable range of flow conditions and have discontinuities that can be identified at successive downstream stations. Pertinent data on lower Tennessee River gaging stations are given in Table 7. Gage-height graphs are shown for Pickwick lower lock (Tenn.), Savannah (Tenn.), Perryville (Tenn.), Johnsonville (Tenn.), Buchanan (Tenn.), and Gilbertsville (Ky.) gages whenever the records for these stations are available for the wave selected. Stages at Gilbertsville are affected by Ohio River stages at all times, and high stages on the Ohio River affect stages as far upstream as Johnsonville.

Wave Velocities.—Wave velocities for the reach from Savannah to Buchanan are computed by the same formulas as are used for the Clinch River waves. These results, together with observed velocities determined from the beginning-of-rise, midpoint-of-rise, and beginning-of-fall points, are listed in Table 8.

TABLE 7.—LOWER TENNESSEE RIVER STATIONS

Station (see Fig. 8)	River mile	Elevation[a]	Drainage area (sq miles)
Pickwick lower lock	206.4	350.0	32,820
Savannah	189.9	341.61	33,140
Perryville	134.9	325.27	34,500
Johnsonville (near)	100.5	319.61	38,520
Buchanan	66.2	303.0	39,720
Gilbertsville	21.7	299.56	40,200
Ohio River	0	....	40,910

[a] Elevation of gage zero above Mean Gulf Level.

Discharge ratings, area, and channel width curves for each station are given in Table 9. The Pickwick lower lock to Savannah reach was excluded from the velocity comparison because the channel and discharge character at neither of these stations are representative of the intervening reach, and the Buchanan to Gilbertsville reach was excluded because points on very few waves can be identified satisfactorily at Gilbertsville due to the effect of the Ohio River. The method of applying formulas for wave velocities is similar to that previously described for waves on the Clinch River.

Computed wave velocities c_1 and c_2 for the beginning-of-rise point are generally lower than the observed velocity c_0. On the average c_0 is about 1.5 times c_1 and 1.4 times c_2. However, the variation is too large to be considered as a consistent relation. For the midpoint-of-rise, computed velocities in general agree much better with the observed. There is also better agreement between c_1 and c_2 than in computed velocities for the beginning-of-rise points. For beginning-of-fall points, the agreement between computed and observed velocities is about the same as for the midpoint-of-rise.

A study of velocities of midpoint-of-fall shows no agreement between observed and computed velocities, the computed velocities being much higher than the observed. When a falling wave travels down the lower Tennessee River, its shape is gradually modified until it finally becomes a recession that follows the characteristic curve of water draining out of the channel.

Factors Affecting Results.—During periods of rapidly changing stage, such as exist during the passage of a wave, the slope of the water surface and the discharge differ considerably from the steady flow conditions. Due to the flat slopes that normally exist on the lower Tennessee River, these variations have a relatively greater effect on the discharge than on the Clinch River which has a steeper slope. This factor accounts in part for results being less satisfactory for the lower Tennessee River than for the Clinch River, and would be most pronounced on the beginning-of-rise where the poorest agreement was found.

Rising waves on the lower Tennessee River have a tendency to flatten and lengthen at successive downstream stations in contrast to the tendency of Clinch River rising waves to maintain their height and to shorten. Falling waves in both rivers have a tendency to recede on a characteristic pattern which depends on the volume of the river channel.

The wide variation and lack of consistency in observed velocities are due partly to inability to identify selected points on the wave with any degree of certainty, particularly at the two downstream stations. The midpoint-of-rise can be determined with the most certainty when the wave consists of one continuous rise; but unfortunately this occurs in very few waves.

CHARACTERISTICS OF TRANSLATORY WAVES

When a rising wave is developed by a fairly uniform increase in discharge, as is the case in most of the Clinch River waves, the rising face of the wave tends to retain the initial rate of increase in discharge at successive downstream stations. When the wave develops on an empty channel, as in Fig. 2(*c*), the beginning-of-rise continues to be abrupt at successive stations; but when the wave develops on a considerable initial flow, as in Fig. 2(*a*), a fillet develops at the beginning-of-rise which enlarges as the wave travels downstream.

A similar fillet occurs as the wave approaches fully developed rise. As the wave progresses downstream these two fillets continue to enlarge until the upper limb of the beginning-of-rise fillet meets the downward limb of the end-of-rise fillet. Although these fillets are enlarging, the duration of rise at the initial rate becomes shorter and finally disappears. On the Clinch River (see Fig. 1) this seems to occur at some point above Wheat, 65 miles below Norris, and on the lower Tennessee (see Fig. 8) at a point above Perryville, 71 miles below Pickwick.

In the case of a falling wave, a characteristic recession tends to develop regardless of the initial rate of reduction in discharge. This recession is retained at successive stations on the Clinch River until fillets at the beginning-of-fall and the end-of-fall enlarge to cover the entire falling face of the wave. This again appears to occur by the time that waves reach Wheat or Perryville.

When the period of maximum discharge at the crest of a wave continues for only a short period, as in Fig. 2(*c*), the spreading fillets at the end-of-rise and at the beginning-of-fall gradually shorten this period as the wave progresses downstream. Eventually the two fillets will overlap and the discharge will begin to fall off before the full rise has been developed. When this occurs flattening of the wave begins and the magnitude of rise becomes progressively smaller. A valley between two rises is affected in a similar manner, resulting in a gradual reduction in the depth of the valley as is shown in Figs. 2(*e*) and 2(*f*).

CONCLUSIONS

1. Velocities of translatory waves, both rising and falling, can be approximated with either Eq. 1*a* or Eq. 1*b* in natural channels such as the Clinch and

lower Tennessee rivers when rated stations at representative sections are located at suitable intervals throughout the reach.

2. Midpoints of rise or fall are best suited for determining the velocity of an observed wave.

3. Eqs. 2*a* and 2*b* give similar results for velocities of translatory waves in Wheeler Reservoir, but these results are consistently higher than observed velocities.

DISCUSSION

HAROLD A. WEGGEL,[4] JUN. AM. SOC. C. E.—A noteworthy detailed study of translatory waves is presented in this paper; yet in a positive sense the conclusions enumerated do not seem to compensate for the effort expended. It would be desirable to go one step further than simply to prove or disprove the validity of the use of certain theoretical formulas. Some of the conclusions have been known since 1842–1843 when John Scott Russell presented the "Report on Waves"[5] to the British Association for the Advancement of Science; and later experimenters have observed the remaining conclusions. However, very few observers have been able to apply corrections for change in slope of water surface, friction, and channel storage. The data in the paper seem to indicate that the channel characteristics could be determined for the particular waves studied so that corrections could be applied to the theoretical formulas.

The velocity of the wave is affected by the slope of the original water surface, being greater for steep channels and less for channels of flat slope. In the limiting condition of steep slope, the velocity of a small wave is twice the mean velocity of the channel, and, in the other extreme of a flat slope, the velocity of the wave is equal to the surface velocity of the channel.[6,7]

Theoretically, the wave velocity in quiet water is $\sqrt{g\,y_m}$ but experiments by A. Zeitlinger[8] at the Hydraulic Laboratory in Graz, Austria, showed that, in shallow water, friction caused a decrease in the velocity of the wave to

$$c = 0.91 \sqrt{g\,y_m} \qquad (3)$$

Perhaps a correction factor similar to Eq. 3 would make the results of Eq. 2*b* comparable with, instead of consistently higher than, observed velocities.

In a similar manner, Eq. 1*b* should be changed to

$$c_2 = V_1 + \frac{(V_2 - V_1)\,A_2}{A_2 - A_1} \qquad (4)$$

Eq. 4 separates the superimposed wave from the initial velocity V_1 so that a correction factor for wave friction may be applied. It is apparent from Figs. 4(*b*) and 4(*d*) that this friction factor must be relatively constant over a wide range for the midpoint-of-rise and for the midpoint-of-fall. In the solitary wave of translation these points are the only parts of the wave that really travel as a wave front or movement of constant flow or wave height.

In the case of translatory waves on rivers of flat slope, such as the lower section of the Tennessee River, it is realized that some of the difficulties of the problem are practically insurmountable due to channel storage. Nevertheless, it may be possible to obtain some empirical coefficient which would give closer agreement between formulas and observed data on translatory waves.

Perhaps a study of the reflected waves in the Decatur section (see Fig. 5) may be helpful in an approximate determination of a factor to be applied to the velocity of the channel, since a difference of 5 miles per hr was noted for the wave travel (see heading, "Translatory Waves in Wheeler Reservoir: Velocities of Translatory Waves in Wheeler Reservoir"). The time of surges in Wheeler Reservoir, about 11 hr over a distance of 2 × 74 miles, or 148 miles, gives 13.5 miles per hr, or the average velocity downstream only. Do the surges travel upstream at the same rate or at some rate differing by a factor of channel velocity, such as that indicated by the equation:[9,10]

$$c = K \sqrt{g\, y_m} \pm \left(\tfrac{1}{4}\, V_1 + \tfrac{3}{4}\, V_2\right) \qquad (5)$$

A solution of these perplexing problems would do much to enhance the knowledge of the variations in velocities of translatory waves.

W. M. LANSFORD,[11] M. AM. SOC. C. E.—The problem of translatory waves is of much importance to hydraulic engineers, and the author has presented interesting and valuable data on the subject.

A few years ago the writer conducted some experiments on translatory waves in a rectangular channel in the Hydraulics Laboratory at the University of Illinois at Urbana. The channel used was made of concrete 5 ft wide and 4.5 ft deep and had a straight horizontal length between head gate and tail gate of 147 ft. The tail gate was used to control the depth and the head gate was used to help control the discharge. A vertical steel plate ½ in. thick which fitted into grooves cut in the sides of the channel was dropped across the channel to stop the flow, thereby causing a wave to travel upstream. This gate was placed 7 ft upstream from the tail gate.

The velocity of the wave was measured over a 114.6-ft length of the channel by means of floats connected by electric contacts to a pen which recorded on a revolving drum. The water used was taken from a standpipe from which approximately 6,500 gal per min could be supplied at a constant head of about 65 ft.

The observed wave velocities were compared with the theoretical values as computed from the formula proposed by Professor King[12,13] for abrupt waves in

[a] Exceptions: Test No. 14, $\bar{y}_1$ = 1.52; Test No. 15, $\bar{y}_1$ = 1.52; and Test No. 16, $\bar{y}_1$ = 1.51.

in which c_w is the velocity of the wave, in feet per second; V_1 is the initial velocity of the water, in feet per second; and $\bar{y}_1$ and $\bar{y}_2$ are the depths in feet before and after the wave, respectively. The results of these tests are given in Table 10.

The results given in Table 10*A* are for tests in which the discharge was maintained at a constant value. In Table 10*B* the initial velocity was kept constant, and in Table 10*C* the depth $\bar{y}_1$ was kept constant. In all the tests the percentage difference between observed and computed values of the wave velocities is small except in extreme cases of very low or very high values. The effect of the depth $\bar{y}_1$ seems more pronounced than it should because of the limited range over which these tests were made.

Although the data presented by the author in Table 9 show a rather wide variation between observed values of wave velocity and values computed by use of Eq. 2*a*, the data in Table 10 seem to indicate a fairly good agreement between these values. As mentioned by the author, the widening of the stream very likely accounts for some of the discrepancies. Within the limits of the tests herein presented Eq. 6 seems to yield reliable results.

M. A. CHURCHILL,[14] ASSOC. M. AM. SOC. C. E.—The Society is indebted to the author for the presentation and interpretation of a wealth of observed, not theoretical, data on translatory waves in natural channels. In an attempt to make the paper of still greater value, the writer presents herewith some supporting data on observed waves in natural channels and in reservoirs, together with corresponding data on observed rates of water travel.

[14] Hydr. Engr., TVA, Knoxville, Tenn.

Wave Travel in Lower Holston River.—In connection with a determination of the time required for water to travel 46.6 miles from Cherokee Dam on the Holston River to a point near the head of Fort Loudoun Reservoir above Knoxville, Tenn., the velocity of a negative wave of translation was also observed. The negative wave was produced by reduction for a period of 24 hr in the discharge of Cherokee Dam on November 7, 1943, from 7,530 cu ft per sec to 3,840 cu ft per sec, and then an abrupt increase to 7,740 cu ft per sec. This negative wave was observed at four stations on the Holston River below Cherokee Dam as shown by Fig. 10(*a*) (stages) and Fig. 10(*b*) (discharges). Stages were observed at all four stations, but discharges are known only at the station immediately below Cherokee Dam and at Straw Plains. (Stages below Cherokee Dam and at Straw Plains are from continuous recorder charts. Stages at Nances Ferry and at Highway 70 Bridge are from staff gage readings at intervals of 2 hr or less.) Discharges at Nances Ferry and at Highway 70 Bridge were approximated. Table 11 gives pertinent data on this negative wave. The theoretical rates of travel (footnotes (^{c}) and (^{d}), Table 11) were computed by Eq. 1*b*, based on discharges and areas at the two gaging stations in the reach. It is recognized that the relatively good agreement between observed and computed wave velocities, when the computed velocities are based on only two, relatively short, rated river reaches, is "more luck than sense." The

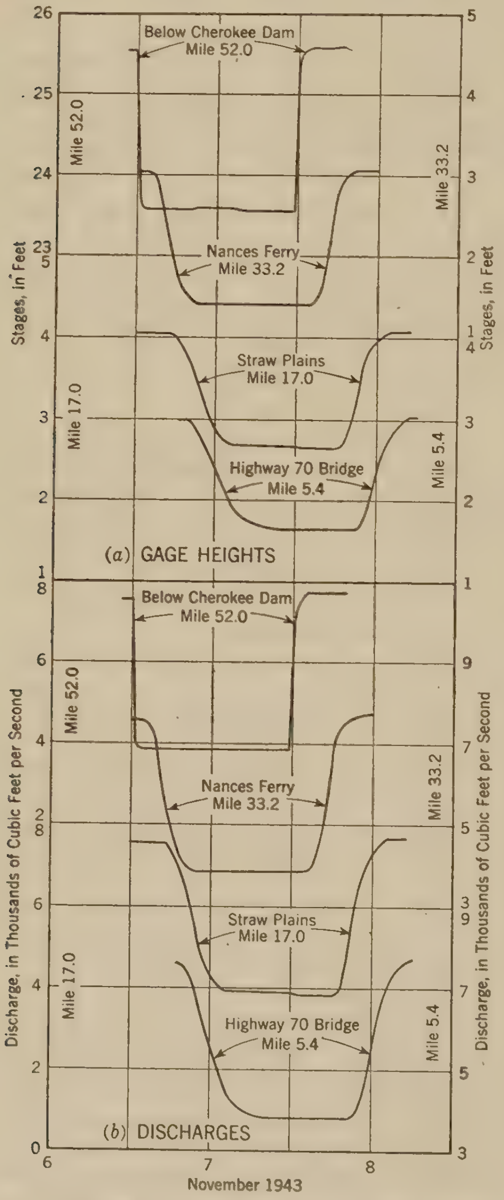

FIG. 10.—STATION OBSERVATIONS ON THE LOWER HOLSTON RIVER, TENNESSEE, NOVEMBER 7 AND 8, 1943

author necessarily based his comparisons of observed and computed rates on similar data and so it is rather remarkable that his results on Clinch River show such good agreement with the theory.

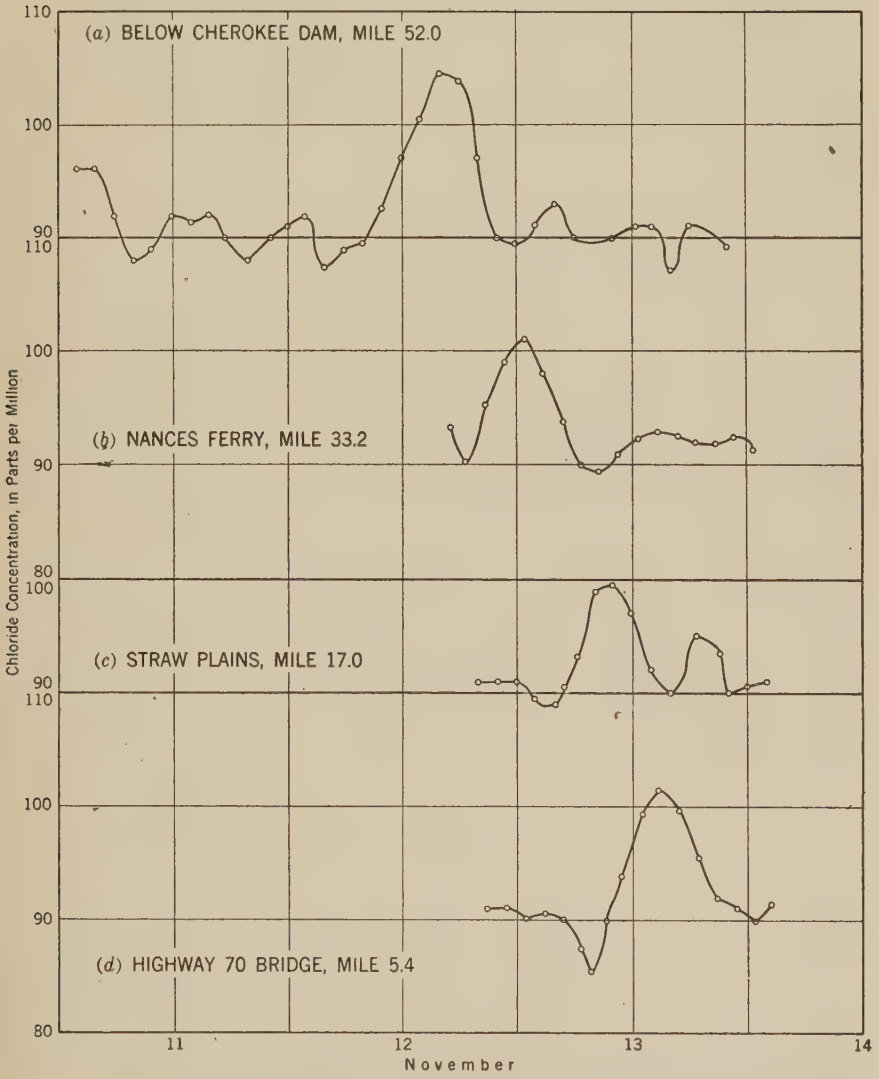

Fig. 11.—Chloride Concentrations at Observation Stations on the Lower Holston River, November 12 and 13, 1943

Water Travel in Lower Holston River.—The rate of water travel, as distinguished from wave travel, through the same reach of river was observed between November 12 and 14, 1943, during which time the release from

Cherokee Dam was nearly the same as both before and after the negative wave generated on November 7, 1943. (The release from Cherokee Dam on November 12 increased gradually from 7,770 cu ft per sec at 1:00 a.m. to 8,070 cu ft per sec at midnight.) To determine the rate of water travel, samples were collected at 2-hr intervals from the same four points at which the wave was observed. These samples were analyzed chemically for chloride concentration, with results as shown in Fig. 11. The presence in the river of an industrial waste of varying chloride concentration made possible the use of the chloride concentrations for identifying a particular mass of water at the successive downstream stations. Table 11(*c*) gives pertinent data on the rate of water travel.

Ratio of Wave Velocity to Water Velocity, Lower Holston River.—A comparison of the rate of wave travel with the rate of water travel in the lower Holston River indicates that the rate of wave travel is slightly more than twice the rate of water travel, for the particular rates of discharge observed. This ratio tends to support the author's contention (see heading, "Translatory Waves on the Clinch River: Velocity of a Translatory Wave") that "The water velocity is about half the wave velocity at ordinary stages * * *." In fact, the data presented in this discussion on the relation of wave to water velocities are probably better proof of this statement (as it applies to the general case) than the data presented by the author, since the author used water velocities at only four points in the 64.2-mile reach of the Clinch River between the Norris and Wheat gages.

Wave and Water Travel, Watauga and South Holston Rivers.—Observations have been made of the time required for water and for waves of translation to travel through a reach of 40 miles on the Watauga and South Holston rivers. The waves were produced by variations in release from a power dam at the head of the reach. Discharges varied from 200 to 1,300 cu ft per sec. The average time for a series of waves was determined to be 16 hr. Water travel over the same reach required 91 hr.

Comparison of wave-travel and water-travel rates shows that, for the particular rates of discharge existing, the waves traveled 5.7 times as fast as the water.

This ratio of wave to water velocity is rather high for a natural river channel, particularly considering the rather wide range of flow between crests and troughs of the various waves. As the author states, however, the ratio will be higher for low discharges, and during these observations the average rate of flow was about one third of the mean annual rate. The existence of a relatively large number of long, deep pools in the lower Watauga and South Fork Holston rivers could explain the high ratio. In any case, the wide difference in the relation of wave to water velocities found here, as compared with the relation found on the lower Holston River, indicates the possibilities of error in trying to use wave velocities as a basis for computing water velocities without rather complete data on physical conditions of the reaches involved.

Wave and Water Travel, Fort Loudoun Reservoir.—Observations of wave travel through Fort Loudoun Reservoir (42.8 miles) showed an over-all wave velocity of 21.4 miles per hr. The theoretical rate of wave travel was computed by Eq. 2*b*. The mean depth of the reservoir was found to vary essentially as a straight line from 14 ft at the upper gage to 48 ft at the dam, when the pool elevation is 811.5. The wave velocity, except for the influence of the water velocity, can be expressed as $\sqrt{g\,y_m} = \frac{dL}{dt}$; or:

$$dt = \frac{dL}{\sqrt{g\,y_m}} \qquad \text{(7)}$$

Therefore,

$$t = \int_0^L \frac{dL}{\sqrt{g\,y_m}} = 0.176 \int_0^{226{,}000} \frac{dL}{\sqrt{14 + 0.0001504\,L}} \qquad \text{(8)}$$

and $t = 0.176 \left(\frac{2\sqrt{14 + 0.0001504\,L}}{0.0001504} \right)_0^{226{,}000} = 7{,}460 \text{ sec} = 2.08 \text{ hr.}$

A total time of 2.08 hr represents an average velocity through the 42.8-mile (L = 226,000 ft) reach of reservoir of 20.6 miles per hr. Due to thermal stratification and a density underflow, water velocities on the surface existed only in the upper end of the reservoir. Therefore, V_1 in Eq. 2*b* was essentially zero. The theoretical wave velocity is thus computed to be 20.6 miles per hr as compared with the observed velocity of 21.4 miles per hr.

Measurements of actual water travel by chemical identification methods indicate that a period of 190 hr is required through the 42.8 miles of reservoir. This rate of travel is 0.22 mile per hr. Had the moving water occupied the full depth of the reservoir throughout the entire length of the pool, the water velocity would have been even slower than the observed value.

The wave velocity was 95 times as fast as the water velocity, over-all. This ratio explains why the author's conclusion is true that the water velocity has little influence on the wave velocity in a reservoir.

Basic Concepts of the Relation of Wave to Water Velocity.—In an attempt to get a clear understanding of exactly how a translatory wave could run ahead of the water which originally formed it, the writer formulated the following relations several years ago:

Assume a smooth, straight natural channel in which the flow is gradually increased from a steady flow of Q_1 to a higher flow Q_2. Under such conditions, a profile of the channel and water surface would appear as shown in Fig. 12. Since the hydraulic radius is greater for the higher flow Q_2, the velocity V_2 is greater than V_1, assuming that Q_2 is less than bankfull discharge. Since this is the case, water moving at mean velocity V_2 tends to overtake water moving at mean velocity V_1. This action produces a result similar to an express train crashing into the rear end of a slow freight. In that case the rear cars of the

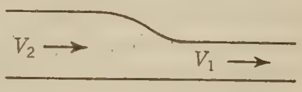

FIG. 12.—TRANSLATORY WAVE IN A CHANNEL OF UNIFORM WIDTH

freight are telescoped by the express. In the river, the slower moving water is "telescoped" by that moving at velocity V_2. The quantity of water per second so "telescoped" is expressed mathematically by $(V_2 - V_1) A_1$, in which A_1 is the cross-sectional area corresponding to V_1. This quantity of water is actually squeezed out of its original position in the river channel and is forced into that portion of the channel represented by $A_2 - A_1$. This quantity of water is thereby added each second in front of that advancing at the velocity V_2. Therefore, the rate of advance of the wave front is $\frac{(V_2 - V_1) A_1}{A_2 - A_1}$, relative to V_2. The actual rate of advance of the face of the wave is $V_2 + \frac{(V_2 - V_1) A_1}{A_2 - A_1}$. From this expression it is obvious that the wave velocity is always greater than the water velocity, provided the channel has an initial flow in it, since the second term is always positive. By simple algebra, this expression for the wave velocity can be shown to be equal to the familiar expression, Eq. 1*b*, except for the constant used to convert feet per second to miles per hour.

Wave-Height Reduction.—The author explains what happens to a translatory wave produced by a release of short duration, when its height is reduced (heading, "Characteristics of Translatory Waves"), without explaining the reasons for these happenings. The author states that "* * * the spreading fillets at the end-of-rise and at the beginning-of-fall gradually shorten this [crest] period as the wave progresses downstream." It seems to the writer that, in addition to any so-called "channel-storage" effects, the basic reasons why the crest of a wave of short duration is gradually lowered are as follows: As the wave moves downstream, it pushes the water already in the channel ahead of it, as explained previously herein, and forces this water into that area of the channel represented by $A_2 - A_1$. However, this pushed water is not spread uniformly over the area $A_2 - A_1$, but rather it tends to resist movement and stay near the lower edge of this area, where the channel width is the narrowest. This nonuniformity tends to push the beginning-of-rise point out farther and farther ahead of the crest of the rising wave. As the nose runs farther ahead, the rising face of the wave is thereby flattened; only a little water is added to the rising face of the wave, at and near the crest.

Although little water is added on to the forward end of the crest, a considerable quantity is removed from the rear. Since water at the crest stage moves at a velocity higher than that at the lower stage to the rear, a quantity of water equal to $(V_2 - V_3) A_3$ is removed from the rear face of the wave each second. This constant drain on the rear face of the wave eats it away and thus shortens the crest length until finally the original crest is all gone. Then the remaining crest is still further flattened until finally no wave exists.

An additional reducing influence is the fact that, due to the increased slope of the rising face, the water composing it tends to run faster than the falling face where the slope is flatter. Thus the wave tends to stretch out in length at the base, and consequently is lowered at the crest.

J. H. Wilkinson,[15] M. Am. Soc. C. E.—The comments and suggestions presented in the discussion of this paper are appreciated greatly. Mr. Weggel suggests that a correction factor provides a method for increasing the agreement between observed and computed velocities. This should be useful for predicting wave travel from data available on a given stream.

The writer is not entirely certain that, referring to the midpoint-of-rise and the midpoint-of-fall,

> "In the solitary wave of translation these points are the only parts of the wave that really travel as a wave front or movement of constant flow or wave height."

In connection with Wave 3, Fig. 2(*b*), if the increase in release at Norris Dam had stopped at 10:00 a.m., on December 12, a wave with $Z_2 = 6.0$ ft would have developed at the Norris gage. This phenomenon occurred in the case of Wave 5. Below the 6.0-ft stage, Wave 3 is practically identical to Wave 5. The portion of Wave 3 below the 6.0-ft stage travels as a wave front as much as does the portion of Wave 3 below the 8.0-ft stage. In a natural channel, the height of a wave varies with the characteristics of the river channel. Wave 3 rose 5 ft at the Norris gage, 5 ft at the Edgemoor gage, and 9 ft at the Wheat gage. At each station, the depth increased to that necessary to discharge the increased flow. Wave heights are constant only in a uniform channel.

When the midpoint-of-rise is used to determine the velocity of a wave in a natural channel, it is assumed that this is an identical point on the wave as it passes successive stations—that half the rise represents the same increase in discharge at successive stations. This is seldom exactly true.

Professor Lansford presents experimental results which are in excellent agreement with computed velocities by Eq. 6 for the entire range of depths and flows. These experiments eliminate the uncertainties of variable channel areas and slopes and of local inflow. The results show that the approximate Eq. 2*b* cannot be depended upon for accurate results.

Mr. Churchill presents some interesting data on wave and water velocities for the lower Holston River. The high chloride concentration provides an excellent means of identifying the wave at successive stations and gives much more dependable results for water velocity than does the process of estimating the wave from measurements at four gaging stations as was the case on the Clinch River. Fig. 10 presents observed stages and discharges throughout both the falling and rising waves. The stage-discharge relation which exists at a gaging station under normal flow does not hold during periods of rapidly changing stage such as exist during the passage of a wave. Discharges can be approximated by the Jones formula,[16] but it seems impracticable to attempt to determine discharge throughout a wave.

[16] "A Method of Correcting River Discharge for a Changing Stage," by B. E. Jones, *Water-Supply Paper No. 375–E*, U. S. Geological Survey, 1915, pp. 117–130.

The 5.7 ratio of wave to water velocity for the Watauga and South Holston rivers with a flow one third of the mean annual flow is slightly higher than that for the Clinch River, where the computed ratio for a corresponding flow is 3.8. Probably, the water velocity at gaging stations is somewhat higher than average for this flow.

Conversion of the wave velocity equation into the form of Eq. 7 simplifies the computation. The writer was fortunate in selecting a reservoir having a uniform variation in mean depth and results indicate that he was able to estimate, accurately, the effective mean depth of the reservoir.

CONSTRUCTION OF THE FLOW NET FOR HYDRAULIC DESIGN

BY H. ALDEN FOSTER,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. J. W. HOWE, CLARENCE S. JARVIS, AND H. ALDEN FOSTER.

SYNOPSIS

The general principle of the flow net has been known for many years, and its application to problems in hydraulics, electricity, and heat transmission has been described in various publications. The construction of a flow net by customary methods, however, is very tedious and the results are frequently far from precise.

In this paper, certain graphical and analytical methods are presented by means of which the construction of the hydraulic flow net in any particular case can be facilitated greatly, and much greater precision can be attained in the determination of velocities and pressures. The methods are applied both to conditions of fixed boundaries and to cases in which one of the boundaries is exposed to the atmosphere. Their application to certain cases of three-dimensional flow is also explained, together with a specific example.

INTRODUCTION

The usefulness of the flow net in hydraulic design has long been recognized, and graphical methods for constructing such a net have been described (1).[2] The flow net is of particular importance in any design problem involving the determination of pressures occurring under curvilinear flow. Under such conditions, the pressure variation does not follow the hydrostatic law (that pressure increases directly in proportion to depth of water), since the velocity is not uniform across the section. To compute the pressure by Bernoulli's formula, the velocity at any point must be known, and in many problems the only way in which the velocity can be determined with any degree of precision is by a model test or by construction of a flow net. If a flow net can be con-

structed accurately in conformance with certain fundamental conditions, the velocities determined from the flow net should conform closely to those in the actual structure, provided friction and impact losses are of a minor nature.

In the flow-net method as generally presented, emphasis is placed on constructing the net by freehand sketching, with gradual adjustment and correction until the streamlines and potential lines intersect at right angles and form curvilinear squares. This is a laborious process; and even when accurately done the resulting velocity determinations will not be very precise if the streamlines are close together, or if the streamlines are only slightly curved and the variation in velocity across the section is rather gradual. A graphical method of checking the spacing of the streamlines, which also permits a more precise determination of the velocities, is described in this paper. The basis of this method is given by Hunter Rouse, M. Am. Soc. C. E. (2), and by R. L. Daugherty (3). However, so far as the writer knows, the detailed application of the method has not been made generally available to engineers.

NOTATION

The letter symbols used in this paper are defined where they first appear and are assembled for convenience of reference in Appendix II.

TWO-DIMENSIONAL FLOW WITH FIXED BOUNDARIES

Consider first the case of two-dimensional flow within fixed boundaries, as shown in Fig. 1(*a*). A section of the water passage one unit in depth (normal to the plane of the paper) is considered. The radii of curvature of the fixed boundaries are r_s and r_c; these need not be concentric. The width of the water passage, measured along the curved potential line, APC, is d. Assuming that the streamlines have been plotted, as in Fig. 1(*a*), the radius of curvature of the streamline at any point along the line APC can be shown as a curve of r versus y, line $A_1P_1C_1$ in Fig. 1(*c*), y being measured from the outer curved boundary toward the center of curvature as indicated in Fig. 1(*a*). Then the basic theory of the flow net, with uniform energy distribution along the water passage (no friction or impact losses) requires that

$$\frac{V}{r} = \frac{dV}{dy} \qquad \text{.............................(1)}$$

in which V = velocity at any point, P, in the water passage, and r = radius of curvature of the streamline at point P.

A curve, A_2C_2, showing V versus y can be constructed in Fig. 1(*c*) as follows:

A value of unity is assumed for the velocity, V_s, at point A_2, where $y = 0$. Starting at this point, the slope (dV/dy) of the velocity curve will be V_s/r_s, according to Eq. 1. This slope is laid off graphically, as shown on the diagram, by swinging point A_1 along a circular arc of radius r_s, until it reaches the position A_3 on the axis of y. The straight line A_3A_2, extended a short distance beyond A_2 in the direction of y, gives the tangent of the velocity curve at point A_2, in accordance with Eq. 1. For all practical purposes, this piece of tangent may be taken as the true curve for a short distance, such as A_2D_2.

In this way, a new value of V is obtained at point D_2; at which point the process is repeated, using the value of r given by the point D_1 on A_1C_1, directly above point D_2 (construction not indicated in Fig. 1(c)). Thus, a new determination

of the tangent is obtained at point D_2, and the velocity curve is again extended a short distance beyond point D_2. The process is repeated at short intervals until the velocity curve is extended across the entire width of the water passage.

The ordinates of the velocity curve, A_2C_2, so determined, give values of V/V_s at any point in the line APC of Fig. 1(*a*). Note that, in this construction, the same scale must be used for r and y in Fig. 1(*c*), but this does not need to be the same as the scale of the flow net in Fig. 1(*a*).

The spacing of the streamlines in Fig. 1(*a*) is based on the condition that the discharge, q, of any stream channel between successive streamlines must be constant for all channels. Let the width of any stream channel be Δy, and the average velocity of the channel be V; then

$$q = V\,\Delta y \quad \text{(2a)}$$

Let Q = the total area under the curve A_2C_2; that is, the total discharge:

$$Q = \int V\,dy \quad \text{(2b)}$$

If there are N stream channels (eight in Fig. 1(*a*)),

$$q = \frac{Q}{N} = \frac{\int V\,dy}{N} = V\,\Delta y \quad \text{(2c)}$$

and Δy, for any stream channel, will equal $\frac{Q}{N}\frac{1}{V}$.

Divide the total width, d, into N_s equal segments (four in Fig. 1(*c*)), and note the value of V at the midpoint of each segment, $(V_1)'$, $(V_2)'$, $(V_3)'$, and $(V_4)'$. Lay off these values on the vertical line through $y = 0$, as OM. Since the width of each segment is $\frac{d}{N_s} = y_0$, the area under the velocity curve is (approximately) equal to $\overline{\text{OM}} \times y_0$ or $\Sigma V\,y_0$; that is,

$$\Sigma V\,y_0 = \int V\,dy = Q \quad \text{(3)}$$

The successive values, $(V_1)'$, $(V_1 + V_2)'$, $(V_1 + V_2 + V_3)'$, etc., are then projected to the right side of their respective segments, giving the points marked with double circles, to form the curve OPN, the ordinates of which represent the summation of the areas of the respective segments of the velocity curve, divided by y_0. If this area curve is then cut into N parts by horizontal lines equally spaced, and the points so located are projected vertically to the velocity curve, the latter will be subdivided into N segments of equal area. In other words, these N segments (indicated at the top of Fig. 1(*c*)) will give the required spacing of the streamlines to correspond with the originally assumed variation in the radius of curvature of the streamlines.

This graphical check should be made for several cross sections of the water passage, and the streamlines plotted as in Fig. 1(*a*). In general, the resulting lines will differ in spacing from those originally assumed. The radii of curvature at the two boundaries, of course, will remain the same, but the shape of the curve of r versus y may require modification. In that case, the velocity curve should be replotted, and a revised spacing of the streamlines determined.

From Eq. 3, the average velocity, V_a, will equal Q/d; or

$$V_a = \frac{Q}{N_s\,y_0} = \frac{\Sigma V}{N_s} = \frac{\overline{\text{OM}}\,V_s}{N_s} \quad \text{(4)}$$

and $V_a/V_s = \overline{\mathrm{OM}}/N_s$. The ratio V_a/V_s can therefore be determined directly from the "area curve," as shown in Fig. 1(*c*). Then,

$$V_s = \frac{V_a}{V_a/V_s} \tag{5a}$$

and

$$V_c = V_s \times \frac{V_c}{V_s} \tag{5b}$$

The ratio V_c/V_s may be read directly at the right end of the velocity curve, where $y = d$.

Free Vortex.—If the two boundary surfaces are cylindrical and concentric, and all the streamlines have the same center of curvature, $dy = -dr$. From Eq. 1, $\frac{dV}{V} = \frac{dy}{r}\cdot$ Hence,

$$\frac{dV}{V} + \frac{dr}{r} = 0 \tag{6}$$

Integrating Eq. 6, $\log V + \log r = \log C$, or $\log (V r) = \log C$, in which C is a constant. Hence, $V r = C = V_s r_s$; or

$$V = \frac{V_s r_s}{r} \tag{7}$$

This is the condition existing in a "free vortex" (2*a*); but

$$Q = \int_0^d V\,dy = -\int_{r_s}^{r_c} \frac{V_s r_s\,dr}{r} = V_s r_s \times \log_e \frac{r_s}{r_c} \tag{8}$$

Since $Q = V_a d$,

$$V_a = \frac{V_s r_s}{d} \log_e \frac{r_s}{r_c} \tag{9}$$

and

$$\frac{V_a}{V_s} = \frac{r_s}{d} \log_e m \tag{10}$$

in which $m = \frac{r_s}{r_c}\cdot$ Accordingly, with two-dimensional flow and parallel cylindrical walls for the water passage, so that "free-vortex" conditions apply, the velocity distribution can be obtained directly by Eqs. 7 and 10, and the graphical construction previously described can be omitted.

THREE-DIMENSIONAL FLOW WITH FIXED BOUNDARIES

The basic formula for the flow net (Eq. 1), as derived by Professor Rouse (2*b*)(2*c*), depends on the variation of the velocity in the direction y, taken normal to the streamline tangent at the particular point considered. In three-dimensional flow, this tangent may not remain in the same plane as one progresses along a given streamline in space. Likewise, the direction of y may not remain in the same plane. However, the mathematical relation shown by Eq. 1 will remain valid.

The previous discussion is applied to two-dimensional flow, or where the water passage is rectangular in section—that is, of constant depth b, perpendicular to the plane of the paper. For three-dimensional flow, or where the depth of the water passage is variable, the same methods can be used to determine the relative velocities, V/V_s, provided that the radius of curvature in space of the streamline at a given point remains approximately equal to what it would be for two-dimensional flow. This will be true if the cross section of the stream passage remains constant in the direction of flow; and, even if there is some degree of convergence in the water passage, the curvature of the streamlines may not change to any extent (3). Experimental proof of the assumption that the two-dimensional methods may be applied directly to three-dimensional flow is noted subsequently in this paper.

Assuming that the velocity distribution obtained by the two-dimensional method will also apply to three-dimensional flow, the actual velocities may be determined as follows:

Trapezoidal Section.—Assume that the cross section of the water passage is a trapezoid, as in Fig. 1(*b*). Divide the water passage into N strips of width Δy; the widths Δy may be equal or variable. Then total discharge is

$$Q = \sum_{y=0}^{y=d} V\, b\, \Delta y = \sum_{y=0}^{y=d} \frac{V}{V_s} V_s\, b\, \Delta y \ldots\ldots\ldots\ldots (11a)$$

If the values of Δy are equal,

$$Q = \Delta y\, V_s \sum \left(\frac{V}{V_s} b \right) \ldots\ldots\ldots\ldots (11b)$$

and

$$V_s = \frac{Q}{\Delta y \sum \left(\frac{V}{V_s} b \right)} \ldots\ldots\ldots\ldots (12)$$

If the values of Δy correspond to the streamlines as obtained for the two-dimensional condition, $V\, \Delta y$ = constant = $V_1\, \Delta y_1$, in which V_1 is the average velocity in stream channel 1, Fig. 1(*a*), and Δy_1 is the width of that channel. Hence,

$$Q = V_1\, \Delta y_1\, \Sigma b \ldots\ldots\ldots\ldots (13)$$

$$V_1 = \frac{Q}{\Delta y_1\, \Sigma b} \ldots\ldots\ldots\ldots (14a)$$

and

$$V_s = \frac{V_1}{V_1/V_s} \ldots\ldots\ldots\ldots (14b)$$

In either case, $V_c = V_s\, (V_c/V_s)$. In using Eqs. 11 to 14, the values of V/V_s, V_c/V_s, and V_1/V_s are taken from the velocity curve of Fig. 1(*c*). The variable depth, b, is to be computed from the geometry of the water passage. It should be noted that the value of V_a/V_s, shown in Fig. 1(*c*), is of no significance in this case because of the variable depth b.

For the "free-vortex" condition, since $b = b_s + \frac{y}{d}(b_c - b_s) = \frac{b_s\, d + y\, (b_c - b_s)}{d}$,

$r = r_s - y$, and $V = \dfrac{V_s r_s}{r}$:

$$Q = \int_0^d V\, b\, dy = V_s r_s \left\{ \frac{\log_e m}{d} [b_s d + r_s (b_c - b_s)] - (b_c - b_s) \right\} \quad \ldots (15)$$

Since $Q = V_a \dfrac{(b_c + b_s)\, d}{2}$ and $V_a = \dfrac{2\,Q}{(b_c + b_s)\, d}$,

$$\frac{V_a}{V_s} = \frac{2\, r_s}{(b_c + b_s)\, d} \left\{ \frac{\log_e m}{d} [b_s d + r_s (b_c - b_s)] - (b_c - b_s) \right\} \quad \ldots (16)$$

When $b_c = b_s = 1.0$, as in two-dimensional flow, $\dfrac{V_a}{V_s} = \dfrac{r_s}{d} \log_e m$ (see Eq. 10).

Circular Section.—If the cross section of the water passage is circular, with a diameter d (Fig. 2): $b = d \sin \theta$, $y = \dfrac{d}{2}(1 - \cos \theta)$, and $dy = \dfrac{d}{2} \sin \theta\, d\theta$. Then

$$Q = \int_0^d b\, V\, dy = \int_0^\pi d \sin \theta\, V \frac{d}{2} \sin \theta\, d\theta$$

$$= \frac{d^2}{2} \int_0^\pi V \sin^2 \theta\, d\theta \quad \ldots (17)$$

Let V_a = average velocity = $\dfrac{4\,Q}{\pi\, d^2}$. If the semicircle is divided into N_s segments with equal angles $\Delta\theta$,

$$V_a = \frac{4}{\pi\, d^2} \frac{d^2}{2} \sum_0^\pi V_s \frac{V}{V_s} \sin^2 \theta\, \Delta\theta$$

$$= \frac{2\, V_s}{\pi} \sum_0^\pi \frac{V}{V_s} \sin^2 \theta\, \Delta\theta \quad \ldots (18)$$

and

$$\frac{V_a}{V_s} = \frac{2\, \Delta\theta}{\pi} \sum_0^\pi \frac{V}{V_s} \sin^2 \theta \quad \ldots (19)$$

By constructing the velocity curve (V versus y) as explained herein, values of V/V_s can be determined for the several values of the angle θ, and substituted in Eq. 19 to obtain V_a/V_s. Then V_s is determined as $\dfrac{V_a}{V_a/V_s}$; and $V_c = V_s \dfrac{V_c}{V_s}$.

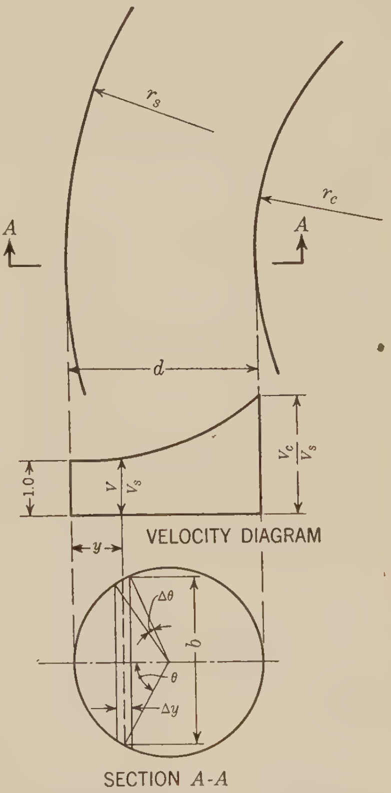

FIG. 2.—CIRCULAR WATER PASSAGE

For a standard bend in which $d = r_s - r_c$, if the streamlines are concentric the "free-vortex" condition may be assumed. Then, from Eq. 7,

$$V = \frac{V_s r_s}{r_s - y} = \frac{2\, V_s r_s}{(2\, r_s - d) + d \cos \theta} \quad \ldots (20)$$

and

$$\frac{V_a}{V_s} \doteq \frac{4\,r_s\,\Delta\theta}{\pi} \sum_{0}^{\pi} \frac{\sin^2\theta}{(2\,r_s - d) + d\cos\theta} \quad \text{(21)}$$

Actually in a standard pipe-bend, the streamlines will follow a spiral course instead of being two-dimensional curves. Nevertheless, experiments have shown that the velocity distribution approximates that of the free vortex, although the actual value of V_c/V_s is somewhat smaller than that indicated by the foregoing theory (4*a*)(5*a*)(6*a*).

Two-Dimensional Flow with Boundaries not Fixed

As shown in the preceding section, the graphical check of the flow net can be made without difficulty when the boundaries of the water passage are fixed. If one or more of the boundaries are exposed to the atmosphere, as in discharge over a straight spillway weir, the construction of the flow net becomes more difficult. However, the same graphical check can be applied after the flow net is laid out approximately.

It is first necessary to sketch in the streamlines of the flow net freehand, as described elsewhere (1). The flow net must satisfy the following requirements:

(*a*) The radius of curvature of the streamlines must vary in conformance with the aforementioned graphical method $\left(\frac{V}{r} = \frac{dV}{dy}\right)$;

(*b*) The drop in the water surface at any section, measured below the reservoir level, must equal the velocity head of the water flowing at the surface $V^2_s/2\,g$; and

(*c*) The average velocity multiplied by the depth, measured along any potential line, must equal the rate of discharge per foot of crest length.

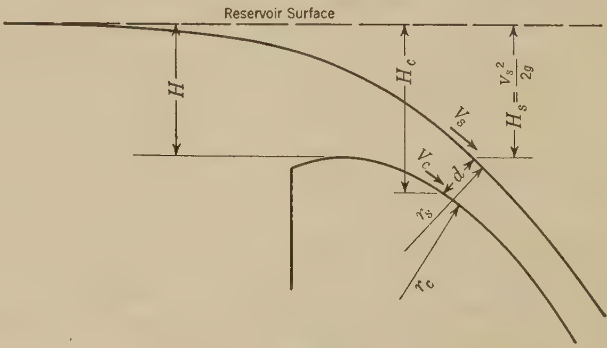

Fig. 3

Since the rate of discharge per foot of crest is not known in advance, this must be assumed. (In the case of a weir, it may be estimated by the use of known weir coefficients.) The flow net should then be sketched in freehand (see Fig. 3). When the aforementioned checks are applied, it may be impossible to make the second and third conditions agree with the first condition. This is an indication that the assumed rate of discharge is incorrect, and a new value of discharge must be assumed. There is only one value of discharge that will permit all three conditions to be satisfied simultaneously.

In the case of a weir, the correct discharge should be determined before attempting to extend the flow net downstream from the crest. The completion of the flow net then is much simplified, as the surface velocity becomes more nearly equal to the average velocity. Where the depth of flow is relatively small, compared with the radius of curvature of the streamlines, the latter may be assumed constant; that is, $r = r_c = r_s$. Under these conditions, the theory gives $\frac{dV}{dy} = \frac{V}{r}$ in which r is constant. Then $\frac{dV}{V} = \frac{dy}{r}$; and $\log_e V = \frac{y}{r} + C$. When $y = 0$, $V = V_s$; $C = \log_e V_s$; $\log_e \frac{V}{V_s} = \frac{y}{r}$; $\frac{V}{V_s} = e^{y/r}$:

$$Q = \int_0^d V\,dy = V_s\,r\,(e^{d/r} - 1) \qquad (22)$$

The average velocity equals $V_a = Q/d$; hence,

$$\frac{V_a}{V_s} = \frac{r}{d}(e^{d/r} - 1) \qquad (23)$$

By assuming a value for d at any given section, and taking r as the radius of the concrete surface, V_a/V_s can be computed by Eq. 23. Then

$$V_s = \frac{V_a}{V_a/V_s} = \frac{Q/d}{V_a/V_s} \qquad (24)$$

This value of V_s can be checked by the condition that $V^2{}_s/2\,g$ must agree with the elevation of the water surface at the given section. Having determined V_s, the next step is to compute V_c: Since $V = V_s\,e^{y/r}$,

$$V_c = V_s\,e^{d/r} \qquad (25)$$

Check with Experimental Weir Nappes.—The writer has checked the methods described herein for testing a flow net by applying them to the case of a sharp-crested weir with aerated lower nappe. Curves for the upper and lower surface of the freely-discharging jet can be plotted by means of the table prepared by E. W. Lane, M. Am. Soc. C. E. (7). At any section through the jet, the elevations of the upper and lower water surfaces may be determined with respect to the reservoir surface (H_s and H_c in Fig. 3). Since atmospheric pressure prevails on both surfaces, $V_c/V_s = \sqrt{H_c/H_s}$.

By measuring the thickness of the jet and the radius of curvature of the upper and lower nappes at the given section, the value of V_c/V_s may also be computed by the graphical or analytical methods described herein. The results, as obtained by the writer, give a very close check with the values of V_c/V_s obtained from the velocity heads.

THREE-DIMENSIONAL FLOW WITH BOUNDARIES NOT FIXED

As in the case for fixed boundaries, the methods described herein for two-dimensional flow can be extended to three-dimensional flow with one or more boundaries exposed to the atmosphere. An example of this condition is the "morning-glory" type of spillway, or a sharp-crested weir which is circular in plan (8).

The flow net in this case is to be constructed in a manner similar to that described for two-dimensional flow, except that, in determining the actual velocities, the shape of the water passage must be taken into account, as described herein for fixed boundaries.

Fig. 4.—Flow Net for a Morning-Glory Spillway

The writer has applied such methods to the case of a sharp-crested weir of circular plan, such as described by C. E. Camp, Assoc. M. Am. Soc. C. E., and J. W. Howe, M. Am. Soc. C. E. (8), whose work presents the results of tests made at the University of Iowa, Iowa City, including curves for the upper and lower nappes of freely discharging weirs with various radii of curvature. The test was applied to a weir with a radius of 36.6 ft and a weir head equal to 10.45 ft. After plotting the upper and lower nappe curves, the values of H_c and H_s were scaled for several sections through the jet and V_c/V_s was computed ($= \sqrt{H_c/H_s}$). The graphical and analytical methods previously described were then used to compute values of V_c/V_s for the same sections, using values of the radii of curvature and thickness of the jet scaled from the plotted

curves. As with the straight weir, the agreement with the velocity head computations was very close, particularly in the region of the jet where the streamlines have large radii of curvature. Near the weir crest the agreement was less satisfactory, but probably within the limits of accuracy of the curves used by Messrs. Camp and Howe (8) which are drawn at a rather small scale.

EXAMPLE

To illustrate the methods outlined herein, the case of a morning-glory spillway weir will be given. The profile of the crest is shown in Fig. 4, the high point of the weir being located in plan on a circle whose radius r_{ac} is 34.45 ft, and whose circumferential length is 217 ft. The discharge capacity is assumed as 21,500 cu ft per sec, or 99 cu ft per sec per foot of crest. The analysis is made for a sector 1.0 ft wide at the crest.

Because of the circular plan of the spillway, a section through the water jet, such as section D in Fig. 4, will be essentially trapezoidal in shape, the depth of the section at any point (normal to the paper) being equal to $r_a/34.45$, in which r_a is the radius measured from the axis of the spillway.

Preliminary studies indicate that the head over the spillway crest required to discharge 99 cu ft per sec per ft will be about 8.90 ft. Using this head, the flow net is sketched in as shown in Fig. 4. The radii of curvature of the water surface, the mid-streamline, and the concrete surface are scaled at various sections. For this purpose, a template on tracing paper showing curves of various radii is convenient.

The graphical check for section A, Fig. 4, is shown in Fig. 5(a), in which the area curve is divided into eight stream channels ($N = 8$). The computations for V_s and V_c are given in Tables 1, 2, and 3, the width d being divided into six equal segments ($N_s = 6$). As a check on the accuracy of the flow net, it will be noted that $V^2{}_s/2\,g$ should equal H_s. The pressure head at the concrete surface, H_p, is computed as equal to $H_c - \frac{V^2{}_c}{2\,g}$, and is plotted in Fig. 4 vertically from the concrete surface.

($Q = 99$ CU FT PER SEC)

$\frac{V^2{}_s}{2\,g}$	V_c (Eq. 5b)	$\frac{V^2{}_c}{2\,g}$	H_s (ft) (Fig. 4)	H_c (in feet) (Fig. 4)	H_p (in feet) $H_c - V^2{}_c/2\,g$	Section (Fig. 4)

15.5	$31.6 \times 1.113 = 35.2$	19.2	15.3	18.3	$18.3 - 19.2 = -0\;9$	E

[b] $V_a = \frac{99}{6.8} = 14.58.$

Section B is approximately vertical, and hence rectangular, with constant depth, $b = 1.0$. The graphical check is given in Fig. 5(*b*); and the computations are shown in Tables 1 to 3. In this case, V_a/V_s and V_c/V_s are obtained from the graphical check.

The computations for section C are made in the same manner as for section A, with d divided into four equal segments. The graphical check is given in Fig. 5(*c*).

At section D the graphical check is given in Fig. 5(*d*). Here the velocity curve is practically a straight line and the cross section of the stream passage is a trapezoid. The discharge may then be computed as

$$Q = (V_c\, b_c + V_s\, b_s)\, \frac{d}{2} \quad \dotfill (26)$$

or

$$V_s = \frac{2\,Q}{\left(\dfrac{V_c}{V_s}\, b_c + b_s\right) d} \quad \dotfill (27)$$

V_c/V_s being read from Fig. 5(*d*). The approximate method, using a constant radius of curvature for the streamlines, may also be used, in which case $V_c/V_s = e^{d/r}$. As shown in the computations, this gives an error of less than 1% in the value of V_c/V_s, even though there is an appreciable difference between r_c and r_s.

At section E the streamlines have practically a constant radius, and the approximate method is used to compute V_c/V_s. Then V_s is computed by Eq. 27 as in section D; thus:

$$\begin{aligned} \log_{10} e &= \ 0.43429 \\ &\ \ \times\ \underline{0.1073} \qquad \left(= \frac{d}{r};\ \text{see Table 1}\right) \\ \log e^{d/r} &= \ 0.04660 \\ e^{d/r} &= 1.113 = \frac{V_c}{V_s} \qquad (\text{see Eq. 25}) \end{aligned}$$

The graphical checks for sections A to D, inclusive, give the theoretical spacings of the streamlines, which are used to check the construction of the flow net. If there is any appreciable change to be made in the curvature of the streamlines, the graphical check should be revised accordingly. In the preliminary construction of the flow net it may be found that the computed $V^2_s/2\,g$ at any section does not agree with H_s shown on the flow net. The position of the water surface must then be shifted until these values agree.

In this example, considerable time is required to determine the correct head (H) over the spillway crest, for the given value of discharge. Several trial arrangements of the flow net between section A and section C must be laid out, using different values of H, until the values of H_s and $V^2_s/2\,g$ are brought into agreement. The flow net is not extended beyond section C until the correct value of Q has been determined.

This example was selected intentionally to illustrate the complications of a three-dimensional problem with water surface exposed to the atmosphere. A two-dimensional problem, such as a weir with straight crest, or a problem involving fixed boundaries for the water passage, would be appreciably easier to construct.

SUMMARY

The writer has found by experience that the methods outlined herein greatly facilitate the construction of a flow net, and permit much more precise velocity determinations than can be obtained merely by freehand sketching of the streamlines. The experience of other investigators (1), and the check computations, made by the writer, on the results of experiments on straight and curved sharp-crested weirs, lead to the conclusion that, when a flow net is carefully constructed and checked by the methods presented herein, the resulting computed velocities and pressures will be a reasonable indication of those to be expected in the prototype structure. However, it should be recognized that the flow-net method is not applicable in cases where friction and impact or eddy losses may be expected to have a controlling effect on velocities and pressures.

NOTATION

The following letter symbols, used in the paper, conform essentially to American Standard Letter Symbols for Hydraulics,[3] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942:

---

[3] ASA—Z10.2—1942.

b = breadth of flow (Fig. 1(b)), b_s and b_c, respectively, being breadths at the outside and inside of the curved stream channel;
C = a constant (see Eq. 6);
d = depth, or total maximum width of a water passage measured along a curved potential line (see Fig. 1);
e = base of Napierian logarithms (see Eq. 8);
g = acceleration of gravity;
H = elevation of reservoir surface above weir crest (see Fig. 4);
H_c and H_s = respectively, the elevation of the lower and upper surfaces of the water at any section of a jet, measured downward from the reservoir surface:
H_p = pressure head on masonry surface (see Fig. 4);
m = the ratio r_s/r_c (Eq. 10);
N = total number of hypothetical channels in a stream (Fig. 1(a));
N_s = number of hypothetical segments for velocity curve, Fig. 1(c);
Q = total discharge, or total area under the curve A_2C_2, Fig. 1(c);
q = discharge in any given stream channel, or Q/N (Eq. 2c);
r = radius of curvature of a stream, the radii for individual channels (Fig. 1(a)) being designated by appropriate subscripts; the radii of the boundaries of the jet are denoted by r_s and r_c (Fig. 1(a));
r_a = radius of "morning-glory" spillway measured from the axis of the spillway shaft to a point in any section of a jet, the radii to the lower and upper surfaces at any section being designated by r_{ac} and r_{as}, respectively (see Fig. 4);
V = velocity of flow at any point P, Fig. 1(a), in the water passage, the velocity for individual channels (Fig. 1(c)) being designated by appropriate subscripts; average velocity is designated V_a, and the velocity at the inner and outer surfaces of any section is designated V_c and V_s, respectively:
V_1 = average velocity in stream channel 1 (see Fig. 1(c));
$(V_1)'$ = value of V at the midpoint of segment 1 of the velocity curve;
y = a part of d measured from the outer curved boundary toward the center of curvature (see Fig. 1(a));
y_0 = width of any single segment of area curve, Fig. 1(c)), equals d/N_s;
Δy_1 = width of stream channel 1 (Eq. 13);
θ = angle measured at the center of a circular channel (Fig. 2):
$\Delta\theta$ = central angle of the arc subtended by a segment of the velocity curve (Fig. 1(c)).

DISCUSSION

J. W. Howe,[4] M. Am. Soc. C. E.—The amplification of a graphical method for checking the location of streamlines in a flow net, as presented by the author, offers detailed working directions which should prove useful to any one desiring to make such a check. Experience, patience, and no little skill are essential in drawing a correct network, and even with these the labor may be considerable. The graphical checking of the tentative location of streamlines is also time consuming and probably offers little advantage to an experienced hand. To the inexperienced, however, such methods, no doubt, will provide a somewhat more rapid approach to a solution, since an essentially correct location at one point in the network is of material aid in shaping the pattern for a considerable distance in either direction.

The flow net has proved useful in many situations involving two-dimensional flow which is essentially irrotational. Its application to three-dimensional flow is subject to question, however. The writer is of the opinion that the accuracy of such an application would vary directly with the departure from two-dimensional conditions.

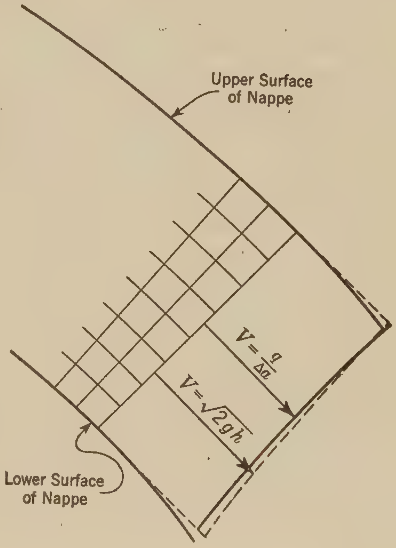

Fig. 6

In the experimental work done by Cecil S. Camp, Assoc. M. Am. Soc. C. E. (8), only the discharge and the position of the nappe surfaces were determined; pressure measurements in the nappe were not made. Because of the radial convergence of stream filaments in passing over the circular weir there must be pressure in the nappe even in regions where the streamlines of the two-dimensional flow net are parallel.

The writer applied the graphical method to a section downstream from a circular weir (head-diameter ratio, 0.14) at a point where the streamlines were practically parallel (such as point E, Fig. 4). The boundaries of the nappe were taken from Professor Camp's experimental data, and the location of streamlines was verified by the author's graphical method. The cross-sectional areas of the stream filaments were determined, and from these and the discharge, the mean velocities were computed. If the flow were two-dimensional, no pressure could exist in the nappe at this section and the velocity at any point would equal $\sqrt{2\,g\,h}$. A comparison of the latter quantity with the velocity obtained from the flow net is shown in Fig. 6. There is an indication of some pressure in the nappe although it does not reduce to zero at the underside as it should. Since the degree of convergence was quite small in this example, the indicated pressure may be of about the right magnitude. However, experimental substantiation of this possibility would be required to establish the validity of the flow net in such a case.

---

[4] Prof. and Head, Dept. of Mechanics and Hydraulics, State Univ. of Iowa, Iowa City, Iowa.

Clarence S. Jarvis,[5] M. Am. Soc. C. E.—This presentation of the flow-net problem by Mr. Foster is original in approach and concept. Too often, however, a tendency toward abstract expression is confusing, and a more elementary presentation might prove acceptable to nonspecialists. In the structural feature employed by the author, for example, it seems preferable to concentrate on: (*a*) Access capacity over the "morning-glory" spillway rim; (*b*) outlet capacity of the stem or throat, leading to the open drainage channel below the dam; and (*c*) important phenomena associated with normal operation.

The usual behavior of such structures—laboratory models and also ordinary funnels—indicates that considerable turbulence and entrapment of air will occur where the converging filaments of swiftly flowing water crowd the outlet stem. Perhaps hydrostatic head will be built up as required to dispose of the changing overflow at the upper rim. Pressures resulting from the turbulence and the entrapped air doubtless would exceed the total pressures subjected to variations due to changing velocities of flow over concrete or some other structural surface.

Surely the first investigations should concern the discharge capacity over the rim, in accordance with the author's presentation. Thus:

$$Q = 3.28\,L\,H^{3/2} \qquad (28a)$$

or for a full circle,

$$Q = 10.36\,D\,H^{3/2} \qquad (28b)$$

For the example under consideration, in which the diameter is 68.9 ft, Eq. 28*b* yields

$$Q = 714 \times H^{3/2} \qquad (28c)$$

For $H = 9$ ft in Eq. 28*c*, Q becomes 19,300 cu ft per sec; or, for $H = 16$ ft, $Q = 45{,}700$ cu ft per sec.

Until the engineer can compute the vibration due to the inevitable shock of the readjustment of the section by the descending sheet of water and the motion for steady discharge in a nearly horizontal conduit before the discharge escapes into an open channel, it seems unimportant to determine the slight changes in velocity and related pressures, while totally neglecting friction, impact, and eddy losses. According to the author's statement in the concluding sentence of the "Summary," "* * * the flow-net method is not applicable in cases where friction and impact or eddy losses may be expected to have a controlling effect on velocities and pressures." Surely friction, impact, and eddy losses are not negligible, or the author's estimate for the discharge capacity of spillway lip under a head of about 8.90 ft could not be taken as 21,500 cu ft per sec—more than 10% in excess of the quantity derived (8*a*) from the use of Eq. 28*a*.

---

[5] Senior Civ. Engr., Intelligence Dept., Office, Chf. of Engrs., Washington, D. C.

Considerations of economy would probably so limit the dimensions of the spillway stem and horizontal outlet conduit that it would be questionable whether a flow of 45,500 cu ft per sec could be accommodated. If the conduit capacity were somewhat less, it would become the controlling factor, causing a relatively quiet pondage over the entire morning-glory area except near the center, where the tendency to circular motion might establish the well-defined vortex so familiar to observers of eddies in turbulent stream surfaces. Obviously, the neglected factors of friction, impact, and eddy losses would control to such an extent that the length as well as the cross section of the outlet conduit would have to be considered in the determination of the actual capacity of the spillway under a given head of water in the reservoir and also under the total head above the downstream end of the outlet conduit.

Such theoretical studies and analyses should be encouraged, but the results should be reduced to a practical working basis.

H. ALDEN FOSTER,[6] M. AM. SOC. C. E.—The fact that so little discussion has been submitted on the paper might seem to indicate that there is not much general interest in the subject of flow nets as applied to hydraulic design. However, as noted by Professor Howe, the flow net has been used to good advantage in solving problems of two-dimensional flow. In the writer's opinion, the graphical method described in the paper does materially assist in the construction of the flow net; and, in many cases, the method should permit a much more precise determination of the velocity distribution, which, as a rule, is the primary purpose for which the flow net is constructed.

The extension of the graphical method to problems of three-dimensional flow has seemed to the writer to be logical, provided that the radius of curvature of the streamlines, in space, is not appreciably different from that for two-dimensional flow. Such an assumption is subject to verification by experiment. Unfortunately, there are few experimental data available on which to base a reliable test. The application of the graphical method to the experiments (8) by Cecil S. Camp, Assoc. M. Am. Soc. C. E., as noted by Professor Howe, indicates at least an approximate agreement when applied to a three-dimensional problem.

Essentially, a flow net for any particular hydraulic structure would be constructed only as a substitute for a model test. There is nothing to be determined by the flow net that cannot be learned with greater accuracy from a model test. However, model tests are often expensive and time consuming; and, in general, it should be possible to prepare a flow net at a considerable saving in cost and time. Even if a model test is to be conducted, it may be worth while to make a preliminary flow-net study as a guide to the construction and testing of the model. Any device that would facilitate the preparation of the flow net should be worth consideration by the designer.

Mr. Jarvis seems to be under the impression that the writer's primary intention was to present a method for the design of "morning-glory" spillways.

---

[6] Designing Engr., Parsons, Brinckerhoff, Hogan & Macdonald, New York, N. Y.

Actually, this problem was discussed only for the purpose of illustrating the application of the flow-net method to the more complicated conditions of three-dimensional flow when one boundary of the water passage is exposed to the atmosphere.

The writer is in general agreement with most of Mr. Jarvis' comments on morning-glory spillways. However, this subject is entirely beyond the scope of the paper. Consequently, it does not appear advisable to discuss the questions raised by Mr. Jarvis. In the writer's opinion, no adequate treatment of the complete theory of the design of such spillways has yet been published. He hopes, however, that the present paper may prove useful in the design of morning-glory spillways as well as in that of many other types of hydraulic structures.

CHARACTERISTIC REDUNDANTS USED FOR ANALYZING STATICALLY INDETERMINATE STRUCTURES

By John B. Wilbur,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Charles A. Ellis, Ralph W. Stewart, Myle J. Holley, Jr., M. W. Huggins, Leon Beskin, Frederick S. Merritt, and John B. Wilbur.

Synopsis

Orthogonal functions are commonly used in the solution of vibration problems. To a lesser degree such functions have been applied to some of the more complicated static analyses, as, for example, to plate analysis and to the determination of beam deflections by trigonometric series. In this paper, forces acting on relatively simple structures are reduced to characteristic forces which are orthogonal, and methods of analysis based on these characteristic forces are discussed.

The heart of the multiply indeterminate solution may be interpreted by means of the determination of so-called characteristic forces. After these forces have been found, redundant stresses corresponding to any condition of loading or distortion may be evaluated without the further solution of simultaneous equations, regardless of the degree to which the structure may be statically indeterminate.

It is not claimed that the methods suggested are either more quickly applied or more easily understood than other methods which are commonly used. It is hoped, however, that they will be of interest because they differ so radically from the usual methods. Being so different, it is possible that other applications of the principles involved may lead to methods of solution which constitute an improvement on the methods outlined herein.

Notation

The symbols used in this paper are defined where they first appear, either by text or diagram, and are assembled for convenience of reference in the Appendix.

Note.—Published in June, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Prof., Structural Eng., Mass. Inst. Tech., Cambridge, Mass.

1. Characteristic Forces

Suppose an elastic structure to be acted upon by a number of concentrated forces $P_a, P_b, \cdots, P_n$, which are applied at points a, b, $\cdots$, n, respectively, as shown in Fig. 1. Let:

Δ_a = total deflection at point a in the direction of P_a due to forces $P_a, P_b, \cdots, P_n$;

Δ_b = total deflection at point b in the direction of P_b due to forces $P_a, P_b, \cdots, P_n$;

. . . .

Δ_n = total deflection at point n in the direction of P_n due to forces $P_a, P_b, \cdots, P_n$.

Let values of $P_a, P_b, \cdots, P_n$ be determined in such a manner that

$$\left.\begin{aligned} \Delta_a &= \kappa P_a \\ \Delta_b &= \kappa P_b \\ &\cdots\cdots \\ \Delta_n &= \kappa P_n \end{aligned}\right\} \cdots\cdots\cdots\cdots (1)$$

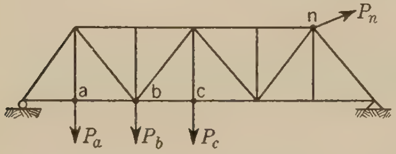

Fig. 1

in which κ is a proportionality factor having the same value in each of Eqs. 1. A set of forces which satisfy Eqs. 1 will be called "characteristic forces."

2. Determination of Characteristic Forces

If δ_{mn} is the deflection at any point m in the direction of P_m, due to a unit value of P_n, then, by superposition:

$$\left.\begin{aligned} P_a\,\delta_{aa} + P_b\,\delta_{ab} + \cdots + P_n\,\delta_{an} &= \Delta_a \\ P_a\,\delta_{ba} + P_b\,\delta_{bb} + \cdots + P_n\,\delta_{bn} &= \Delta_b \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ P_n\,\delta_{na} + P_b\,\delta_{nb} + \cdots + P_n\,\delta_{nn} &= \Delta_n \end{aligned}\right\} \cdots\cdots\cdots\cdots (2)$$

Substituting values of $\Delta_a, \Delta_b, \cdots, \Delta_n$ from Eqs. 1, Eqs. 2 may be rewritten as

$$\left.\begin{aligned} P_a\,(\delta_{aa} - \kappa) + P_b\,\delta_{ab} + \cdots + P_n\,\delta_{an} &= 0 \\ P_a\,\delta_{ba} + P_b\,(\delta_{bb} - \kappa) + \cdots + P_n\,\delta_{bn} &= 0 \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ P_a\,\delta_{na} + P_b\,\delta_{nb} + \cdots + P_n\,(\delta_{nn} - \kappa) &= 0 \end{aligned}\right\} \cdots\cdots\cdots\cdots (3)$$

Since the right-hand side of Eqs. 3 is zero, the numerator determinant will be zero. Hence, in order for the forces $P_a, P_b, \cdots, P_n$ to have values other than zero, it is necessary that the denominator determinant formed by the coefficients to $P_a, P_b, \cdots, P_n$ on the left side of these equations be also equal to zero. This condition is represented by

$$\begin{vmatrix} \delta_{aa} - \kappa; & \delta_{ab}; & \cdots; & \delta_{an} \\ \delta_{ba}; & \delta_{bb} - \kappa; & \cdots; & \delta_{bn} \\ \cdots & \cdots & \cdots & \cdots \\ \delta_{na}; & \delta_{nb}; & \cdots; & \delta_{nn} - \kappa \end{vmatrix} = 0 \cdots\cdots\cdots\cdots (4)$$

The expansion of the determinant of Eq. 4 leads to an nth degree algebraic equation in terms of κ. If n forces are being considered, there will be n values of κ which will satisfy this equation. These n values of κ will be denoted by $\kappa_1, \kappa_2, \cdots, \kappa_n$, taken in order of descending magnitude.

Each of these values of κ_m may now be substituted separately into Eqs. 3. The simultaneous solution of any $n - 1$ equations of Eqs. 3 will then permit the expression of any $n - 1$ of the forces $P_{am}, P_{bm}, \cdots, P_{nm}$ in terms of any one of these forces such as P_{am}. The nth equation of Eqs. 3 may be used to check both κ_m and the solution of the $n - 1$ equations. Since there are n values of κ_m, n sets of characteristic forces exist, which are determined by the foregoing procedure. The complete set of characteristic forces corresponding to κ_m will be denoted by P_m.

There will result then, the following n sets of characteristic forces:

$$\left.\begin{array}{l}
\text{For } \kappa_1, \\
\qquad P_{a1} = P_{a1};\quad P_{b1} = A_{b1}\,P_{a1};\quad \cdots;\quad P_{n1} = A_{n1}\,P_{a1} \\
\text{for } \kappa_2, \\
\qquad P_{a2} = P_{a2};\quad P_{b2} = A_{b2}\,P_{a2};\quad \cdots;\quad P_{n2} = A_{n2}\,P_{a2} \\
\qquad \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\
\text{and, for } \kappa_n, \\
\qquad P_{an} = P_{an};\quad P_{bn} = A_{bn}\,P_{an};\quad \cdots;\quad P_{nn} = A_{nn}\,P_{an}
\end{array}\right\}\ldots\ldots\ldots(5)$$

In Eqs. 5, A_{mn} is a factor by which P_{an} is multiplied to obtain P_{mn}, values of A_{mn} having been determined by the simultaneous solution of $n - 1$ equations of Eqs. 3.

3. Normalizing of Characteristic Forces

In Section 2 methods were presented whereby each set of characteristic forces P_m could be expressed in terms of any one force of the set, such as P_{am}. The relations of Eqs. 5 do not define P_{am}, however, which may be given any value without altering the characteristic aspect of the loads. As a matter of mathematical convenience in the development to follow, P_{am} is chosen arbitrarily so that:

$$(P_{am})^2 + (P_{bm})^2 + \cdots + (P_{nm})^2 = +1 \ldots\ldots\ldots\ldots\ldots(6)$$

To satisfy Eq. 6, substitute values of P_m from Eqs. 5 and solve for P_{am}:

$$P_{am} = \frac{1}{\sqrt{1 + (A_{bm})^2 + \cdots + (A_{nm})^2}} \ldots\ldots\ldots\ldots\ldots(7)$$

When values of P_{am} are determined in this manner, a set of characteristic forces is said to be "normalized." In the following treatment, normalized characteristic forces will be denoted by Q. Thus Q_{mn} represents the normalized characteristic force at m corresponding to $\kappa = \kappa_n$. Similarly, Q_m represents the complete set of normalized characteristic forces for points a, b, $\cdots$, n, corresponding to $\kappa = \kappa_m$. Using this new notation, Eqs. 7, 5, and 6, respectively, should be rewritten as

$$Q_{am} = \frac{1}{\sqrt{1 + (A_{bm})^2 + \cdots + (A_{nm})^2}} \quad \text{(8)}$$

$$\left.\begin{array}{l} \text{For } \kappa_1, \\ \qquad Q_{a1} = Q_{a1}; \quad Q_{b1} = A_{b1}\,Q_{a1}; \quad \cdots; \quad Q_{n1} = A_{n1}\,Q_{a1} \\ \text{for } \kappa_2, \\ \qquad Q_{a2} = Q_{a2}; \quad Q_{b2} = A_{b2}\,Q_{a2}; \quad \cdots; \quad Q_{n2} = A_{n2}\,Q_{a2} \\ \qquad \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ \text{for } \kappa_n, \\ \qquad Q_{an} = Q_{an}; \quad Q_{bn} = A_{bn}\,Q_{an}; \quad \cdots; \quad Q_{nn} = A_{nn}\,Q_{an} \end{array}\right\} \quad \text{(9)}$$

and (see Eq. 6):

$$(Q_{am})^2 + (Q_{bm})^2 + \cdots + (Q_{nm})^2 = +1 \quad \text{(10)}$$

4. Orthogonality of Normalized Characteristic Forces

Suppose that a structure acted upon by one set of normalized characteristic forces Q_m is subjected to a virtual distortion corresponding to the deformation that occurs when a second set of normalized characteristic forces Q_n is applied to the structure. The external virtual work done by the forces Q_m may be expressed by

$$W_{mn} = Q_{am}\,\Delta_{an} + Q_{bm}\,\Delta_{bn} + \cdots + Q_{nm}\,\Delta_{nn} = \kappa_n\,(Q_{am}\,Q_{an} + Q_{bm}\,Q_{bn} + \cdots + Q_{nm}\,Q_{nn}) \quad \text{(11)}$$

Now suppose that the same structure, when acted upon by the forces Q_n, is subjected to a virtual distortion corresponding to the deformation that occurs when the forces Q_m are applied to the structure. The external virtual work done by forces Q_n may be expressed by

$$W_{nm} = Q_{an}\,\Delta_{am} + Q_{bn}\,\Delta_{bm} + \cdots + Q_{nn}\,\Delta_{nm} = \kappa_m\,(Q_{an}\,Q_{am} + Q_{bn}\,Q_{bm} + \cdots + Q_{nn}\,Q_{nm}) \quad \text{(12)}$$

Betti's law[2] states that the virtual work done by a group of external forces R_m during a distortion due to a group of external forces R_n is equal to the virtual work done by the forces R_n during a distortion due to the forces R_m. Hence, W_{mn} and W_{nm} can be equated from Eqs. 11 and 12, respectively, leading to

$$\kappa_n\,(Q_{am}\,Q_{an} + Q_{bm}\,Q_{bn} + \cdots + Q_{nm}\,Q_{nn}) = \kappa_m\,(Q_{an}\,Q_{am} + Q_{bn}\,Q_{bm} + \cdots + Q_{nn}\,Q_{nm}) \quad \text{(13)}$$

Since the parenthetical expressions on the two sides of Eq. 13 are identical, and, since $\kappa_n \neq \kappa_m$, it follows that the equation can be satisfied only when

$$Q_{am}\,Q_{an} + Q_{bm}\,Q_{bn} + \cdots + Q_{nm}\,Q_{nn} = 0 \quad \text{(14)}$$

Thus, for any two sets of normalized characteristic forces, the sum of the cross products of forces applied at the same point vanishes. Thus the two sets of normalized characteristic forces are orthogonal; and orthogonality does not depend on normalizing.

[2] "Theory of Statically Indeterminate Structures," by W. M. Fife and J. B. Wilbur, McGraw-Hill Book Co., Inc., New York, N. Y., 1937, p. 39.

5. First Virtual Work Theorem

Because of the orthogonality of normalized characteristic forces, it follows from Eq. 11 that if $n \neq m$,

$$W_{mn} = \kappa_n(0) = 0 \quad\text{(15)}$$

Thus the external virtual work done by any one set of normalized characteristic forces Q_m, during a distortion caused by any other set of normalized characteristic forces Q_n, is equal to zero. This conclusion will be called the first virtual work theorem for normalized characteristic forces. Its validity does not depend on normalizing.

6. Second Virtual Work Theorem

Assuming that $n = m$, it follows from Eq. 11 that

$$W_{mm} = \kappa_m\left[(Q_{am})^2 + (Q_{bm})^2 + \cdots + (Q_{nm})^2\right] = \kappa_m \quad\text{(16)}$$

since the forces Q_m are normalized. Thus the virtual work done by a given set of normalized characteristic forces Q_m, during a distortion caused by the same set of normalized characteristic forces Q_m, is equal to κ_m. This conclusion will be called "the second virtual work theorem for normalized characteristic forces." Its validity does depend on normalizing.

7. Expression of Actual Forces in Terms of Normalized Characteristic Forces

Referring to Fig. 1, let $R_a, R_b, \cdots, R_n$ be any set of actual forces applied at points a, b, $\cdots$, n, respectively, along the lines of action of the characteristic forces $P_a, P_b, \cdots, P_n$, respectively. These actual forces may be expressed in terms of normalized characteristic forces by superposition as follows:

$$\left.\begin{aligned} R_a &= B_1 Q_{a1} + B_2 Q_{a2} + \cdots + B_n Q_{an} \\ R_b &= B_1 Q_{b1} + B_2 Q_{b2} + \cdots + B_n Q_{bn} \\ &\cdots\cdots\cdots\cdots \\ R_n &= B_1 Q_{n1} + B_2 Q_{n2} + \cdots + B_n Q_{nn} \end{aligned}\right\} \quad\text{(17)}$$

in which $B_1, B_2, \cdots, B_n$ may be called the participation factors for the first, second, $\cdots$, and nth sets of normalized characteristic forces, respectively, with respect to forces $R_a, R_b, \cdots, R_n$. If $R_a, R_b, \cdots, R_n$ are known, the participation factors may be evaluated as follows:

With the forces $R_a, R_b, \cdots, R_n$ acting on the structure, suppose the structure to undergo a virtual distortion due to the further application of the mth set of normalized characteristic forces Q_m. The virtual movements of points a, b, $\cdots$, n will be given respectively by $\Delta_{am} = \kappa_m Q_{am}$; $\Delta_{bm} = \kappa_m Q_{bm}$; $\cdots$; $\Delta_{nm} = \kappa_m Q_{nm}$. The virtual work done by forces $R_a, R_b, \cdots, R_n$ is given by

$$W_{Rm} = R_a \Delta_{am} + R_b \Delta_{bm} + \cdots + R_n \Delta_{nm} = \kappa_m (R_a Q_{am} + R_b Q_{bm} + \cdots + R_n Q_{nm}) \quad\text{(18)}$$

Substituting the relations of Eqs. 17 into Eq. 18 and simplifying:

$$\begin{aligned} W_{Rm} = + \kappa_m \{ & B_1 (Q_{a1} Q_{am} + Q_{b1} Q_{bm} + \cdots + Q_{n1} Q_{nm}) \\ & + B_2 (Q_{a2} Q_{am} + Q_{b2} Q_{bm} + \cdots + Q_{n2} Q_{nm}) \\ & + \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \\ & + B_m [(Q_{am})^2 + (Q_{bm})^2 + \cdots + (Q_{nm})^2] \\ & + B_n (Q_{an} Q_{am} + Q_{bn} Q_{bm} + Q_{nn} Q_{nm}) \} \end{aligned} \tag{19a}$$

From the relations of Eqs. 14 and 10 it follows that

$$W_{Rm} = \kappa_m B_m \tag{19b}$$

Equating Eqs. 18 and 19*b* for W_{Rm} and solving for B_m,

$$B_m = R_a Q_{am} + R_b Q_{bm} + \cdots + R_n Q_{nm} \tag{20}$$

With values of B_m determined by Eq. 20, the superposition of Eqs. 17 is completely defined.

8. Reciprocal Relations

Letting B_m as defined by Eq. 20 be substituted into the *m*th equation of Eqs. 17, and simplifying,

$$\begin{aligned} R_m = & R_a (Q_{a1} Q_{m1} + Q_{a2} Q_{m2} + \cdots + Q_{an} Q_{mn}) \\ & + R_b (Q_{b1} Q_{m1} + Q_{b2} Q_{m2} + \cdots + Q_{bn} Q_{mn}) \\ & + \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \cdot \\ & + R_m [(Q_{m1})^2 + (Q_{m2})^2 + \cdots + (Q_{mn})^2] \\ & + R_n (Q_{n1} Q_{m1} + Q_{n2} Q_{m2} + \cdots + Q_{nn} Q_{mn}) \end{aligned} \tag{21}$$

Eq. 21 must hold irrespective of the values assigned to $R_a, R_b, \cdots, R_n$. Assigning a value to R_m but making all other values of R equal to zero:

$$(Q_{m1})^2 + (Q_{m2})^2 + \cdots + (Q_{mn})^2 = 1 \tag{22}$$

If R_n be assigned a value, but all other values of R be taken as zero:

$$Q_{n1} Q_{m1} + Q_{n2} Q_{m2} + \cdots + Q_{nn} Q_{mn} = 0 \tag{23}$$

In a sense, Eqs. 22 and 23 are reciprocal expressions to Eqs. 10 and 14.

9. Use of Normalized Characteristic Forces in Computing Deflections

Referring to Section 7, let it be required to compute δ_m, the total deflection of point m in the direction of R_m, due to known actual forces $R_a, R_b, \cdots, R_n$. By Eqs. 17 these actual forces may be replaced by the characteristic forces $B_1 Q_1, B_2 Q_2, \cdots, B_n Q_n$. The deflection of point m due to the normalized characteristic forces Q_1 is given by $\Delta_{m1} = \kappa_1 Q_{m1}$. Hence, by superposition,

$$\delta_m = B_1 \kappa_1 Q_{m1} + B_2 \kappa_2 Q_{m2} + \cdots + B_n \kappa_n Q_{mn} \tag{24}$$

10. Choice of Characteristic Redundants

Let it be required to find the redundant stresses $X_a, X_b, \cdots, X_n$ in an indeterminate structure such as that shown in Fig. 2(*a*), due to any condition of external loading or imposed strains such as those caused by temperature changes or pier settlements. These redundant stresses may be considered as external loads acting on a statically determinate primary structure, as shown in Fig. 2(*b*), the values of $X_a, X_b, \cdots, X_n$ being so determined that $\delta_a, \delta_b, \cdots, \delta_n$, which represent the relative movements of points a, b, $\cdots$, n, respectively, due to all causes, are in each instance equal to zero.

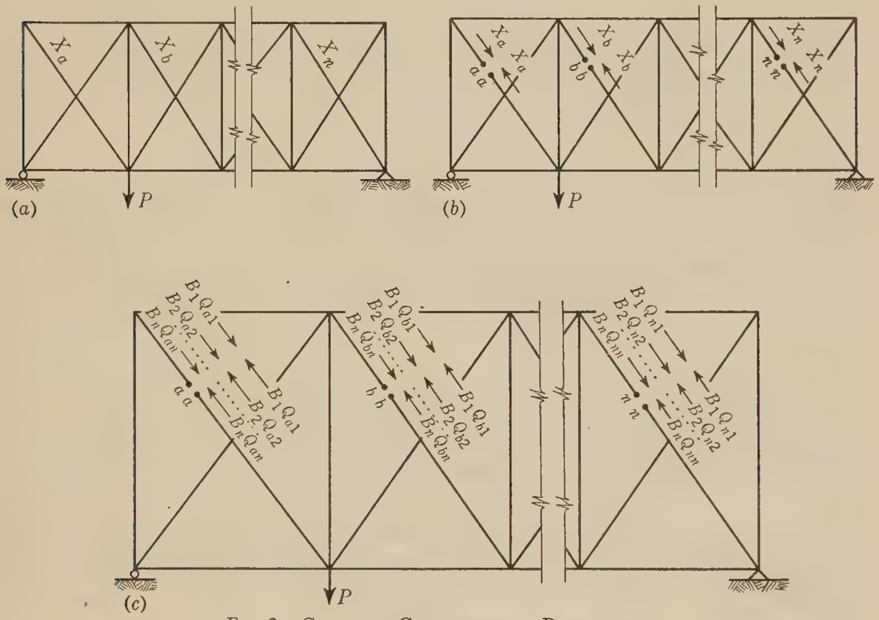

FIG. 2.—CHOICE OF CHARACTERISTIC REDUNDANTS

The redundants $X_a, X_b, \cdots, X_n$, however, may be expressed in terms of normalized characteristic forces, in accordance with Eqs. 17 as follows:

$$\left.\begin{array}{l} X_a = B_1 Q_{a1} + B_2 Q_{a2} + \cdots + B_n Q_{an} \\ X_b = B_1 Q_{b1} + B_2 Q_{b2} + \cdots + B_n Q_{bn} \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ X_n = B_1 Q_{n1} + B_2 Q_{n2} + \cdots + B_n Q_{nn} \end{array}\right\} \quad \cdots\cdots\cdots\cdots (25)$$

Thus one may replace the redundant forces shown in Fig. 2(*b*) with the characteristic forces shown in Fig. 2(*c*), wherein, if the normalized characteristic forces $Q_1, Q_2, \cdots, Q_n$ have previously been determined, the participation factors $B_1, B_2, \cdots, B_n$ are the unknowns that must be determined in order that $X_a, X_b, \cdots, X_n$ may be computed from Eqs. 25.

11. EVALUATION OF PARTICIPATION FACTORS

Since $X_a, X_b, \cdots, X_n$ are not immediately known, values of $B_1, B_2, \cdots, B_n$ cannot be computed by Eq. 20. One may proceed as follows, however:

To evaluate B_m, apply the *m*th set of normalized characteristic forces Q_m, consisting of $Q_{am}, Q_{bm}, \cdots, Q_{nm}$ at points a, b, $\cdots$, n, respectively, as virtual forces that act on the primary structure during its distortion due to all causes combined. Note that Q_{am} consists of a pair of equal and opposite forces applied at points a, etc.

The distortion of the primary structure may be considered as due to three classes of causes:

(*a*) Distortion due to external forces, temperature changes, pier settlements, etc., including all causes except the redundant stresses themselves;

(*b*) Distortion due to the redundant $B_m\,Q_m$ (which consists of forces $B_m\,Q_{am}$, $B_m\,Q_{bm}, \cdots, B_m\,Q_{nm}$); and

(*c*) Distortion due to all other redundants—that is, $B_1\,Q_1, B_2\,Q_2, \cdots, B_n\,Q_n$, but not including $B_m\,Q_m$.

Let $\delta_{ao}, \delta_{bo}, \cdots, \delta_{no}$ be the relative deflections of points a, b, ···, n, respectively, due to the first class of causes, these deflections being taken as positive when they act in the directions of $X_a, X_b, \cdots, X_n$, respectively, as shown in Fig. 2(*b*). Then, assuming the virtual forces Q_m to act in the directions shown in Fig. 2(*c*), the external virtual work done by the virtual forces Q_m during this part of the distortion is given by

$$W_1 = Q_{am}\,\delta_{ao} + Q_{bm}\,\delta_{bo} + \cdots + Q_{nm}\,\delta_{no} = \sum(Q_m\,\delta_{mo}) \ldots\ldots \tag{26a}$$

Due to redundant $B_m\,Q_m$, the external virtual work done by the virtual forces Q_m is seen by the second virtual work theorem (Section 6) to be given by

$$W_2 = B_m\,\kappa_m \ldots\ldots \tag{26b}$$

Due to each of the other redundants, the external virtual work done by the virtual forces Q_m is seen by the first virtual work theorem (Section 5) to be given by

$$W_3 = B_m(0) = 0 \ldots\ldots \tag{26c}$$

The total external virtual work done by the virtual forces Q_m is given by $W_1 + W_2 + W_3$. This total must equal zero since points a, b, ···, n undergo no relative movements when all causes are considered. Hence $\sum(Q_m\,\delta_{mo} + B_m\,\kappa_m) = 0$; and

$$B_m = -\frac{\sum(Q_m\,\delta_{mo})}{\kappa_m} \ldots\ldots \tag{27}$$

For structures in direct stress, if F_{nm} is the stress in any bar of the primary structure due to a unit value of Q_{nm}, and if ΔL is the change of length of any bar of the primary structure due to external loads or temperature changes,

$$\begin{aligned} \sum(Q_m\,\delta_{mo} &= Q_{am}\,\delta_{ao} + Q_{bm}\,\delta_{bo} + \cdots + Q_{nm}\,\delta_{no}) \\ &= Q_{am}\sum(\Delta L\,F_{am} + Q_{bm})\sum(\Delta L\,F_{bm} + \cdots + Q_{nm})\sum(\Delta L\,F_{nm}) \\ &= \sum[\Delta L\,(Q_{am}\,F_{am} + Q_{bm}\,F_{bm} + \cdots + Q_{nm}\,F_{nm})] \ldots\ldots \end{aligned} \tag{28a}$$

but $Q_{am}\,F_{am} + Q_{bm}\,F_{bm} + \cdots + Q_{nm}\,F_{nm}$ equals the stress in any bar of the primary structure due to all the virtual forces Q_m acting simultaneously, and may be denoted by F_m, whence

$$\sum(Q_m\,\delta_{mo}) = \sum(\Delta L\,F_m) \ldots\ldots \tag{28b}$$

Considering only the action of external forces, ΔL is given by

$$\Delta L = \frac{F_o L}{A E} \quad \text{(29)}$$

in which F_o is the stress in any bar of the primary structure due to external forces only. Therefore,

$$\sum (Q_m \delta_{mo}) = \sum \left(\frac{F_o F_m L}{A E} \right) \quad \text{(30)}$$

and Eq. 27 becomes

$$B_m = -\frac{1}{\kappa_m} \sum \left(\frac{F_o F_m L}{A E} \right) \quad \text{(31)}$$

Thus, $B_1, B_2, \cdots, B_n$ may be evaluated by Eq. 27 or 31. Then the redundant stresses $X_a, X_b, \cdots, X_n$ may be determined by Eqs. 25.

It may be noted that, although the determination of characteristic loads involves the solution of Eqs. 3, the evaluation of redundant stresses corresponding to any condition of loading or distortion involves no further solution of simultaneous equations, regardless of the degree to which the structure is statically indeterminate.

12. Illustrative Solution

The use of characteristic redundants in analyzing a statically indeterminate structure is illustrated by an example evaluating the stresses X_a, X_b, and X_c in the structure shown in Fig. 3(*a*). For convenience, assume that for each member, $\frac{L}{A E} = 25$.

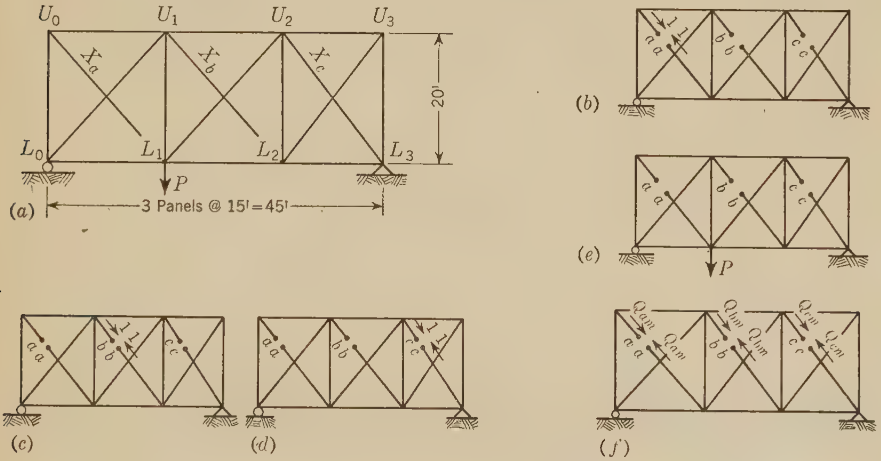

FIG. 3.—ILLUSTRATIVE SOLUTION

Determination of Normalized Characteristic Loads.—Four steps are required to normalize the characteristic loads: (*a*) Evaluation of δ_{mn}; (*b*) evaluation of κ_m; (*c*) determination of characteristic loads; and (*d*) normalizing.

(*a*) Evaluation of δ_{mn} (By Method of Virtual Work).—Let F_{am}, F_{bm}, and F_{cm} be the stresses in any bar due to the condition of loading shown in Figs. 3(*b*), 3(*c*), and 3(*d*), respectively. The computations for δ_{mn} are arranged as shown in Table 1. For example, $\delta_{aa} = \sum\left[\frac{(F_{am})^2\,L}{A\,E}\right] = \sum 25\,(F_{am})^2 = +\,100.$

TABLE 1.—EVALUATION OF δ_{mn}

Σ =	....	....	....	+100	+100	+100	+16	0	+16

Similarly $\delta_{bb} = +\,100$; and $\delta_{cc} = +\,100$. Also, $\delta_{ab} = \delta_{ba} = \sum\left(\frac{F_{am}\,F_{bm}\,L}{A\,E}\right) = \sum 25\,F_{am}\,F_{bm} = +\,16$; $\delta_{ac} = \delta_{ca} = \sum\left(\frac{F_{am}\,F_{cm}\,L}{A\,E}\right) = \sum 25\,F_{am}\,F_{cm} = 0$; and $\delta_{bc} = \delta_{cb} = \sum\left(\frac{F_{bm}\,F_{cm}\,L}{A\,E}\right) = \sum 25\,F_{bm}\,F_{cm} = +\,16.$

(*b*) Evaluation of κ_m (Using Eq. 4).—Eq. 4 becomes—

$$\begin{vmatrix} +\,100 - \kappa; & +\,16 \quad ; & 0 \quad ; \\ +\,16 \quad ; & +\,100 - \kappa; & +\,16 \quad ; \\ 0 \quad ; & +\,16 \quad ; & +\,100 - \kappa; \end{vmatrix} = 0$$

which reduces to

$$(100 - \kappa)\,(+\,9{,}488 - 200\,\kappa + \kappa^2) = 0 \ldots\ldots\ldots\ldots (32)$$

The roots to Eq. 32 are: $\kappa_1 = +\,122.63$; $\kappa_2 = +\,100.00$; and $\kappa_3 = +\,77.37$.

(*c*) Determination of Characteristic Loads (Using Eqs. 3).—For κ_1,

$$\left.\begin{aligned} &(+\,100.00 - 122.63)\,P_{a1} + 16\,P_{b1} = 0; \\ &P_{b1} = +\,\frac{22.63}{16}\,P_{a1} = 1.414\,P_{a1} \doteq \sqrt{2}\,P_{a1}; \qquad (A_{b1} = +\,\sqrt{2}) \\ &+\,16\,P_{b1} + (+\,100.00 - 122.63)\,P_{c1} = 0; \\ &P_{c1} = +\,\frac{16\,P_{b1}}{22.63} = \frac{P_{b1}}{\sqrt{2}} = \frac{\sqrt{2}\,P_{a1}}{\sqrt{2}} = P_{a1}; \qquad (A_{c1} = +\,1) \end{aligned}\right\} \ldots (33a)$$

For κ_2,

$$\left.\begin{aligned}
&(100.00 - 100.00)\,P_{a2} + 16\,P_{b2} = 0; \\
&P_{b2} = \frac{0}{16}\,P_{a2} = 0; \qquad\qquad (A_{b2} = 0) \\
&+16\,P_{a2} + (100.00 - 100.00)\,P_{b2} + 16\,P_{c2} = 0; \\
&P_{c2} = -\frac{16}{16}\,P_{a2} = -P_{a2}; \qquad\qquad (A_{c2} = -1)
\end{aligned}\right\}\ldots(33b)$$

For κ_3,

$$\left.\begin{aligned}
&(+100.00 - 77.37)\,P_{a3} + 16\,P_{b3} = 0; \\
&P_{b3} = -\frac{22.63}{16}\,P_{a3} = -\sqrt{2}\,P_{a3}; \qquad\qquad (A_{b3} = -\sqrt{2}) \\
&+16\,P_{b3} + (+100.00 - 77.37)\,P_{c3} = 0; \\
&P_{c3} = -\frac{16}{22.63}\,P_{b3} = -\frac{P_{b3}}{\sqrt{2}} = -\frac{-\sqrt{2}\,P_{a3}}{\sqrt{2}} = +P_{a3}; \qquad (A_{c3} = +1)
\end{aligned}\right\}\ldots(33c)$$

Hence the characteristic loads are defined by:

$$\left.\begin{aligned}
&P_{a1} = +P_{a1}; \quad P_{b1} = +\sqrt{2}\,P_{a1}; \quad P_{c1} = +P_{a1} \\
&P_{a2} = +P_{a2}; \quad P_{b2} = 0 \qquad\quad ; \quad P_{c2} = -P_{a2} \\
&P_{a3} = +P_{a3}; \quad P_{b3} = -\sqrt{2}\,P_{a3}; \quad P_{c3} = +P_{a3}
\end{aligned}\right\}\ldots\ldots\ldots(34)$$

(*d*) Normalizing of Characteristic Loads.—Substituting in Eq. 8, $Q_a = \frac{1}{\sqrt{1+2+1}} = +\frac{1}{2}$. Similarly, $Q_{a2} = +\frac{1}{\sqrt{2}}$; and $Q_{a3} = +\frac{1}{2}$. Hence, by Eq. 9, the normalized characteristic loads are given by:

$$\left.\begin{aligned}
&Q_{a1} = +\tfrac{1}{2} \quad ; \quad Q_{b1} = +\frac{\sqrt{2}}{2}; \quad Q_{c1} = +\tfrac{1}{2} \\
&Q_{a2} = +\frac{\sqrt{2}}{2}; \quad Q_{b2} = 0 \quad ; \quad Q_{c2} = -\frac{\sqrt{2}}{2} \\
&Q_{a3} = +\tfrac{1}{2} \quad ; \quad Q_{b3} = -\frac{\sqrt{2}}{2}; \quad Q_{c3} = +\tfrac{1}{2}
\end{aligned}\right\}\ldots\ldots\ldots(35)$$

Evaluation of Redundants.—The first step is to determine the value of B_m. Let F_o and F_m be the stress in any bar due to the condition of loading shown in Figs. 3(*e*) and 3(*f*), respectively. Note that the F_m-stresses may be obtained from the F_{am}, F_{bm}, and F_{cm} stresses given in Table 1 by superposition. The arrangement of the computation is shown in Table 2, which supplies the remaining values to be substituted in Eq. 31, thus:

$$\begin{aligned}
B_m &= -\frac{1}{\kappa_m}\sum\left(\frac{F_o\,F_m\,L}{A\;E}\right) = -\frac{1}{\kappa_m}\sum\left(\frac{120\,F_o\,F_m}{120}\right)\times 25 \\
&= -\frac{5}{24\,\kappa_m}\sum(120\,F_o\,F_m)\ldots\ldots\ldots\ldots\ldots\ldots(36)
\end{aligned}$$

Hence, $B_1 = \dfrac{-5\,(-34\,P + 18\sqrt{2}\,P)}{24\,(+122.63)} = +0.0145\ P$. Similarly, $B_2 = +0.4890\,P$ and $B_3 = +0.1601\,P$. The redundants are then determined by substitution in Eqs. 25, thus:

$$X_a = +0.0145\,P\,(+\tfrac{1}{2}) + 0.4890\,P\left(+\frac{\sqrt{2}}{2}\right) + 0.1601\,P\,(+\tfrac{1}{2}) = +0.4330\,P.$$

Similarly, $X_b = -0.1030\,P$ and $X_c = -0.2586\,P$.

TABLE 2.—EVALUATION OF B_m

Bar	$12\,F_o$	$10\,F_1$	$10\,F_2$	$10\,F_3$	$120\,F_oF_1$	$120\,F_oF_2$	$120\,F_oF_3$

U_2L_3	0	$+5$	$-5\sqrt{2}$	$+5$	0	0	0
L_2U_3	$+5\,P$	$+5$	$-5\sqrt{2}$	$+5$	$+25\,P$	$-25\sqrt{2}\,P$	$+25\,P$
$\Sigma =$	....	....	....	....	$-34\,P+18\sqrt{2}\,P$	$-166\sqrt{2}\,P$	$-34\,P-18\sqrt{2}\,P$

It will be noted that the additional computation required to investigate a second condition of loading is not very great, since modifying the F_o-stresses will change only a part of the computation for B_m and consequently only a part of the final step.

13. ALTERNATE METHOD OF ANALYZING STATICALLY INDETERMINATE STRUCTURES BY MEANS OF CHARACTERISTIC FORCES

If the number of independent components of displacement for a structure is less than the degree to which the structure is statically indeterminate, it may be desirable to modify the details of the analysis.

Characteristic forces which correspond to the independent components of distortion may be determined and normalized. For the actual external loading condition to be investigated, participation factors for the normalized characteristic forces may be evaluated. Deflections of the points of application of these forces may then be computed, following which, the evaluation of stresses in the structure is straightforward.

Suppose, for example, it is required that the end moments in the frame of Fig. 4(*a*) be determined, due to the load P acting as shown. Corresponding to the three independent components of distortion θ_A, θ_B, and d, there will be considered as a set of characteristic forces the external moments X_a, X_b, and the external force X_c, respectively, acting as shown in Fig. 4(*b*).

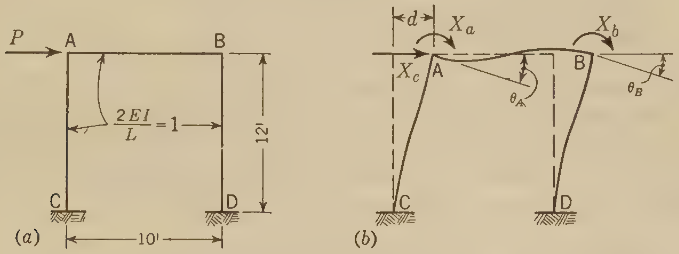

FIG. 4.—ALTERNATE METHOD OF ANALYSIS

By statics, the following three equations may be written:

$$\left.\begin{aligned} +12\,X_e + M_{AC} + M_{CA} + M_{BD} + M_{DB} &= 0\\ +\ X_a\ - M_{AB} - M_{AC} &= 0\\ +\ X_b\ - M_{BA} - M_{BD} &= 0 \end{aligned}\right\}\ldots\ldots\ldots\ldots(37)$$

Expressing end moments by the slope deflection equations, these reduce to

$$\left.\begin{aligned} 12\,X_e + 3\,\theta_A + 3\,\theta_B - d &= 0\\ 4\,X_a + 16\,\theta_A - 4\,\theta_B + d &= 0\\ 4\,X_b - 4\,\theta_A - 16\,\theta_B + d &= 0 \end{aligned}\right\}\ldots\ldots\ldots\ldots(38)$$

By Eq. 1, since X_a, X_b, and X_e are characteristic forces, $d = \kappa\,X_e$; $\theta_A = \kappa\,X_a$, and $\theta_B = \kappa\,X_b$, whence

$$\left.\begin{aligned} 3\,\kappa\,X_a + 3\,\kappa\,X_b + (12-\kappa)\,X_e &= 0\\ (4-16\,\kappa)\,X_a - 4\,\kappa\,X_b + \kappa\,X_e &= 0\\ -4\,\kappa\,X_a + (4-16\,\kappa)\,X_b + \kappa\,X_e &= 0 \end{aligned}\right\}\ldots\ldots\ldots\ldots(39)$$

Eqs. 39 correspond to Eqs. 3, and Eq. 4 becomes

$$\begin{vmatrix} +3\,\kappa & ; & +3\,\kappa & ; & +12-\kappa\\ +4-16\,\kappa & ; & -4\,\kappa & ; & +\kappa\\ -4\,\kappa & ; & +4-16\,\kappa & ; & +\kappa \end{vmatrix} = 0\ldots\ldots\ldots\ldots(40)$$

the roots to which are: $\kappa_1 = +17.23$; $\kappa_2 = +0.3333$; and $\kappa_3 = +0.1990$. Successively substituting these values of κ into Eqs. 39, the characteristic forces are determined as follows:

$$\left.\begin{aligned} X_{a1} &= +X_{a1}; & X_{b1} &= +X_{a1}; & X_{c1} &= +19.77\,X_{a1}\\ X_{a2} &= +X_{a2}; & X_{b2} &= -X_{a2}; & X_{c2} &= 0\\ X_{a3} &= +X_{a3}; & X_{b3} &= +X_{a3}; & X_{c3} &= -0.1012\,X_{a3} \end{aligned}\right\}\ldots\ldots\ldots(41)$$

Using Eq. 8 to normalize the characteristic forces,

$$Q_{a1} = \frac{1}{\sqrt{1+(+1)^2+(+19.77)^2}} = +0.0505.$$

Likewise, $Q_{a2} = +0.7071$ and $Q_{a3} = +0.7053$. The normalized characteristic forces are, therefore,

$$\left.\begin{array}{lll} Q_{a1} = +0.0505; & Q_{b1} = +0.0505; & Q_{c1} = +0.9975 \\ Q_{a2} = +0.7071; & Q_{b2} = -0.7071; & Q_{c2} = 0 \\ Q_{a3} = +0.7053; & Q_{b3} = +0.7053; & Q_{c3} = -0.0714 \end{array}\right\} \qquad (42)$$

The participation factors to be applied to each of these sets of normalized characteristic forces in order that they may correspond to the loading shown in Fig. 4(*a*) are now computed by Eq. 20: $B_1 = P\,Q_{c1} = +0.9975\,P$; $B_2 = P\,Q_{c2} = 0$; and $B_3 = P\,Q_{c3} = -0.0714\,P$. The independent components of distortion for this condition of loading are now computed by Eq. 24:

$$\left.\begin{array}{rl} \theta_A = & +0.9975\,P\,(+17.23)\,(+0.0505) \\ & \quad -0.0714\,P\,(+0.1990)\,(+0.7053) = +0.857\,P \\ \theta_B = & +0.9975\,P\,(+17.23)\,(+0.0505) \\ & \quad -0.0714\,P\,(+0.1990)\,(+0.7053) = +0.857\,P \\ d = & +0.9975\,P\,(+17.23)\,(+0.9975) \\ & \quad -0.0714\,P\,(+0.1990)\,(-0.0714) = +17.14\,P \end{array}\right\} \qquad (43)$$

Therefore, $\psi = \dfrac{d}{12} = +1.428\,P$ and the end moments in the frame are as follows:

$$\left.\begin{array}{l} M_{AB} = 2\,\theta_A + \theta_B = 3\,(+0.857\,P) = +2.571\,P = M_{BA} \\ M_{AC} = 2\,\theta_A - 3\,\psi = 2\,(+0.857\,P) - 3\,(+1.428\,P) = -2.571\,P = M_{BD} \\ M_{CA} = \theta_A - 3\,\psi = +0.857\,P - 3\,(+1.428\,P) = -3.428\,P = M_{DB} \end{array}\right\} \quad (44)$$

14. INTERDEPENDENCY OF CHARACTERISTIC FORCES

For the general case, Eqs. 3 consist of n simultaneous equations with n unknowns. The solution then requires the evaluation of the nth order determinant of Eq. 4 and, for each of the n roots κ thus obtained, the simultaneous solution of $n - 1$ equations of Eqs. 3.

Under certain circumstances, however, the points of application and the directions of characteristic forces may be such that the n equations of Eqs. 3 may break down into two or more groups, each of which may be solved by itself. For example, one might obtain for Eqs. 3, for five forces P_a, P_b, $\cdots$, P_e:

$$P_a\,(\delta_{aa} - \kappa) + P_b\,\delta_{ab} = 0 \qquad (45a)$$

$$P_a\,\delta_{ba} + P_b\,(\delta_{bb} - \kappa) = 0 \qquad (45b)$$

$$P_c\,(\delta_{cc} - \kappa) + P_d\,\delta_{cd} + P_e\,\delta_{ce} = 0 \qquad (45c)$$

$$P_c\,\delta_{dc} + P_d\,(\delta_{dd} - \kappa) + P_e\,\delta_{de} = 0 \qquad (45d)$$

and

$$P_c\,\delta_{ec} + P_d\,\delta_{ed} + P_e\,(\delta_{ee} - \kappa) = 0 \qquad (45e)$$

This condition would arise, for example, if neither of the forces P_a or P_b caused displacements at points c, d, or e along the lines of action of any of the forces

P_c, P_d, or P_e, respectively. In Eqs. 45 there are two separate groups. Eqs. 45*a* and 45*b* may be solved together, involving only a second-order determinant. From these two equations two sets of characteristic forces are found, for each of which P_a and P_b have values, whereas P_c, P_d, and P_e are zero. Eqs. 45*c*, 45*d*, and 45*e* may then be solved together, involving a third-order determinant. From these three equations three sets of characteristic forces are found, for each of which P_c, P_d, and P_e have values, whereas P_a and P_b are zero.

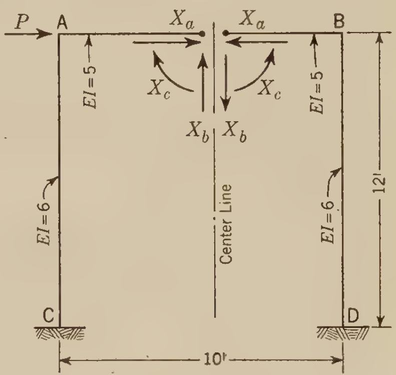

FIG. 5

When Eqs. 3 break down in this manner, a considerable saving in computation is possible, as is illustrated with reference to the structure of Fig. 4(*a*), by taking the redundants as shown in Fig. 5. Values of δ_{mn} may be determined by the usual methods of structural analysis, leading to

$$\left.\begin{array}{lll} \delta_{aa} = +192; & \delta_{ab} = \quad 0\;; & \delta_{ac} = +24 \\ \delta_{ba} = \quad 0; & \delta_{bb} = +116.6; & \delta_{bc} = \quad 0 \\ \delta_{ca} = +\;24; & \delta_{cb} = \quad 0\;; & \delta_{cc} = +\;6 \end{array}\right\} \qquad (46)$$

Eqs. 3 become:

$$P_a(+192 - \kappa) + P_c(+24) = 0 \qquad (47a)$$

$$P_b(+116.6 - \kappa) = 0 \qquad (47b)$$

$$P_a(+24) + P_c(+6 - \kappa) = 0 \qquad (47c)$$

First, solving Eq. 47*b* directly, $\kappa_2 = +116.6$ and $P_{b2} = +P_{b2}$. Next, solving Eqs. 47*a* and 47*c* simultaneously,

$$\begin{vmatrix} +192 - \kappa; & +24 \\ +\;24\quad; & +6-\kappa \end{vmatrix} = 0$$

which reduces to $\kappa^2 - 198\,\kappa + 576 = 0$, from which $\kappa_1 = +195$ and $\kappa_3 = +2.95$. For $\kappa_1 = +195$,

$$\left.\begin{array}{l} P_{a1} = +P_{a1}; \quad P_{c1} = +0.127\,P_{a1} \\ \text{and, for } \kappa_3 = +2.95, \\ P_{a3} = +P_{a3}; \quad P_{c3} = -7.88\,P_{a3} \end{array}\right\} \qquad (48)$$

By Eq. 8, $Q_{a1} = +0.992 \left(= \dfrac{1}{\sqrt{1 + (0.127)^2}} \right)$; $Q_{b2} = +1.000$; and Q_{a3}

$= +0.126$. Thus the normalized characteristic forces are:

$$\left.\begin{array}{ll}
\text{For } \kappa_1 = +195, & \\
& Q_{a1} = +0.992; \quad Q_{c1} = +0.126 \\
\text{for } \kappa_2 = +116.6, & \\
& Q_{b2} = +1.000 \\
\text{and, for } \kappa_3 = +6.00, & \\
& Q_{a3} = +0.126; \quad Q_{c3} = -0.992
\end{array}\right\} \dots\dots\dots\dots\dots (49)$$

By the usual methods of structural analysis, the following deflections due to load P may be obtained: $\delta_{ao} = +96\,P$; $\delta_{bo} = -60\,P$; $\delta_{co} = +12\,P$. Then, by Eq. 27:

$$\left.\begin{aligned}
B_1 &= -\frac{1}{195}\left[+0.992\,(+96\,P) + 0.126\,(+12\,P)\right] = -0.496\,P \\
B_2 &= -\frac{1}{116.6}\left[+1.000\,(-60\,P)\right] = +0.514\,P \\
B_3 &= -\frac{1}{6.00}\left[+0.126\,(+96\,P) - 0.992\,(+12\,P)\right] = -0.063\,P
\end{aligned}\right\} \quad (50)$$

and, by Eqs. 25:

$$\left.\begin{aligned}
X_a &= -0.496\,P\,(+0.992) - 0.063\,P\,(+0.126) = -0.500\,P \\
X_b &= +0.514\,P\,(+1.000) = +0.514\,P \\
X_c &= -0.496\,P\,(+0.126) - 0.063\,P\,(-0.992) = 0
\end{aligned}\right\} \dots (51)$$

The end moments in the members of the frame may now be computed by statics, and will be found to equal those obtained in Section 13.

15. Use of Characteristic Redundants Acting at Elastic Center

In the analysis of a fixed end arch, it is well known that the redundants may be advantageously taken as acting at the elastic center of the arch. The resulting solution may be interpreted as one wherein the redundants are characteristic forces, chosen in such a manner that Eqs. 3 break down into three independent equations. To illustrate the foregoing, consider the structure of Fig. 4(*a*) by taking the redundants as acting at the elastic center as shown in Fig. 6, and applying the procedures developed in this paper. For this structure, the elastic center lies on the vertical axis of symmetry for the structure, and 4.00 ft below the girder AB.

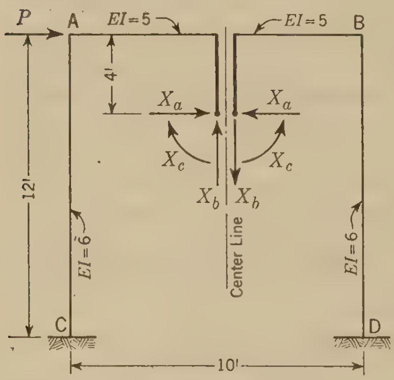

Fig. 6

Values of δ_{mn} may be determined by the usual methods of structural analysis, leading to:

$$\left.\begin{array}{lll}
\delta_{aa} = +96.0; & \delta_{ab} = 0\;; & \delta_{ac} = 0 \\
\delta_{ba} = 0\;; & \delta_{bb} = +116.6; & \delta_{bc} = 0 \\
\delta_{ca} = 0\;; & \delta_{cb} = 0\;; & \delta_{cc} = +6.00
\end{array}\right\} \dots\dots\dots (52)$$

Eqs. 3 become:

$$\left.\begin{aligned} P_a\,(+96.0-\kappa)&=0\\ P_b\,(+116.6-\kappa)&=0\\ P_c\,(+6.00-\kappa)&=0 \end{aligned}\right\}\qquad(53)$$

Solving these equations separately:

$$\left.\begin{aligned} \kappa_1&=+116.6; & P_{b1}&=+P_{b1}\\ \kappa_2&=+\ \ 96.0; & P_{a2}&=+P_{a2}\\ \kappa_3&=+\ \ 6.00; & P_{c3}&=+P_{c3} \end{aligned}\right\}\qquad(54)$$

Application of Eq. 8 leads to the following sets of normalized characteristic loads: $Q_{b1}=\frac{1}{\sqrt{1}}=+1$; $Q_{a2}=\frac{1}{\sqrt{1}}=+1$; and $Q_{c3}=\frac{1}{\sqrt{1}}=+1$. By the usual methods of structural analysis, the following deflections due to load P may be obtained: $\delta_{ao}=+48\,P$; $\delta_{bo}=-60\,P$; and $\delta_{co}=+12\,P$. Then, by Eq. 27:

$$\left.\begin{aligned} B_1&=-\frac{1}{116.6}(+1)(-60\,P)=+0.514\,P\\ B_2&=-\frac{1}{96.0}\ (+1)(+48\,P)=-0.500\,P\\ B_3&=-\frac{1}{6.00}\ (+1)(+12\,P)=-2.000\,P \end{aligned}\right\}\qquad(55)$$

and, by Eqs. 25,

$$\left.\begin{aligned} X_a&=-0.500\,P\,(+1)=-0.500\,P\\ X_b&=+0.514\,P\,(+1)=+0.514\,P\\ X_c&=-2.000\,P\,(+1)=-2.000\,P \end{aligned}\right\}\qquad(56)$$

The end moments in the members of the frame may now be computed by statics, and will be found to equal those obtained in Section 13.

16. Remarks Concerning Solution of Eqs. 3

In Section 2, it was assumed that all values of κ were real and separate. In all solutions made by the writer, values of κ have been real. Should imaginary values of κ be encountered, it is believed that the physical conditions stated by Eqs. 3 are impossible of fulfilment, and that as a result the analysis cannot properly be applied. It is considered doubtful that this condition will arise.

It is possible for two or more values of κ to be equal numerically, however, although this condition is infrequent. Suppose that of the n values of κ, a given value κ' appears m times. It will then be found that only $n-m$ equations of Eqs. 3 are independent when κ' is substituted, so that only $n-m$ values of P can be expressed in terms of the remaining m values of P. This leaves $m-1$ degrees of freedom for each value of κ', so that $m\,(m-1)$ further conditions must be imposed. These conditions must lead to m separate sets of characteristic forces, which must be mutually orthogonal. Within the limitation of these requirements, arbitrary conditions may be imposed, since

Eqs. 3 will be satisfied. The foregoing may be illustrated by the following example: Consider the equations

$$\left.\begin{array}{r} (10.62 - \kappa)\, P_a - 2.25\, P_b - 2.25\, P_c + 0.88\, P_d = 0 \\ - 2.25\, P_a + (10.62 - \kappa)\, P_b + 0.88\, P_c - 2.25\, P_d = 0 \\ - 2.25\, P_a + 0.88\, P_b + (10.62 - \kappa)\, P_c - 2.25\, P_d = 0 \\ + 0.88\, P_a - 2.25\, P_b - 2.25\, P_c + (10.62 - \kappa)\, P_d = 0 \end{array}\right\} \ldots\ldots (57)$$

The determinant formed by the coefficients to forces P reduces to: $(\kappa - 16.00)(\kappa - 9.74)^2 (\kappa - 7.00) = 0$. The roots are: $\kappa_1 = + 16.00$; $\kappa_2 = + 9.74$; $\kappa_3 = + 9.74$; and $\kappa_4 = + 7.00$. When the double root $\kappa_2 = \kappa_3 = + 9.74$ is substituted into Eqs. 57, only two independent equations are formed, which reduce to

$$P_a = - P_d \quad \text{and} \quad P_b = - P_c \ldots\ldots (58a)$$

Since Eqs. 58*a* do not define the relations between P_a and P_b, any assumption may be made regarding this relation, and Eqs. 57 will be satisfied. Suppose that for one set of characteristic forces, one such assumption is made arbitrarily, such as $P_b = C\, P_a$, in which C is a numerical factor. This arbitrary assumption defines the following set of characteristic forces:

$$P_a = + P_a; \quad P_b = + C\, P_a; \quad P_c = - C\, P_a; \quad \text{and} \quad P_d = - P_a \ldots (58b)$$

For the second set of characteristic forces, a second assumption such as $P_b = D\, P_a$ may be made, in which D is another numerical factor which cannot, however, be chosen arbitrarily. This defines the second set of characteristic forces as:

$$P_a = + P_a; \quad P_b = + D\, P_a; \quad P_c = - D\, P_a; \quad \text{and} \quad P_d = - P_a \ldots (58c)$$

The two sets of characteristic forces defined by Eqs. 58*b* and 58*c* must satisfy the orthogonal requirements of Eq. 14, whence

$$\begin{array}{l} (+ P_a)(+ P_a) + (+ C\, P_a)(+ D\, P_a) \\ \quad + (- C\, P_a)(- D\, P_a) + (- P_a)(- P_a) = 0 \ldots\ldots (59) \end{array}$$

and $D = - 1/C$. Thus for κ_2, for example, one may choose C as $- 1$ arbitrarily; that is, one may select $P_b = - P_a$, thus defining the first set of characteristic forces as:

$$P_{a2} = + P_{a2}; \quad P_{b2} = - P_{a2}; \quad P_{c2} = + P_{a2}; \quad \text{and} \quad P_{d2} = - P_{a2} \ldots (60a)$$

Then for κ_3, D must be computed from the relation $D = - 1/C = - 1/- 1 = + 1$, thus leading to the second set of characteristic forces:

$$P_{a3} = + P_{a3}; \quad P_{b3} = + P_{a3}; \quad P_{c3} = - P_{a3}; \quad \text{and} \quad P_{d3} = - P_{a3} \ldots (60b)$$

Since these two sets of characteristic forces are both associated with the same numerical value of κ, the distinction as to which shall be given the subscript 2 and which the subscript 3 is arbitrary. A different assumption as to the value of C would have led to different sets of characteristic forces, but it is believed that the over-all solution would not be modified thereby.

17. ALTERNATE BASIS FOR ORTHOGONALITY

In the treatment to this subject, sets of characteristic forces have been used, which were orthogonal with respect to each other. It is not necessary that the orthogonality exist between sets of forces; an alternate basis for procedure would be to operate on sets of forces so chosen that the qth set of forces is orthogonal with respect to the deflections caused by the rth set of forces. This condition may be illustrated by the equation

$$S_{aq}\,\Delta_{ar} + S_{bq}\,\Delta_{br} + \cdots + S_{nq}\,\Delta_{nr} = 0 \qquad (61)$$

In Eq. 61, the force applied at point m, of the qth set of such forces, is denoted by S_{mq}; Δ_{mr} denotes the total deflection at point m due to the rth set of such forces.

If n such sets of forces, each composed of n forces, are to be determined, there are in all n^2 forces to which values must be assigned. For the first, second, $\cdots$, nth sets of forces one may arbitrarily assign $n, n-1, n-2, \cdots, 1$ forces, respectively, the only limitation in assigning these values being that each set of forces shall be independent with respect to the other sets. The remaining forces, which consist of $0, 1, \cdots, n-1$ forces for the first, second, $\cdots$, nth sets of forces, respectively, must be computed on the basis of Eq. 61; this will necessitate the respective solution of $0, 1, \cdots, n-1$ sets of simultaneous equations. By the judicious choice of the $\frac{n}{2}(n+1)$ arbitrary values to be assigned (such as by assigning values of $+1$ and 0), the amount of computation in arriving at the $\frac{n}{2}(n-1)$ dependent values may be greatly reduced.

In a truss statically indeterminate to the nth degree, let the redundant stresses $X_a, X_b, \cdots, X_n$ be expressed in terms of such forces by superposition, as follows:

$$\left.\begin{array}{l} X_a = C_1\,S_{a1} + C_2\,S_{a2} + \cdots + C_n\,S_{an} \\ X_b = C_1\,S_{b1} + C_2\,S_{b2} + \cdots + C_n\,S_{bn} \\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot \\ X_n = C_1\,S_{n1} + C_2\,S_{n2} + \cdots + C_n\,S_{nn} \end{array}\right\} \qquad (62)$$

in which $C_1, C_2, \cdots, C_n$ are participation factors for the 1st, 2d, $\cdots$, nth sets of forces, respectively. Let the set of forces $S_{aq}, S_{bq}, \cdots, S_{nq}$ be denoted by S_q; let the total stress in any bar due to S_q acting on the primary structure be denoted by F_q. Let F_o be the total stress in any bar due to external loads acting on the primary structure.

Suppose the primary structure, acted upon by the external loads and by all the redundants $C_1\,S_1, C_2\,S_2, \cdots, C_n\,S_n$, be subjected to a virtual distortion due to an increase in the value of C_m by ΔC_m. Then the redundant $C_m\,S_m$ will do external virtual work which may be expressed by

$$\begin{aligned} W_1 = {} & C_m\,F_{am}\,(\Delta C_m\,\Delta_{am}) + C_m\,F_{bm}\,(\Delta C_m\,\Delta_{bm}) + \cdots \\ & + C_m\,F_{nm}\,(\Delta C_m\,\Delta_{nm}) = \Delta C_m\,C_m \sum (F_m\,\Delta_m) \qquad (63a) \end{aligned}$$

The other redundants will do no external virtual work in accordance with Eq. 61. The external loads will do external virtual work, which may be expressed by

$$W_2 = \Delta C_m \sum\left(\frac{F_o F_m L}{A E}\right) \qquad \text{(63}b\text{)}$$

Thus the total external virtual work, which equals zero, is given by $W_1 + W_2$, whence

$$C_m = -\frac{\sum\left(\frac{F_o F_m L}{A E}\right)}{\sum(F_m \Delta_m)} \qquad (64)$$

Hence if n sets of forces satisfying Eq. 61 can be obtained, Eqs. 64 and 62 lead to the evaluation of $X_a, X_b, \cdots, X_n$. The manner in which these n sets of forces may be obtained, as well as the application of this entire procedure, may be illustrated by a consideration of the structure of Fig. 3(a), for which $\frac{L}{A E} = 25$ for each member. By the usual methods of structural analysis (see Section 12) the following values of δ_{mn} are obtained:

$$\left.\begin{array}{lll} \delta_{aa} = +100; & \delta_{ab} = +16; & \delta_{ac} = 0 \\ \delta_{ba} = +16; & \delta_{bb} = +100; & \delta_{bc} = +16 \\ \delta_{ca} = 0; & \delta_{cb} = +16; & \delta_{cc} = +100 \end{array}\right\} \qquad (65)$$

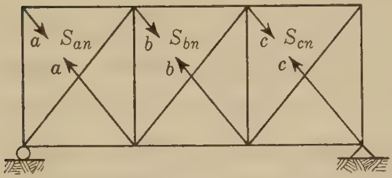

FIG. 7

Referring to Fig. 7, the first set of forces will be arbitrarily chosen as: $S_{a1} = +1$; $S_{b1} = 0$; and $S_{c1} = 0$. Then

$$\left.\begin{array}{l} \Delta_{a1} = +1\,(\delta_{aa}) = +100 \\ \Delta_{b1} = +1\,(\delta_{ba}) = +16 \\ \Delta_{c1} = +1\,(\delta_{ca}) = 0 \end{array}\right\} \qquad (66)$$

The second set of forces, by inspection, is: $S_{a2} = 0$; $S_{b2} = 0$; and $S_{c2} = +1$. For these forces: $\Delta_{a2} = +1\,(\delta_{ac}) = 0$; $\Delta_{b2} = +1\,(\delta_{bc}) = +16$; and $\Delta_{c2} = +1\,(\delta_{cc}) = +100$ so that Eq. 61 is obviously satisfied. For the third set of forces, $S_{b3} = +1$ is selected arbitrarily but S_{a3} and S_{c3} must be computed so as to satisfy Eq. 61. Considering the first and third sets of forces: $S_{a3}\,(+100) + 1\,(+16) + S_{c3}\,(0) = 0$; and $S_{a3} = -0.160$. Considering the second and third sets of forces: $S_{a3}\,(0) + 1\,(+16) + S_{c3}\,(+100) = 0$; and $S_{c3} = -0.160$. For the S_3 forces:

$$\left.\begin{array}{l} \Delta_{a3} = -0.160\,\delta_{aa} + 1.000\,\delta_{ab} - 0.160\,\delta_{ac} = 0 \\ \Delta_{b3} = -0.160\,\delta_{ba} + 1.000\,\delta_{bb} - 0.160\,\delta_{bc} = +94.88 \\ \Delta_{c3} = -0.160\,\delta_{ca} + 1.000\,\delta_{cb} - 0.160\,\delta_{cc} = 0 \end{array}\right\} \qquad (67)$$

To summarize, the three sets of forces are:

For S_1,

$$S_{a1} = +1; \quad S_{b1} = 0; \quad S_{c1} = 0$$

for S_2,

$$S_{a2} = 0; \quad S_{b2} = 0; \quad S_{c2} = +1$$

and, for S_3,

$$S_{a3} = -0.160; \quad S_{b3} = +1; \quad S_{c3} = -0.160 \qquad (68)$$

The total deflections due to these forces are, respectively:

For S_1,

for S_2,

and, for S_3,

$$\left.\begin{aligned} &\Delta_{a1} = +100; \quad \Delta_{b1} = +16\ \ ; \quad \Delta_{c1} = 0 \\ &\Delta_{a2} = 0; \quad \Delta_{b2} = +16\ \ ; \quad \Delta_{c2} = +100 \\ &\Delta_{a3} = 0; \quad \Delta_{b3} = +94.88; \quad \Delta_{c3} = 0 \end{aligned}\right\} \ldots\ldots\ldots (69)$$

Values of $\sum\left(\frac{F_o F_m L}{A E}\right)$ are obtained from Table 3 wherein values of F_o may be obtained by statics. Values of F_m are also obtainable by statics; they may be obtained by superposition from stresses due to unit values of X_a, X_b, and X_c, which will already be available, since they will have been used (see Section 12) in evaluating δ_{mn}. For substitution into Eq. 64: $\sum\left(\frac{F_o F_1 L}{A E}\right) = -1.667\,P\,(25) = -41.7\,P$; $\sum\left(\frac{F_o F_2 L}{A E}\right) = +1.101\,P\,(25) = +27.5\,P$; and $\sum\left(\frac{F_o F_3 L}{A E}\right) = +0.390\,P\,(25) = +9.75\,P$. Further,

TABLE 3.—EVALUATION OF C_m; ALTERNATE BASIS

Bar	F_o	F_1	F_2	F_3	$F_o F_1$	$F_o F_2$	$F_o F_3$
L_0L_1	+0.500 P	−0.600	....	+0.096	−0.300 P	....	+0.048 P
L_1L_2	+0.250 P	....	....	−0.600	....	....	−0.150 P
L_2L_3	....	....	−0.600	+0.096	....	....	....
U_0U_1	....	−0.600	....	+0.096	....	....	....
U_1U_2	−0.500 P	....	....	−0.600	....	....	+0.300 P
U_2U_3	−0.250 P	....	−0.600	+0.096	....	+0.150 P	−0.024 P
L_0U_0	....	−0.800	....	+0.128	....	....	....
L_1U_1	+0.667 P	−0.800	....	−0.672	−0.534 P	....	−0.448 P
L_2U_2	−0.333 P	....	−0.800	−0.672	....	+0.267 P	+0.224 P
L_3U_3	−0.333 P	....	−0.800	+0.128	....	+0.267 P	−0.043 P
U_0L_1	....	+1.000	....	−0.160	....	....	....
L_0U_1	−0.833 P	+1.000	....	−0.160	−0.833 P	....	+0.133
U_1L_2	....	....	....	+1.000	....	....	....
L_1U_2	+0.417 P	....	....	+1.000	....	....	+0.417 P
U_2L_3	....	....	+1.000	−0.160	....	....	....
L_2U_3	+0.417 P	....	+1.000	−0.160	....	+0.417 P	−0.067 P
Σ =	....	....	....	....	−1.667 P	+1.101 P	+0.390 P

$$\left.\begin{aligned} \sum(F_1\,\Delta_1) &= +1\,(+100) + 0\,(+16) + 0\,(0) = +100 \\ \sum(F_2\,\Delta_2) &= +0\,(0) + 0\,(+16) + 1\,(+100) = +100 \\ \sum(F_3\,\Delta_3) &= -0.160\,(0) + 1\,(+94.88) - 0.160\,(0) = +94.88 \end{aligned}\right\} \ldots (70)$$

Hence, by Eq. 64:

$$C_1 = -\frac{-41.7\,P}{+100} = +0.417\,P; \quad C_2 = -\frac{+27.5\,P}{+100} = -0.275\,P;$$

and

$$C_3 = -\frac{+9.75\,P}{+94.88} = -0.103\,P.$$

Finally, by Eqs. 62:

$$\left.\begin{aligned} X_a &= +0.417\,P\,(+1) - 0.275\,P\,(0) - 0.103\,P\,(-0.160) = +0.433\,P \\ X_b &= +0.417\,P\,(0) - 0.275\,P\,(0) - 0.103\,P\,(+1) \qquad\qquad = -0.103\,P \\ X_c &= +0.417\,P\,(0) - 0.275\,P\,(+1) - 0.103\,P\,(-0.160) = -0.259\,P \end{aligned}\right\} \quad (71)$$

A further condition could have been imposed with respect to each set of S forces:

$$S_{aq}\,\Delta_{aq} + S_{bq}\,\Delta_{bq} + \cdots + S_{nq}\,\Delta_{nq} = +1 \ldots\ldots\ldots\ldots (72)$$

This would amount to normalizing each set of forces with respect to the deflections caused by that set of forces. The detail of the solution would then change slightly; if T replaces S to indicate that Eq. 72 has been observed, and if F_m is interpreted as the stress in any bar due to T_m acting on the primary structure, Eq. 63*a* becomes $W_1 = \Delta C_m\,C_m$ and Eq. 63*b* remains unchanged. The denominator $\sum(F_m\,\Delta_m)$ then drops out of Eq. 64. In Eqs. 62, S should now be replaced by T.

This type of solution is possible for any degree of indeterminacy of a structure, although admittedly the labor involved in determining sets of forces which satisfy Eq. 61 would increase rather rapidly with the number of unknowns. Once such sets of forces have been established, however, the redundant stresses may be determined without further recourse to simultaneous equations. This is the same advantage that is gained by use of the elastic center, which, however, is limited in its direct benefits to structures with three or fewer redundants.

18. Conclusion

The purpose of this paper has been to present some of the principles involved in making use of orthogonal forces in the analysis of statically indeterminate structures. Illustrative examples demonstrate these principles, but the structures analyzed were chosen because of their suitability for illustrating principles rather than because their solution by the methods discussed was advantageous.

Structural engineers have been using orthogonal forces for some time in various analyses, but, in some instances, perhaps, without realizing that they were doing so. It is hoped that the presentation of this paper will stimulate further consideration of the possible advantages that may be obtained by their use.

Mechanics,[4] prepared by committees of the American Standards Association, with Society representation, and approved by the Association in 1932 and 1942, respectively:

A = a factor in Eq. 5; A_{mn} is a factor by which P_{an} is multiplied to obtain P_{mn}; also (see Eq. 30), A = cross-section area of a structural member;
B = a participation factor in Eq. 17; $B_1, B_2, \cdots, B_n$ are participation factors for the first, second, and nth sets of normalized characteristic forces, $R_a, R_b, \cdots, R_n$, respectively;
C = a numerical factor in Eq. 58*b*; also, $C_1, C_2, \cdots, C_n$ are participation factors (Eq. 62) for the sets of forces $S_1, S_2, \cdots, S_n$, respectively;
D = a numerical factor in Eq. 58*c*;
d = lateral distortion of the top of a column (Fig. 4(*b*));
E = modulus of elasticity;
F = total internal stress in a member; thus, F_{nm} is the stress in any bar of the primary structure due to a unit value of Q_{nm}; F_o is the stress in any bar of the primary structure due to external forces only;
I = moment of inertia;
L = length of a structural member;
m = a number of times that the value κ' appears in an equation; also used as a general integer;
n = a number in a series; thus, $1, 2, \cdots, n$; or $a, b, \cdots, n$;
P = an external load (Eq. 2);
Q = a normalized characteristic force; thus, Q_{am} (Eq. 8) represents the complete set of normalized characteristic forces for point a, corresponding to κ_m;
q = a particular set of forces S (Eq. 61);
R = resultant external forces (Eq. 18);
r = a particular set of forces S (Eq. 61);
S = set of forces; S_{mq} is the force applied at point m, of the qth set of such forces;
T = set of forces to replace S in Eq. 72; T_m is a load applied to the primary structure which produces a stress F_m;
W = external virtual work; W_{mn} is the external virtual work done by the forces Q_m when a structure acted upon by one set of forces Q_m is subjected to a virtual distortion corresponding to the deformation that occurs when a second set of forces Q_n is applied to the structure;
X = redundant total stress;
Δ = total deflection; Δ_n is the total deflection at point n in the direction of P_n due to forces $P_a, P_b, \cdots, P_n$;
δ = deflection due to unit load; δ_{mn} is the deflection at any point m in the direction of P_m, due to a unit value of P_n;
θ = angular distortion, the subscript denoting point of rotation;
κ = a proportionality factor; κ' is a given value of κ that occurs m times for every n occurrences of κ;
ψ = a rotation factor in Eq. 44.

DISCUSSION

CHARLES A. ELLIS,[5] M. AM. SOC. C. E.—The author expresses the hope that the methods presented in his paper will be of interest because they differ so radically from the usual methods. That they differ no one will deny. Whether they will stimulate interest is a matter of individual opinion.

The great amount of labor involved in giving birth to the concept of his paper is a monument to the ingenuity and patience of the author, who, in his "Theory of Statically Indeterminate Structures,"[6] has shown a decided preference for the principles of least work and virtual work which, although sound in theory, are mathematical abstractions. They permit neither physical conception nor space perception which are so helpful in the understanding and application of any principle or method.

Had the author simplified or clarified these two principles he would have done the profession some service; but, on the contrary, his method requires seven pages and thirty-one formulas or equations for its development. Two applications of the method are made to a truss having redundant members. Three pages, seven equations, and two tables are required for the first application in section 12; and three pages, thirteen equations, and one table, for the alternate application in section 17—and all of it is fairly "tough meat."

The writer prefers the principle of deflections in solving all types of statically indeterminate structures. There are at least four methods of application, including area moments, expression of moments in terms of angular rotations (commonly called the slope deflection method), and moment distribution, all of which are well known to structural engineers. The fourth method—the method of Williot equations—is not so well known. In 1934 he published the first application of his method to the towers of Golden Gate Bridge;[7] and in the same year he derived the Williot equations for the three most common types of quadrilateral units to be found in parallel and inclined chord trusses and trestle bents.[8] Each of these three units has two diagonal members. The equations are derived from the geometrical properties of a Williot diagram for each unit, and give the relation between the strains of the six members in each unit.

A four-panel parallel chord truss having two diagonals in each panel is solved by the methods of least work, virtual work, and Williot equations, showing a comparison of the labor involved in each solution. This method will be used in solving the stresses in the author's similar redundant structure shown in Fig. 3(*a*), and the following equation, stated in words, is applicable:[9]

[7] "Williot Equations for Statically Indeterminate Structures," by Charles A. Ellis, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 580.

[8] "Simplified Analysis of Indeterminate Frames," by Charles A. Ellis, *Engineering News-Record*, April 26, 1934, p. 534.

[9] "Simplified Analysis of Indeterminate Frames," by Charles A. Ellis, *ibid.*, April 26, 1934, p. 534, Eq. 2.

The sum of the strains in the two diagonals multiplied by cosec θ equals the sum of the strains in the two horizontal members multiplied by cot θ, plus the sum of the strains in the two vertical members, where θ is the angle between the diagonal and the horizontal member. ..(73)

Let the quantities, $5\,a$, $5\,b$, and $5\,c$, represent, respectively, the assumed tensile stresses in the three redundant members U_0L_1, U_1L_2, and U_2L_3 caused by the load P at L_1. The computed stresses are as follows:

Member	Stress
L_0L_1	$\frac{1}{2}P - 3\,a$
L_1L_2	$\frac{1}{4}P - 3\,b$
L_2L_3	$-3\,c$
U_0U_1	$-3\,a$
U_1U_2	$-\frac{1}{2}P - 3\,b$
U_2U_3	$-\frac{1}{4}P - 3\,c$
U_0L_0	$-4\,a$
U_1L_1	$\frac{2}{3}P - 4\,a - 4\,b$
U_2L_2	$-\frac{1}{3}P - 4\,b - 4\,c$
U_3L_3	$-\frac{1}{3}P - 4\,c$
U_0L_1	$+5\,a$
L_0U_1	$-\frac{5}{6}P + 5\,a$
U_1L_2	$+5\,b$
L_1U_2	$\frac{5}{12}P + 5\,b$
U_2L_3	$+5\,c$
L_2U_3	$\frac{5}{12}P + 5\,c$

The author assumes a constant value for $\frac{L}{A\,E} = 25$ for each member. In any ordinary truss of the same material throughout, E is constant and $\frac{L}{A}$ a variable. In this case the stress in each member should be multiplied by $\frac{L}{A}$ for the member, to give a quantity proportional to the strain. In this problem each stress is proportional to the strain, and the factor 25, which would appear in all terms of the Williot equation, may be canceled. Substituting in Eq. 73 (in which cosec $\theta = \frac{5}{4}$ and cot $\theta = \frac{3}{4}$):

For the left panel—

$$\left(-\tfrac{5}{6}P + 10\,a\right)\tfrac{5}{4} = \left(\tfrac{1}{2}P - 6\,a\right)\tfrac{3}{4} + \tfrac{2}{3}P - 8\,a - 4\,b \quad\ldots.(74a)$$

for the middle panel—

$$\left(\tfrac{5}{12}P + 10\,b\right)\tfrac{5}{4} = \left(-\tfrac{1}{4}P - 6\,b\right)\tfrac{3}{4} + \tfrac{1}{3}P - 4\,a - 8\,b - 4\,c \quad..(74b)$$

for the right panel—

$$\left(\tfrac{5}{12}P + 10\,c\right)\tfrac{5}{4} = \left(-\tfrac{1}{4}P - 6\,c\right)\tfrac{3}{4} - \tfrac{2}{3}P - 4\,b - 8\,c \quad\ldots.(74c)$$

Equs. 74 reduce to

$$100\,a + 16\,b = \tfrac{50}{6}P \quad\ldots\ldots\ldots\ldots(75a)$$

$$16\,a + 100\,b + 16\,c = -\tfrac{9}{6}P \quad\ldots\ldots\ldots\ldots(75b)$$

and

$$16\,b + 100\,c = -\tfrac{33}{6}\,P \quad \ldots\ldots (75c)$$

whence—

$$\begin{aligned} a &= 0.0866\,P, & 5\,a &= 0.433\,P \\ b &= -\,0.0206\,P, & 5\,b &= -\,0.103\,P \\ c &= -\,0.0517\,P, & 5\,c &= -\,0.2585\,P \end{aligned}$$

—which agrees with the author's solution for the stresses in the redundant members.

Eqs. 75 have one peculiarity in common with slope deflection equations in that the coefficient of one unknown quantity in each equation is large in comparison with the coefficients of the other unknowns in the same equation. The unknown values in equations having this peculiarity converge rapidly when solved by a series of approximations. The solution of slope deflection equations by approximations is analogous to the approximations made in moment distribution. However, when only a few equations are involved, the ordinary methods of solution are quicker.

The rectangular arch which the author shows in section 13 may be solved much more quickly by any one of the first three methods of the principle of deflections previously mentioned.

The author is aware, of course, that his solutions are long and considerably involved in comparison with usual methods. He states that the purpose of his paper is to present some of the principles involved in using orthogonal forces. What the writer would very much like to see is a problem or two for which this method is shorter and therefore superior to usual methods; or perhaps a problem, for which other methods are impotent, that may be solved by this method alone.

Ralph W. Stewart,[10] M. Am. Soc. C. E.—The bending moments in the symmetrical portal frame analyzed in this paper (see Fig. 4) were computed from a full page or more of equations and formulas containing three X-values, two θ-values, one d-value, one κ-value, and nine Q-values. These moments can be obtained from two readings at one setting of a slide rule and a little easy mental arithmetic by sketching a traverse of the elastic curves of this frame (Fig. 8). This traverse diagram shows at a glance that three sevenths of the sum of the moments in either column goes to the top of the column and four sevenths to the bottom. From symmetry and the fact that the sum of all column moments must equal the lateral force multiplied by the frame height:

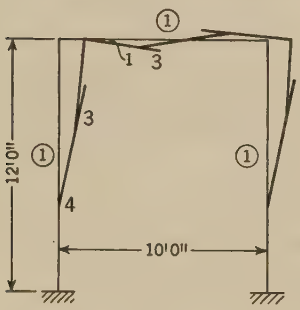

Fig. 8

$$\begin{aligned} \text{Moment at A} &= 3/7 \times 6\,P = 2.5714\,P \\ \text{Moment at C} &= 4/7 \times 6\,P = 3.4286\,P \\ \hline \text{Total (check)} &= 6.0000\,P \end{aligned}$$

---

[10] Bridge Engr., City of Los Angeles, Los Angeles, Calif.

This one-minute solution uses two constants of flexure, one moment balance, and one traverse closure. The author's solution requires three simultaneous equations with sixteen symbols.

Unless a type of problem can be presented for which the method of characteristic redundants is superior to other methods, the writer feels that the paper presents a method which has some value as a mathematical exercise but is not of value as a practical method of computing stresses.

MYLE J. HOLLEY, JR.,[11] ESQ.—A new method for the solution of statically indeterminate structures is suggested in this paper. In addition, an entirely new line of reasoning is introduced which may yield valuable concepts and methods beyond those illustrated by the author. Practical application of the method, along the lines suggested, should prove it more advantageous than conventional methods for some special problems, and, in addition, from such application may develop even more potent analytical methods. For this reason, it is to be hoped that some members of the profession will be encouraged to apply the method to practical problems.

The method of characteristic redundants for the solution of statically indeterminate trusses offers a reduction in the effort of solving simultaneous equations. This gain results from (*a*) the fact that only one set of simultaneous equations need be solved, regardless of the number of different loadings for which the structure is to be analyzed, and (*b*) the fact that there is one less equation in the simultaneous set that must be solved than there would be if a conventional approach were used.

The disadvantages of the method are that it requires the solution of a polynomial equation for the determination of characteristic forces, and that it also requires a substantially larger amount of tabular work for the determination of the participation factors. With these relative advantages and disadvantages in mind one might use the following criteria in deciding whether the author's method would be worth while in a particular case:

1. If the structure is indeterminate to a small degree, the new method will not prove advantageous, even if there are many loadings to be investigated.
2. If the structure is indeterminate to a large degree but only one, or at most a very few, separate loadings must be considered, the method will not prove advantageous.
3. If the structure is indeterminate to a large degree, and there are several separate loadings to be investigated, the method may prove advantageous.

The writer realizes that the foregoing criteria are very crude, but if the analyst follows some such reasoning before starting he may avoid an unfair test of the author's method and may also save himself considerable effort. Of course, only the experience resulting from actual analyses can refine these criteria to a point where they will give critical combinations of the degree-of-indeterminacy and number-of-loadings.

Although the writer can visualize no case in which it would be practicable to use characteristic redundants to determine deflections, it may be of academic interest to point out that this could easily be done. If the deflection of a point at which there is no load is desired, or if the deflection at a loading point in a direction other than that of the actual load is desired, the characteristic set would include a characteristic load at the point in question, in the direction of the desired deflection, as well as a characteristic load at each loading point in the direction of the actual load. The characteristic load at the deflection point will be removed by the participation factors in the superposition process which results in the actual loading. The writer believes, however, that such a procedure would be far more laborious than any of the conventional methods of determining deflections. This is in no way a criticism of the paper, which (as its title indicates) presents a method for analyzing indeterminate structures (not a method for finding deflections) and, for this purpose, the writer believes that the method holds real promise.

---

[11] With S. Morgan Smith Co., Rutland, Vt.

M. W. Huggins,[12] Esq.—The skill displayed in producing this intricate and interesting solution to a complex problem is deserving of high praise. The aim of the author, which was to find what he calls "the heart of the multiply indeterminate solution" (see "Synopsis") and by means of which the analysis of any indeterminate frame is reduced to the solution of one system of simultaneous equations for all loadings, is a laudable one. Unfortunately, the solution obtained has not simplified the analysis of such frames. On the contrary, for most cases, it has added to the complexity of the analysis. It seems quite within the realm of possibility, however, that some future development of the method may serve to simplify the steps.

It would appear that the Wilbur method is in much the same category as the "relaxation method,"[13] proposed by Prof. R. V. Southwell. As an extension of the principles of moment distribution to the solution of multiply redundant trussed frames, Professor Southwell's method was first developed to simplify the analysis of dirigible frames. In it, stresses are determined by a series of approximations, but, unlike the method of moment distribution, the approximations do not converge readily. In fact, considerable skill and patience are required in solving even some of the simpler frames. In spite of this, the method seems to hold promise and has the important advantage that it eliminates, completely, the solution of simultaneous equations. It may be used to analyze any problem which normally involves the solution of simultaneous equations. As with the method proposed by Professor Wilbur, it has its greatest advantage when used to analyze one frame for several different, separate types of loading.

Leon Beskin,[14] Assoc. M. Am. Soc. C. E.—An attempt is made in this paper to apply to statically indeterminate structures a method of calculation which is highly successful in various fields of applied mathematics. The fundamentals of this method, as presented by the author in Sections 1 to 11 and 16 and 17, can be found in various good mathematical treatises;[15,16,17,18] the material in Section 16, however, lacks precision inasmuch as Professor Wilbur does not apply to his problem the classical properties of definite quadratic forms which constitute the basis of the method. This attempt to transpose into the field of statically indeterminate structures a method which is essential in other fields is not successful, due to the fact that the problems to be solved in the case of statically indeterminate structures are considerably simpler than those for which the method has been developed. Only in some special cases, most of which are already well known, does the method present definite advantages. Similar developments were presented in 1907 by S. Müller[19] and in 1944 W. M. Kincaid and V. Morkovin[20] presented a straightforward method of "orthogonalization" limited to the case of rigid frames.

To define the type of problem examined by the author, it must be remembered that the strain energy of a system is a quadratic function of redundants, and can be represented by an ellipse (two redundants), a quadric (three redundants), or a generalized quadric in a hyperspace (more than three redundants), these curves or surfaces corresponding to a determinate value of the strain energy.

The quadratic function is minimum at the center of the quadric, the coordinates of which represent the actual values of the redundants. The solution of a system of linear equations deduced from the condition of minimum strain energy is tantamount to the determination of that center.

Actually, the author examines two methods of determining that center. The first is the study of the principal axes of the quadric, which is of interest when these principal axes are needed as such—for instance, in problems of vibration, in which these axes represent the periods of vibration. When these quantities have no special interest, this method is much too complicated, since it requires the solution of an algebraic equation, the degree of which is equal to the number of redundants. The author has devoted more space to this method than it deserves.

The second method, which is specifically called orthogonalization of linear equations, is the study of an arbitrary set of conjugate axes of the same quadric—a much simpler problem than the first. Once these axes are defined, it is extremely simple to find the coordinates of the center, which are given by independent linear equations, containing one unknown each. This method, to be an improvement, must be shorter than the conventional method involving the direct solution of linear equations. It substitutes for the solution of n linear equations with n unknowns the solution of the sequence, $n - 1$ equa-

tions, $n - 2$ equations, . . . 1 equation. A comparison of the number of operations shows that the method is advantageous only for four unknowns or less. For these small numbers of unknowns, the additional work required by the preparation of the method offsets the theoretical advantage, except when simple formulas can be established for all problems related to a given type of structure (for example, the centroid and principal axes of a beam section or the elastic center in a rigid frame).

Moreover, the most efficient provision for solving simultaneous equations is the Gauss method, a remarkably simple application of which was presented by P. D. Crout[21] in 1941. The Gauss method is a systematic method of eliminating unknowns,[22] which is at the same time a method of orthogonalization. This method is so expeditious that other methods are never justified except when special physical interpretations make them easier to understand, or when further computations require some intermediate steps which the Gauss method by-passes. A few examples are offered to demonstrate the special conditions under which orthogonalization along a definite physical pattern is useful and also to indicate when research involving the principal axes is justifiable.

The problem involving combined bending and direct load is a case in point. When moments are taken with respect to the centroid, the property of orthogonalization will appear; that is, moments then produce only rotation and direct loads produce only translation.

In the general case of bending, the principal axes of inertia have the property of orthogonality—namely, that bending around an axis produces rotation around that axis. In this case, principal directions are defined, thus requiring the solution of an equation of second degree, although, in the previous condition (combined bending and direct load), principal directions are not defined because of their lack of physical significance. In combined bending and direct load, an orthogonal system of the third order is defined.

A more complex case of orthogonalization, introduced in the analysis of open cylindrical shells (aircraft structures and cylindrical roofs of the Zeiss-Dywidag type), is that of torsion bending. When these structures are subjected to twisting forces, transmission of torque produces axial stresses, which can also be produced by externally applied direct forces with no resultant and no resulting couple. These direct forces constitute a mechanical entity which the writer has called a "bicouple."[23] The distribution of stresses under arbitrary forces is determined by a method of orthogonalization, which defines, successively, the direct resultant, two couples at the centroid (along principal axes), and a bicouple in reference to the shear center. The orthogonalization is of the fourth order in this case.

A well-known case of the third order is that of frames. This problem is generally treated by the use of an elastic center, but sometimes it is presented as a case of orthogonalization (complex bending and direct load), and is then called the beam-column analogy.

[23] "Stress Analysis of Open Cylindrical Membranes," by Leon Beskin, *Journal of the Aeronautical Sciences*, Vol. 11, No. 4, October, 1944, pp. 343–355.

The writer has also examined the case of the two-story frame, leading to an orthogonalization of the sixth order,[24] which reduces to a fourth-order and a second-order problem, when the frame is symmetrical.

Incomplete orthogonalization is also used. The three-moment equation for continuous beams is an example: All moments at supports are orthogonal, except moments at three consecutive supports; the two-moment equation (conjugate point method[25]) is an improvement on the three-moment theorem, since only two consecutive moments are not orthogonal to each other. The method can be applied a second time, and new moments can be defined, which are entirely orthogonal to one another.

In all these problems, orthogonalization is justified because it has a physical significance. Incomplete orthogonalization is a compromise which greatly reduces the numerical work necessary to solve simultaneous equations, without introducing additional complications in the preparation of these equations. It is obtained by a rational choice of unknowns which, once established, does not require either any additional computation (continuous beams), or very little additional computation (centroid, elastic center), every time the method is applied.

Sometimes, also, the choice of unknowns facilitates handling equations by reducing the values of the rectangle terms (such as δ_{ab} in Eqs. 2) as compared with those on the first diagonal (δ_{aa}, δ_{bb}, $\cdots$). Then, the solution of the simultaneous equations is less sensitive to small errors in the determination of coefficients δ and in the subsequent numerical computation. This makes it possible to use a slide rule instead of a computing machine. The redundants are chosen in such a manner that the regions of the structure on which they act simultaneously are reduced to a minimum. For instance, considering a structure on elastic supports of various rigidities, it is inadvisable to use as an unknown the reaction of a very flexible support, which greatly increases all the coefficients of the simultaneous equations so that the coupling, represented by $\frac{\delta_{ab}}{\sqrt{\delta_{aa}\,\delta_{bb}}}$, is nearly equal to 1.

The foregoing comments show the broad advantages and limitations of orthogonalization. Details of the method presented by the author will next be examined.

As has already been indicated, Sections 1 to 13 are devoted to a method of determining natural frequencies. This method is also used, when the elastic stability of a structure is considered, to determine critical loads; these loads correspond to zero frequency. The author applies this method to the condition in which all masses and mass moments of inertia are equal to 1. Then the coefficients κ are the reciprocals of the squares of the frequencies ω:

$$\kappa_i = \frac{1}{(\omega_i)^2} \qquad \text{(76a)}$$

---

[24] "Rings for Two Decked Airplanes," by L. Beskin, *Aircraft Engineering*, London, England (publication pending).

[25] "Moments in Restrained and Continuous Beams by the Method of Conjugate Points," by L. H. Nishkian and D. B. Steinman, *Transactions*, Am. Soc. C. E., Vol. 90 (1927), pp. 1–206.

Eq. 76*a* shows that the set of conditions, expressed by Eqs. 1, is unduly restrictive, and that the actual set should be

$$\Delta_{ji} = \frac{\kappa_i}{m_j} P_{ji} \qquad \text{(76b)}$$

in which m_j is a generalized mass at point j (mass if Δ_{ji} is a translation and P_{ji} is a force; and mass moment of inertia, if Δ_{ji} is a rotation and P_{ji} is a couple).

Then, n solutions are found in exactly the same manner as the author's solutions, the latter corresponding to $m_j = 1$. It is obvious that, when couples and forces are used simultaneously (Section 13), the condition $m_j = 1$ leads to coefficients κ which have indefinite units, since they are $F^{-1} L$ for translations and forces and $F^{-1} L^{-1}$ for rotations and couples. Thus, the author's solution is not homogeneous and changes with the choice of the unit length. For instance, a cantilever loaded at the end by a load P and a couple C has a deflection δ and a rotation ϕ:

$$\delta = \frac{P L^3}{3 E I} + \frac{C L^2}{2 E I} = \kappa P \qquad \text{(77a)}$$

and

$$\phi = \frac{P L^2}{2 E I} + \frac{C L}{E I} = \kappa C \qquad \text{(77b)}$$

which gives:

$$\frac{\kappa E I}{L} = \frac{1 + \frac{L^2}{3} \pm \sqrt{1 + \frac{L^2}{3} + \frac{L^4}{9}}}{2} \qquad \text{(78)}$$

If coefficients κ with zero dimension are chosen—for instance,

$$\delta = \frac{\kappa L^2 P}{3 E I} \qquad \text{(79a)}$$

and

$$\phi = \frac{\kappa L C}{E I} \qquad \text{(79b)}$$

—then:

$$\kappa = 1 \pm \frac{\sqrt{3}}{2} \qquad \text{(80)}$$

Remarks Concerning Solution of Eqs. 3.—Some of the statements in Section 16 must be examined. For example, concerning the first paragraph of that section, it is well known that the strain energy of an elastic solid is always a definite positive quadratic function, either of the forces or of the displacements. This means that all coefficients κ are real and, moreover, positive. In other words, all vibration modes are real. Thus, an elastic system of the type examined is always stable. This statement is true when the strain energy is of the form $\frac{1}{2} \Sigma(P \Delta)$. Then, the effect of the change of configuration under load is neglected, which is not the case when problems of elastic stability are examined. It is understood that such cases are not considered by the author, since he uses Eqs. 2 to define displacements.

For the case of equal roots Professor Wilbur's examination of κ is incomplete. When there are two equal roots, the determinant that yields κ can be reduced to the second order by eliminating other roots, thus:

$$(\kappa - a_{11})\,(\kappa - a_{22}) - (a_{12})^2 = 0 \qquad (81)$$

Eq. 81 has equal roots only if

$$(a_{11} - a_{22})^2 = -\,(a_{12})^2 \qquad (82)$$

which requires that $a_{11} = a_{22}$ and that $a_{12} = 0$.

The physical significance of Eq. 82 is that the two corresponding frequencies must be equal. This will happen in any system, if masses are chosen in a correct manner, and will occur for a definite configuration when the dimensions have determinate values.

For instance, in Fig. 9, let a mass be placed at the elastic center, which coincides with the extreme end, E, of the beam. The deflections are:

$$\delta = \frac{P\,L^3}{E\,I}\,\frac{1 + \sqrt{2}}{3\,\sqrt{2}} \qquad (83a)$$

and

$$\phi = \frac{C\,L}{E\,I}\,(1 + \sqrt{2}) \qquad (83b)$$

If the radius of gyration of the end mass is $\bar{r} = \dfrac{L}{\sqrt{3\,\sqrt{2}}}$ ($\bar{r} = 0.486\,L$), the two frequencies are equal. By the author's method, the two values of κ coincide when $\bar{r} = 1$, making $L = \sqrt{3\,\sqrt{2}} = 2.06$. This value is independent of the unit of length. Thus, if the computation is in inches, the cantilever equal to 2.06 in. has the exceptional property that its coefficients κ are equal. If the computation is in yards, a cantilever 74 in. long has the same exceptional property. It is obvious that this is a characteristic that has nothing to do with the structure, but merely with the choice of units. This effect can be eliminated by choosing other units. In other words, the condition imposed by multiple roots is generally of no significance for the problem examined by the author, despite the fact that it has a physical significance in the problem of natural frequencies.

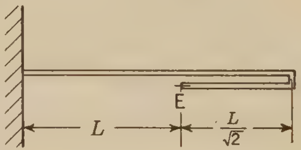

FIG. 9

When consistent units are used, multiple roots may have a physical significance. For instance, if the problem of general bending and axial force is examined in connection with a beam having equal moments of inertia in two directions, there are no principal directions; or, more exactly, all sets of mutually perpendicular axes can be assumed to be principal directions. It is simple and logical, in that case, to choose the principal axes of references as principal axes. The author examines two solutions (see Eqs. 59 and 60)—P_{a2}, $C\,P_{a2}$; and P_{a3}, $-\dfrac{1}{C}P_{a3}$—which define two perpendicular directions in the case of a beam. Factors C and $-1/C$ are the tangents of the angles of the principal directions with the initial axes. The logical choice in that case is P_{a2}, 0; and

0, P_{b2}. Then, instead of defining orthogonal systems by such complex formulas as Eqs. 60, the orthogonal system can be defined by:

$$P_{a2} = P_{a2}; \qquad P_{b2} = 0; \qquad P_{c2} = 0; \qquad P_{d2} = -P_{a2} \ldots\ldots (84a)$$

and

$$P_{a2} = 0; \qquad P_{b2} = P_{b2}; \qquad P_{c2} = -P_{b2}; \qquad P_{d2} = 0 \ldots\ldots (84b)$$

Characteristic Forces.—The first sentence in Section 13 is incorrect, unless the author has in mind a special definition of independent components of displacements. The latter are defined conventionally as the differences between the total number of displacements and the number of equations of statics. Moreover, for the example shown in Fig. 4, the author indicates (see third paragraph, Section 13) that there are three independent components of distortion, and it is well known that a built-in frame is redundant to the third order. Thus, the example is not consistent with the first sentence of Section 13, the meaning of which is obscure.

Alternate Basis.—The approach used in Section 17 is much simpler than that used in the remainder of the paper, and (as has been indicated) is the correct method for nearly all the problems considered here. It is correct to state that a judicious choice of arbitrary values simplifies the determination of dependent values; but simplification is generally obtained not by using values 0 or +1, as stated by the author, but by finding orthogonal groups from physical considerations, such as symmetry, antisymmetry, and polar multiaxial symmetry. In Section 14, the author examines such cases of simplification, but does not connect them with Section 17.

It is useful to clarify the connection between the two methods, seemingly independent in the author's presentation. This connection is very simple when the author's nonhomogeneous special relations (Eqs. 1) are replaced by Eq. 76*b*. Then, if a system is orthogonalized in an arbitrary manner by the second method, there will be a system of values m_j which will satisfy n systems of Eq. 76*b*, written successively for the n independent sets of values obtained by the method of orthogonalization. In Figs. 3 and 7, the values $1/m_j$ can be chosen equal to 1, 1, 0, and the values ω^2 can be taken as 1/100, 0, 1/100. In this case, there are indeterminate quantities 0/0, which can be defined by continuity from orthogonal sets differing from the solution selected, by infinitely small deviations.

These considerations show why the second method is simpler than the first: The system of masses m_j can have arbitrary values in the second method, whereas these masses are equal to 1 in the first. This determination of masses necessitates the solution of an equation of degree n, otherwise useless.

The advantage claimed in the last paragraph of Section 17 is purely fictitious. Experience in manipulating simultaneous equations reveals that, once the unknowns have been eliminated for a given set of loads (second members of the equations), the supplementary work necessary to find the redundancies in other loading conditions is extremely slight. When many loading conditions are contemplated (more than the order of redundancy), the use of unit conditions for the second members reduces the work in great proportions, and, if Mr. Crout's method is applied, this supplementary work is negligible.

FREDERICK S. MERRITT,[26] JUN. AM. SOC. C. E.—Although the purpose of this paper was to present some of the principles involved in utilizing orthogonal forces, the value of the paper as a contribution to structural theory suffers because:

(1) The terminology involved is awkward;
(2) The visualization of the physical processes signified by each step in the calculations is difficult, if not impossible;
(3) In addition to requiring the computation of constants which are used in other well-known methods, this theory requires the solution of simultaneous equations plus the determination of the roots of an nth-degree algebraic equation; and
(4) The one advantage claimed (after the characteristic forces have been found, redundant stresses may be evaluated without the further solution of simultaneous equations) is not exclusive.

The idea underlying advantage (4), however, is of extreme importance to structural theory and deserves further elaboration.

Whether this method of analyzing statically indeterminate structures, using orthogonal forces, can be improved so that it can stand on equal terms with procedures such as the "Dummy Unit Load Method" is questionable. On the other hand, the principles outlined in this paper may be a start in the right direction, especially if the subject of characteristic redundants is approached from another angle than that of orthogonal forces.

(1) A change in viewpoint may improve the terminology. The use of such words as "characteristic forces," "normalizing," and "orthogonality," although mathematically expressive, is discouraging from a structural viewpoint, because certain physical properties are implied which, unfortunately, have no connection with the structure being analyzed. Actually, an abstract mathematical operation is involved. If these terms were more closely related to structural action, their use would not be so awkward.

(2) A different approach may correlate, to a greater extent, the conception of characteristic redundants with the structural action involved. Such correlation is a desirable goal in all structural problems since it provides a continuous check on computations; but it is a goal that cannot always be achieved. As the method is presented, a mass of computation is required to determine A_{mn}, a quantity which, although it is essential to this method, has no immediately perceivable relation to any physical action in the structure. If a relation can be established, the principle involved in using orthogonal forces would be simplified considerably. After a study of the formulas for normalizing and orthogonalizing, the question naturally arises as to whether the concept of vectors and tensors could establish such a desirable relationship. For example, Eq. 10 indicates that Q_{nm} could be the component of a unit vector $\mathbf{Q}_\mathrm{m}$, and, thus, Eq. 14 is the vector equation, $\mathbf{Q}_\mathrm{m} \cdot \mathbf{Q}_\mathrm{n} = 0$, $n \neq m$. If $\mathbf{Q}_\mathrm{m}$ could be shown to have some meaning structurally and if the participation factors are related vectorially to $\mathbf{Q}_\mathrm{m}$, a clearer picture of the principle involved in this method would result.

---

[26] With *Engineering News-Record,* New York, N. Y.

(3) By approaching the problem in a different manner, the solution of simultaneous equations may possibly be avoided or the number of equations may be considerably decreased, much as moment distribution methods have succeeded in doing for continuous, statically indeterminate beams and frames. A vectorial approach, involving the selection of suitable axes to simplify the resolution into components of a vector such as Q_m, may be indicated. However, there are other possibilities in methods not involving characteristic forces.

(4) A change in the method of analysis will not spoil the advantage that, once characteristic forces have been found, redundant stresses may be evaluated without the further solution of simultaneous equations. Almost all the well-known methods possess this advantage because the equations may generally be written so that the coefficients of the unknowns depend solely on the structural framework and are independent of loads or distortions.

However, this advantage is not to be belittled. For example, the popular method of fixed-end moment distribution (which, in general, does not require the solution of simultaneous equations) requires that whenever the load is changed either influence computations must be made in the first place or the structure must be analyzed again. In schoolroom problems, this may not be much of a handicap, but in practical design, where the stresses resulting from dead load, live load, wind forces, longitudinal and lateral forces, earth pressure, earthquake, temperature, shrinkage, and settlement must be determined separately, reanalysis is a big handicap and characteristic redundants are definitely advantageous.

The characteristic redundants need not be orthogonal forces, or even forces at all. This is suggested in the paper by the alternate basis for orthogonality, in which forces and deflections are involved. Deflections alone could be used. Whether or not in the general case the use of deflections would simplify the problem will have to be determined. Such a possibility is indicated by the use of end rotations in the solution of problems involving continuous, statically indeterminate beams and frames.

For example, in the method of moment distribution, by means of moment ratios, advantage is taken of the fact that the ratio of the moment induced at one end of an unloaded span of a continuous structure to the moment "carried over" to the other end is a constant independent of the magnitude of the moments. This ratio is a characteristic redundant in the same sense as the characteristic forces described by Professor Wilbur. By using it, the solution of simultaneous equations is reduced to a minimum or entirely eliminated. Offhand, the moment ratio in a given span might be considered a sort of characteristic force, but, actually, it is a function of the end rotations of the unloaded span considered as simply supported but subjected at either end to a unit torque.

The distribution of an unbalanced moment at a joint to the several connecting members is a function of the moment ratios. Also, in a loaded span, the end moments produced by the loads are a function of the moment ratios and of the end rotations due to the loads when the span is considered as simply supported. Thus, all the elements necessary for the solution of a continuous beam or frame problem are present, when the moment ratios are known.

Are there characteristic redundants in the form of deflections that can be used, in a similar manner, to determine the distribution of a force to each of several structural members which support it at a joint? If so, the problem of analyzing statically indeterminate structures should be approached from a viewpoint using these characteristic redundants.

JOHN B. WILBUR,[27] M. AM. SOC. C. E.—The discussion of this paper has been appreciated. The writer believes that the proposed method would have been more attractive to some if it had been interpreted in terms of the method of least work. The derivation in the paper might have ended with Section 2. The n characteristic forces $P_{a1}, P_{a2}, \cdots, P_{an}$ as defined in Eq. 5 then could have been taken as the n unknowns for a least work solution.

Let F_n denote the stress in any member of a truss due to the nth set of characteristic forces acting on the primary structure, and F_o equal the stress in any member of a truss due to the applied loads acting on the primary structure; then the n simultaneous equations resulting from a least work solution would be as follows:

$$\left.\begin{aligned} \frac{\partial W}{\partial P_{a1}} &= \sum (F_o + F_1 + F_2 + \cdots + F_n) \frac{L}{A\,E} \frac{\partial F}{\partial P_{a1}} = 0 \\ \frac{\partial W}{\partial P_{a2}} &= \sum (F_o + F_1 + F_2 + \cdots + F_n) \frac{L}{A\,E} \frac{\partial F}{\partial P_{a2}} = 0 \\ &\cdots\cdots\cdots\cdots\cdots\cdots \\ \frac{\partial W}{\partial P_{an}} &= \sum (F_o + F_1 + F_2 + \cdots + F_n) \frac{L}{A\,E} \frac{\partial F}{\partial P_{an}} = 0 \end{aligned}\right\} \quad \ldots\ldots (85)$$

Because the characteristic redundants are orthogonal, however, $\sum \frac{F_m\,L}{A\,E} \frac{\partial F}{\partial P_{an}} = 0$ when $n \neq m$; whence, Eqs. 85 reduce to

$$\left.\begin{aligned} \sum \frac{F_o\,L}{A\,E} \frac{\partial F}{\partial P_{a1}} + \sum \frac{F_1\,L}{A\,E} \frac{\partial F}{\partial P_{a1}} &= 0 \\ \sum \frac{F_o\,L}{A\,E} \frac{\partial F}{\partial P_{a2}} + \sum \frac{F_2\,L}{A\,E} \frac{\partial F}{\partial P_{a2}} &= 0 \\ \cdots\cdots\cdots\cdots\cdots\cdots & \\ \sum \frac{F_o\,L}{A\,E} \frac{\partial F}{\partial P_{an}} + \sum \frac{F_n\,L}{A\,E} \frac{\partial F}{\partial P} &= 0 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots (86)$$

Moreover, Eqs. 86 are not simultaneous in character since the first equation involves only P_{a1} as an unknown; the second equation, only P_{a2}; etc.

To illustrate this procedure, consider the analysis of the truss in Fig. 3(*a*) acted upon by the load. The characteristic loads as defined by Eq. 34 are computed as shown in the paper. Now, letting P_{a1}, P_{a2}, and P_{a3} equal X, Y, and Z, respectively, the F_o, F_1, F_2, and F_3 stresses are computed by statics, leading to the results shown in Fig. 10. Since $\frac{L}{A\,E}$ has the same value for all members, the working equations reduce to the following:

---

[27] Prof., Structural Eng., Mass. Inst. Tech., Cambridge, Mass.

$$\left.\begin{aligned}\sum F_o \frac{\partial F}{\partial X} + \sum F_1 \frac{\partial F}{\partial X} &= 0\\ \sum F_o \frac{\partial F}{\partial Y} + \sum F_2 \frac{\partial F}{\partial Y} &= 0\\ \sum F_o \frac{\partial F}{\partial Z} + \sum F_3 \frac{\partial F}{\partial Z} &= 0\end{aligned}\right\} \ldots\ldots\ldots\ldots\ldots\ldots (87)$$

The required summations are obtained in Table 4.

TABLE 4.—EVALUATION OF SUMMATIONS OF EQS. 87

U_1L_2	0	$+1.414\,X$	0	$-1.414\,Z$	0	$+2.000\,X$	0	0	0	$+2.000\,Z$
L_1U_2	$+0.417\,P$	$+1.414\,X$	0	$-1.414\,Z$	$+0.590\,P$	$+2.000\,X$	0	0	$-0.590\,P$	$+2.000\,Z$
U_2L_3	0	$+X$	$-Y$	$+Z$	0	$+1.000\,X$	0	$+1.000\,Y$	0	$+1.000\,Z$
L_2U_3	$+0.417\,P$	$+X$	$-Y$	$+Z$	$+0.417\,P$	$+1.000\,X$	$-0.417\,P$	$+1.000\,Y$	$+0.417\,P$	$+1.000\,Z$
$\Sigma =$	....	....	....	....	$-0.142\,P$	$+19.63\,X$	$-2.767\,P$	$+8.000\,Y$	$-0.991\,P$	$+12.38\,Z$

The equations to determine X, Y, and Z are;

$$\left.\begin{aligned} -\,0.142\,P + 19.63\,X &= 0; & X &= +\,0.007\,P\\ -\,2.767\,P + 8.000\,Y &= 0; & Y &= +\,0.346\,P\\ -\,0.991\,P + 12.38\,Z &= 0; & Z &= +\,0.080\,P\end{aligned}\right\} \ldots\ldots\ldots (88)$$

Hence, the basic unknowns, X_a, X_b, and X_c (see Fig. 3(*a*)), are obtained by superposition from the characteristic redundants as follows:

$$\left.\begin{aligned} X_a &= +\,0.007\,P\,(+\,1) + 0.346\,P\,(+\,1) + 0.080\,P\,(+\,1) = +\,0.433\,P\\ X_b &= +\,0.007\,P\,(+\sqrt{2}) + 0.346\,P\,(0) + 0.080\,P\,(-\sqrt{2}) = -\,0.103\,P\\ X_c &= +\,0.007\,P\,(+\,1) + 0.346\,P\,(-\,1) + 0.080\,P\,(+\,1) = -\,0.259\,P\end{aligned}\right\} . (89)$$

In a minor way, the foregoing solution may answer the objections of Messrs. Ellis, Stewart, and Merritt that the method is too mathematical and too tedious to be of value, but the writer cannot actually hope to answer this criticism. The paper was presented in the belief that ideas that are new to structural engineers should be offered for discussion, even though their direct and immediate practical application may not be apparent—provided there is some hope that these ideas may eventually lead to worth-while methods. Messrs. Huggins and Holley have accepted the efforts of the writer from this viewpoint.

Fig. 10

Mr. Beskin has contributed a learned and critical discussion which adds much to the general picture of the use of orthogonal functions in structural analysis, although he holds little hope for practical applications of this method in the analysis of statically indeterminate structures. He stresses the relation between the proposed method and methods for computing periods of vibration —actually the line of reasoning that led to the proposed method. An understanding of the proposed method of computing characteristic loads may help structural engineers wishing to extend their interests into the field of vibrations. Contrary to Mr. Beskin, the first sentence in Section 13 is correct, since the number of independent components of displacement is not necessarily equal to the number of independent redundant stress components, although equality happens to exist in the example chosen. By independent components of displacement, the writer simply refers to joint and chord rotations as commonly used in the analysis of rigid frames by the slope deflection method.

Summarizing, the writer believes that, once the characteristic forces corresponding to the redundants in an indeterminate structure have been determined, the remainder of the analysis, in terms of these characteristic forces, is simplified to an important degree. As indicated by the writer, the labor involved in determining the characteristic forces in the first place is such that the over-all method is not very promising in its present state of development. Perhaps it is possible to develop a simple method of determining characteristic forces, or perhaps, as Mr. Beskin suggests, these forces should be determined, in some instances, by inspection from physical considerations.

HYDRAULIC MODEL INVESTIGATION OF MITER GATE OPERATION

By Maurice N. Amster,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Edward Soucek, Isaac DeYoung, F. W. Edwards, William A. Tripp, and Maurice N. Amster.

Synopsis

The miter gate is a commonly used type of closure for the chambers of navigation locks. It is a two-leaf arrangement, comparatively simple in design and adaptable to convenient means of operation. In the open position the two leaves are recessed in opposite lock walls with their faces parallel to the walls. For closure each leaf is swung about a vertical axis near its downstream (quoin) end so that the upstream (miter) ends of the leaves contact at the center line of the lock. The bottoms and the quoin ends of the leaves are equipped with sealing arrangements that contact floor and lock walls when the leaves reach their closed positions. In supporting a water load, the gate acts as a three-hinged arch, with the two quoin bearings and the miter bearing forming the hinges and the lock walls acting as abutments for the end thrust. The quoin end of each leaf is supported at the bottom by a pintle assembly and at the top by a gudgeon assembly. Frequently used types of operating machines are: Hydraulic cylinder and piston, cable and drum, and crank and strut.

In the design of machinery for the operation of lock miter gates, it is essential to know, as accurately as possible, the power requirements and the loads that will occur on the operating mechanism throughout the cycle. For lack of better data, designers in the past have had to resort to empirical methods usually based upon arbitrary assumptions as to hydraulic resistance. Mechanical difficulties in operation generally have been avoided by the use of large safety factors. In the design of the operating machinery for the gates of the Third Locks of the Panama Canal, the size of the leaves indicated that the forces to be encountered would exceed those in any similar structures in the past. Because of the large number of machines required, the use of high

---

[1] Formerly, Asst. Engr., Special Eng. Div., The Panama Canal, Diablo Heights, Canal Zone.

safety factors would have been extremely uneconomical. Accordingly, it was decided to conduct model tests to investigate the resisting forces that might be expected in the operation of the Third Locks gates.

THE PROTOTYPE

The mechanism designed for operating the prototype gates is of the crank-and-connecting-rod type, having kinematic characteristics similar to those used in the existing Panama Canal Locks but differing in mechanical details and arrangement. A large gear wheel, driven by two electric motors through trains of speed-reduction gears, rotates a vertical shaft at practically uniform velocity. A crank is keyed on the lower end of the shaft, and a strut is linked to the end of the crank and to the face of the gate leaf. The operating linkage is shown schematically in Fig. 1. The crank arm is driven through an arc of 187°52′31″ to move the gate leaf through an angle of 63°26′04″. The dead-center positions of the crank relative to the strut coincide with the extreme

chamber for distances of 1,125 ft upstream and 625 ft downstream. Details of the gate bay are shown in Fig. 2. The gate leaves were constructed of an angle-iron framework faced with galvanized sheet metal. Holes bored in the tops and the bottoms of the leaves permitted water to flow easily into or out of the leaves during changes of the water-surface elevation in the flume. The weight of the prototype leaves was not simulated.

The model leaves were operated by the mechanism shown in Fig. 3. The position of each linkage relative to its leaf was displaced 180° about the vertical pintle axis for convenience in the model. An electric motor drove two speed reducers with crank arms keyed to their vertical shafts. Each model strut was pin-connected at one end to a crank arm and at the other end to an arm keyed to a vertical alloy-steel shaft $1\frac{1}{4}$ in. in diameter. This shaft transmitted the driving torque to the leaf.

The torque applied to one of the leaves during operation was determined by measuring the twist produced in a reduced section of the drive shaft. The diameter of the reduced section of each shaft was 0.6 in. Details of the measuring apparatus are shown in Fig. 4. A hollow cylinder was keyed to the drive shaft just below the reduced section, and a horizontal arm was bolted to a flange on the top of the cylinder. On another horizontal arm, which was keyed to the drive shaft just above the reduced section, were mounted two dial gages graduated to indicate linear deflections to the thousandth of an inch. The gage plungers were in contact with the arm attached to the cylinder and thus were actuated by the relative movement of the two arms. A value obtained with this arrangement was not exactly a measure of the twist arc, but the difference between a reading and the actual length of the corresponding twist arc was so slight that calibrations of the reduced section over a range considerably greater than that of the tests did not deviate appreciably from straight-line relationship. The twist in the section of the shaft below the point of attachment of the cylinder was negligible.

An extension of the arm attached to the cylinder indicated the angular position of the gate leaf on a segmental scale. Instantaneous values of leaf angle and dial-gage reading were obtained during an operating cycle with a motion-picture camera attached to the drive shaft above the measuring apparatus.

Operating dimensions of the model were derived from prototype values on the basis of Froude's law, as follows

Dimension	Ratio, prototype to model
Length and depth	25 : 1
Volume, weight, and force	15,625 : 1
Time and velocity	5 : 1
Torque	390,625 : 1

Numerical values stated in this paper are in prototype dimensions.

TESTING PROCEDURE

The water level in the flume was adjusted to submerge the gate leaves to the desired depth. Fresh water, only, was used in the tests. The operating speed was adjusted by means of the vari-speed pulley arrangement to complete an operating cycle in the required time. It was established by numerous trials

FIG. 3.—MECHANISM FOR OPERATING THE MODEL

that, for a fixed vari-speed pulley setting, the duration of the cycle varied less than 1 sec, other conditions remaining unchanged. The dial gages were set at zero, the motion-picture camera was started, and finally the operating mechanism was started. When the gate reached its terminal position, the mechanism was stopped by a limit switch, and, after allowance of time for the subsidence of eddy currents or surges, the operation was repeated for the reverse direction.

TESTS

The conditions believed to involve maximum hydraulic resistance in the operation of the prototype gates were: Synchronous operation of the two leaves, submergence of 82.5 ft, upstream chamber length of 1,105 ft, and downstream chamber length of 200 ft. These, together with an operating time of 2 min (which had been selected tentatively) were used as base conditions. The following conditions were tested to determine their individual effects upon the resisting torque: Nonsynchronous operation (differences in starting time of the two leaves from 0 to 20 sec), submergences from 45 to 82.5 ft, upstream chamber lengths from 300 to 1,105 ft, operating times from 1.75 to 2.75 min, two gate-leaf weights—2,000 tons and 2,400 tons, and single-leaf operation.

TEST RESULTS

In all tests, a clearly defined peak torque value was reached in the vicinity of the mitered position of the gate. For each set of operating conditions, peak opening torque was considerably greater than peak closing torque. (This does not include the single-leaf tests, which produced only moderate torque peaks.)

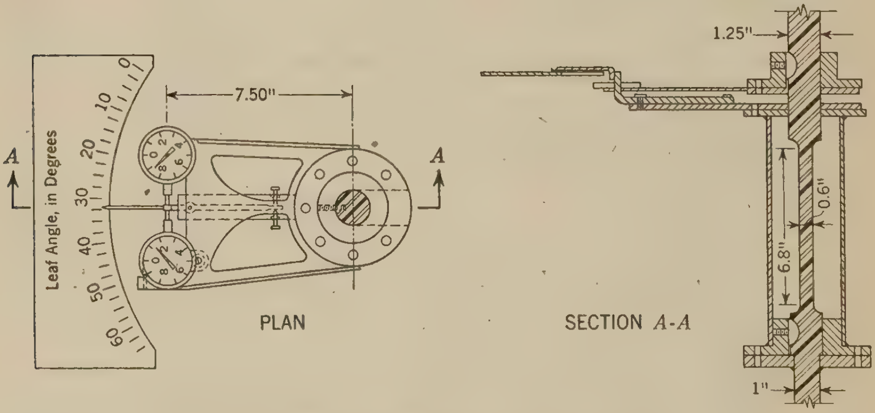

Fig. 4.—Measuring Apparatus

The results of base tests repeated throughout the testing program are compared in Fig. 5. Operating conditions were maintained identical for the base tests: Operating time, 2 min; submergence, 82.5 ft; upstream length of chamber, 1,105 ft; and downstream length of chamber, 200 ft. The extreme deviation from average is about 1,500,000 lb-ft or 8.1% in the opening operation and about 500,000 lb-ft or 3.8% in the closing operation.

The effect of speed variation is shown in Fig. 6(*a*), and the effect of variable submerged depth is shown in Fig. 6(*b*). With the relatively short chamber on one side of the gate, variation of the length of the chamber on the other side had no appreciable effect on the torque for lengths greater than 625 ft. Curves, similar to those in Fig. 6, for these variations indicated that the effects of chamber length were of minor importance compared with those of speed and submergence.

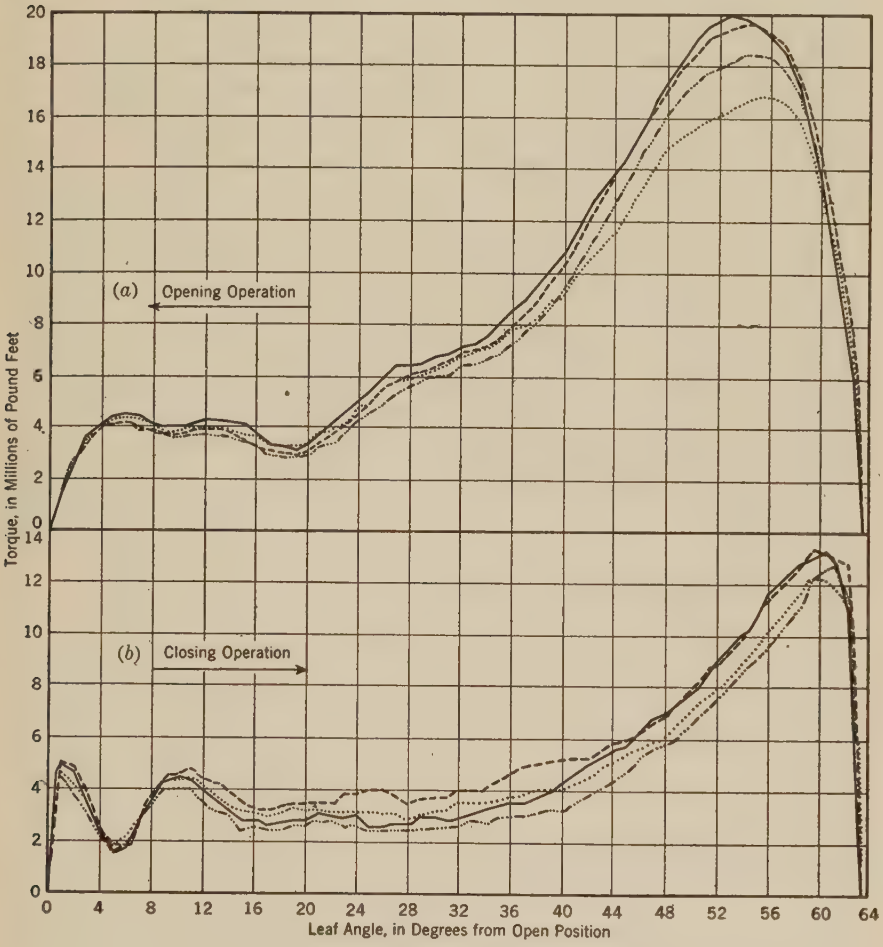

FIG. 5.—MODEL CONSISTENCY, BASE CONDITIONS (OPERATING CONDITIONS CONSTANT)

Likewise, the effect of an increase of 20% in leaf weight was not sufficient to be revealed by the model tests. The addition of weight increases the mechanical frictional resistance and the inertial resistance to acceleration, but generally the forces required to overcome bearing friction and inertia are quite small relative to the total resisting force. The angular acceleration of the

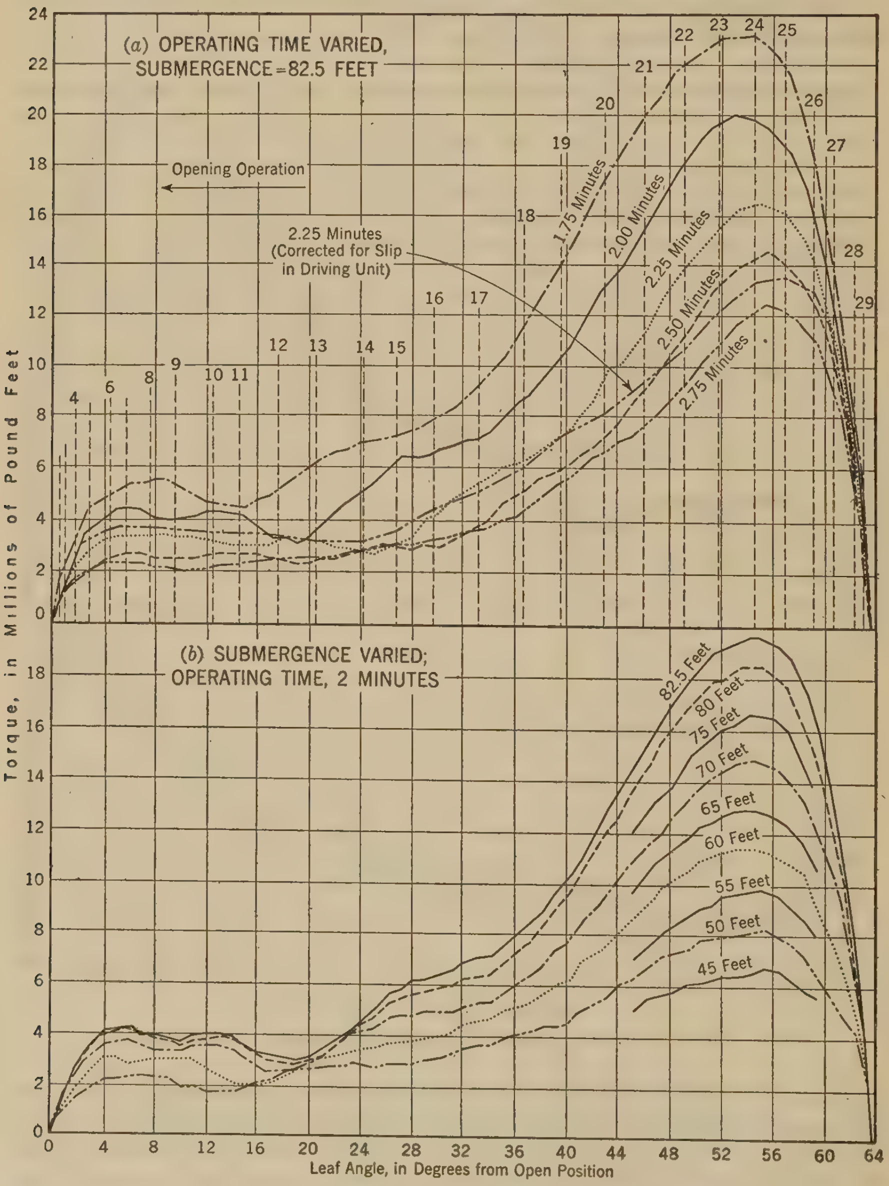

Fig. 6.—Effect of Variable Operating Conditions (Opening Operation)

prototype gate leaf was calculated to be about 0.00019 radians per sec per sec at the time of indicated peak torque, and the moment of inertia about the axis of rotation was estimated to be about 208,000,000 slug-ft². Therefore, the torque necessary to accelerate the leaf at peak-torque position would be 208,000,000 × 0.00019 = 39,500 lb-ft. Since the peak torque values in the opening operation of the base tests ranged from 17,000,000 to 20,000,000 lb-ft (Fig. 5(*a*)), the inertial component is only about 0.2% of the total.

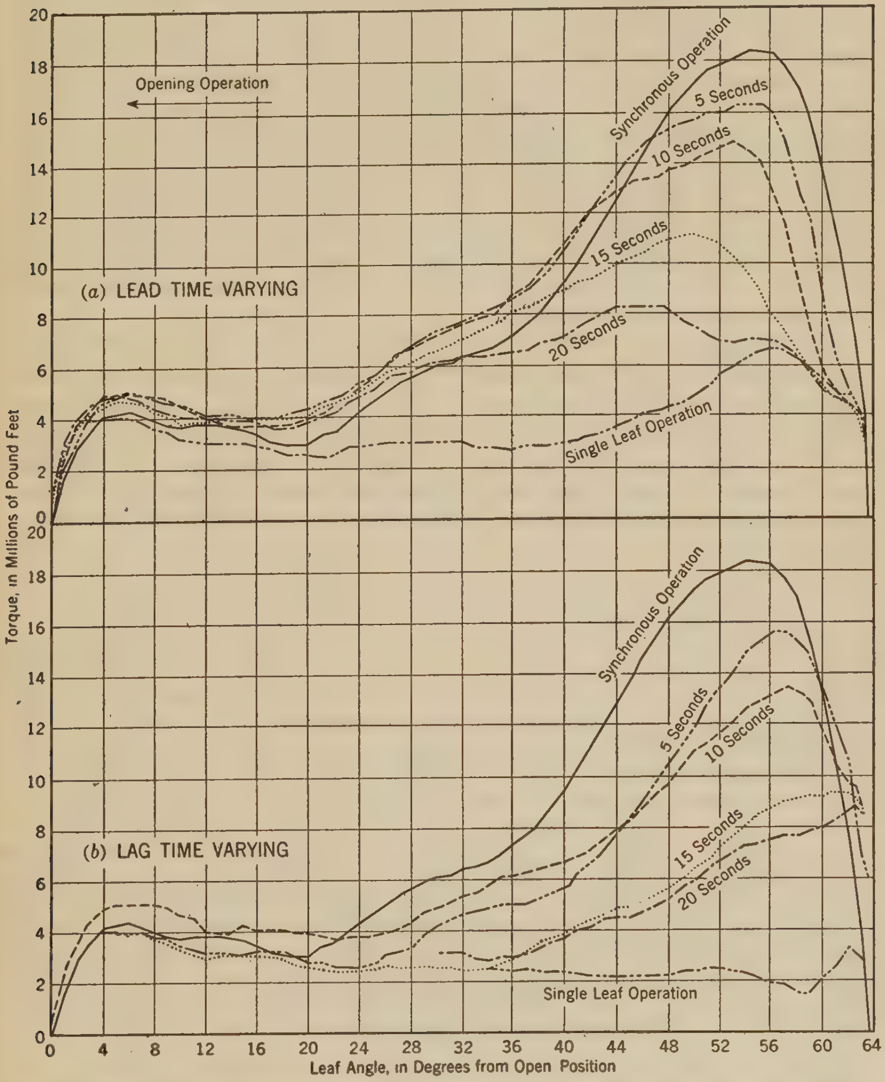

FIG. 7.—EFFECT OF NONSYNCHRONOUS OPERATION OF LEAVES (OPENING OPERATION, BASE CONDITIONS)

Fig. 7 demonstrates that the torque was lowered considerably in the vicinity of the peak values by delaying the starting of one leaf. It is observed that a 20-sec delay reduced the peak values about 50%. Comparison of Figs.

7(*a*) and 7(*b*) indicates that the leaf farthest from the mitered position always required the greater peak of operating torque.

VERIFICATION TESTS

Prior to the initiation of the model tests just described, tests had been conducted on a miter gate of the existing Panama Canal Locks to obtain data from which approximate load values for Third Locks gates could be derived for preliminary design purposes. Because of the availability of these data, the model constructed for tests on the Third Locks gates was used, with certain necessary alterations, for verification tests on the operation of the gate of the existing locks. The gate pintles in the Third Locks, as designed, are farther apart than those in the existing locks, but to simplify the alterations, the locations of the pintle bearings in the model were not changed, and a scale ratio of 1 to 18.813 was obtained for the verification tests. Space limitations prevented model reproduction of the lock-chamber lengths upstream and downstream from the prototype gate.

The tests conducted on the prototype gate of the existing locks consisted of measurements of power input to the driving motor of one of the gate machines during opening and closing operations. The characteristics of the motor were determined separately by means of Prony-brake tests. By taking into account the gear reduction, the mechanical advantage of the crank-and-strut linkage at the recording intervals, and the probable mechanical efficiency, the power-input readings were converted into values of torque about the axis of rotation of the gate leaf.

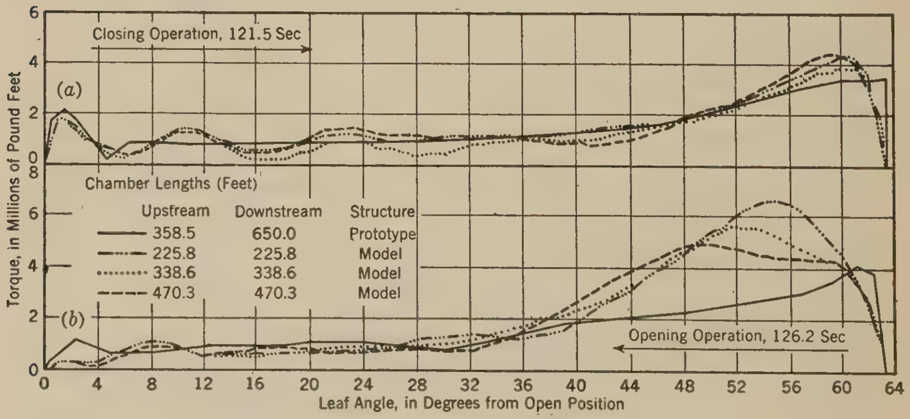

FIG. 8.—VERIFICATION TESTS (SUBMERGENCE, 73.16 FT)

The results of model and prototype tests are shown in Fig. 8. The prototype data represent the average of five test runs, and the model data represent a single run. In all cases, the peak torques observed in the model tests were larger than those recorded in the prototype tests and occurred farther from the mitered position of the gate leaf. The verification is reasonably close for the closing operation but not for the opening operation. There are several factors that could have contributed to the disparity:

(*a*) The driving motor of the model machine had negligible slip. The slip of the prototype motor was found to be very high at the position of peak resisting torque, and the consequent deceleration would tend to reduce the resisting torque.

(*b*) In the prototype tests, it was observed that the two gate leaves did not start or finish their movements simultaneously, even though the operating machines were started simultaneously. The full importance of this condition, which is probably attributable to a difference in the characteristics of the two motors, was not known at the time of the prototype tests, but its influence was demonstrated by the results of the model tests on the Third Locks gate with unsynchronized operation of the leaves (Fig. 7). Delay in starting a leaf in the opening operation reduces the peak load and delays its occurrence.

Conclusions from Tests

Three conclusions are derived from the foregoing:

1. When the two leaves are operated together, peak resistance occurs in the early part of the opening cycle;
2. The peak load can be reduced considerably by delaying the starting of one leaf, but the best load distribution for simultaneous operation of the leaves, whether synchronized or not, can be obtained by the use of an operating cycle involving low speeds at the extremes of travel—especially near the mitered position; and
3. Peak torque varies directly as operating speed and submerged depth of the gate.

Application of Test Results to the Prototype Design

Factors not represented in the model tests were: Hydraulic drag, mechanical friction, transient surge phenomena, salinity heads, and speed variations in the driving unit.

The hydraulic drag and the mechanical friction forces were assumed to be negligible relative to the total resisting force. Opposing surge heads that might exist at the time a gate is operated and the effect of waves produced by external influences such as wind and ship movement were not considered to be practical of reproduction in the model tests. The determination of the probable magnitude of salinity heads and the correction of test results for the effect of slip in the driving units will be discussed herein.

Notation.—The following letter symbols, used in the paper, conform essentially to American Standard Letter Symbols for Hydraulics,[2] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942:

---

[2] ASA—Z10.2—1942.

c = distance of the culvert roof from the lock floor (see Fig. 9);
F = force per unit length of gate:
  F_f = force on the fresh-water side of the gate;
  F_n = net unbalanced force;
  F_s = force on the salt-water side of the gate;
T = torque:
  T_a = torque about the axis of rotation;
  T_g = torque at the gear input shaft;
y = depth:
  y_d = downstream, or salt-water depth to the lock floor;
  y_f = depth of water to the equal-pressure plane on the fresh-water side of the gate;
  y_s = depth of water to the equal-pressure plane on the salt-water side of the gate;
  y_u = upstream, or fresh-water depth to the lock floor;
γ = specific weight:
  γ_f = fresh water;
  γ_s = salt water.

Forces Due to Salinity Head.—When the specific gravity of the water on the two sides of a closed lock gate is not the same—a situation encountered at ocean locks supplied with lockage water from a fresh-water source—the attainment of flow equilibrium in the connecting culvert system is very unlikely to balance the total hydrostatic forces on the two sides of the gate. When the fresh or comparatively fresh water is on the upstream side of a closed miter gate, the direction of the unbalanced hydrostatic force is such as to oppose the opening of the gate, as illustrated in the following analysis.

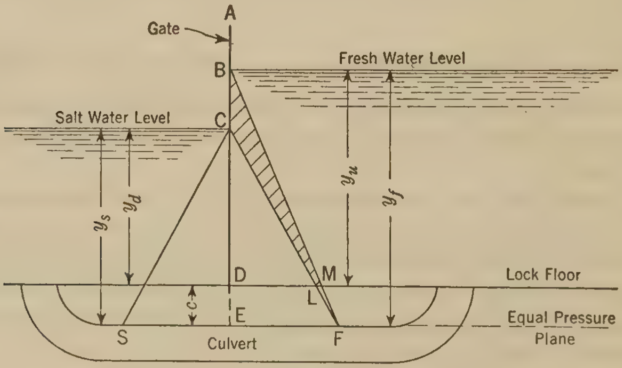

FIG. 9

Fig. 9 is a diagrammatic section parallel to a lock chamber, with the gate represented by the line AD and the pools on the two sides of the gate connected by a culvert running below the level of the gate bottom. For equilibrium to exist and flow to cease, there must be a plane of separation between salt water and fresh water at which the pressure is balanced. Since salt water is heavier than fresh water, the lower part of the culvert will be filled with salt water at least up to the level of the culvert roof. It will be assumed tentatively that the equal-pressure plane is at the same level as the culvert roof.

The pressure diagrams for the two sides of the gate are represented by lines CS and BF, with $\overline{\text{ES}}$ equal to $\overline{\text{EF}}$. The area BCLM represents unbalanced pressure on the fresh-water side of the gate.

By definition (see notation):

$$F_f = \frac{\gamma_f y^2_u}{2}\text{; and } F_s = \frac{\gamma_s y^2_d}{2} \qquad \text{(1)}$$

The net unbalanced force per unit length of gate equals

$$F_n = \frac{\gamma_f y^2_u - \gamma_s y^2_d}{2} \qquad \text{(2)}$$

Since $y_u = y_f - c$ and $y_d = y_s - c$ (see Fig. 9), Eq. 2 becomes:

$$F_n = \frac{\gamma_f(y_f - c)^2 - \gamma_s(y_s - c)^2}{2}$$

$$= \frac{\gamma_f y^2_f - 2\,\gamma_f y_f c + \gamma_f c^2 - \gamma_s y^2_s + 2\,\gamma_s y_s c - \gamma_s c^2}{2} \qquad \text{(3)}$$

For the condition of equilibrium,

$$\gamma_f y_f = \gamma_s y_s \qquad \text{(4)}$$

Substituting Eq. 4 in Eq. 3 reduces the force equation to

$$F_n = \frac{\gamma_s y_s (y_f - y_s) - c^2(\gamma_s - \gamma_f)}{2} \qquad \text{(5)}$$

With the value of y_s known, y_f can be determined from Eq. 4 for assumed values of γ_f and γ_s. With the substitution of $\frac{\gamma_s y_s}{\gamma_f}$ for y_f, Eq. 5 reduces to

$$F_n = \frac{\gamma_s y^2_s(\gamma_s - \gamma_f)}{2\,\gamma_f} - \frac{c^2(\gamma_s - \gamma_f)}{2} = \frac{\gamma_s - \gamma_f}{2}\left(\frac{\gamma_s y^2_s}{\gamma_f} - c^2\right) \qquad \text{(6)}$$

When the connecting culvert is above the level of the gate bottom, Eq. 6 applies without change. If the equal-pressure plane is at the level of the gate bottom, c of Eq. 6 equals 0, and

$$F_n = \frac{\gamma_s y^2_s(\gamma_s - \gamma_f)}{2\,\gamma_f} \qquad \text{(7)}$$

In the application of the developed formulas to the prototype, several factors ordinarily would enter into the decision as to which gate would be used as a criterion and into the assumption of salinity values. If no factual data were available, it would be logical to base the computations on the gate that will have the greatest operating submergence and to assume sea water with a specific weight of 64.0 lb per cu ft on one side and fresh water with a specific weight of 62.5 lb per cu ft on the other side. However, at the existing Panama Canal Locks, which correspond closely with the designed prototype locks and which connect the same bodies of water, information was available as to the location at which the greatest difficulty is encountered from salinity pressures, and the maximum salinity head measured at that location is about 0.7 ft. At the corresponding location in the Third Locks, the maximum salt-water depth to the lock floor on the downstream side of the gate is 68.9 ft, and the lowest culvert roof is 9 ft below the floor. The water on the downstream side is assumed to have a specific weight of 64.0 lb per cu ft. If the salinity of the water on the upstream side were assumed to be uniform for the full depth to the culvert roof, Eq. 6 would apply, but, for a given head difference, the worst condition obviously would be represented by the assumption of sea-water salinity on the upstream side from the lock floor down and a uniform lower salinity from the lock floor up, since pressure difference below the floor does not act on the gate. With this assumption, $y_s = 68.9$ ft and $y_f = 68.9 + 0.7 = 69.6$ ft. Therefore, $\gamma_f = 63.3$ lb per cu ft.

As indicated by this result, entirely fresh water probably will not be found on one side of a gate with undiluted sea water on the other side. Such a condition is prevented by the fact that every time the gate is opened, the sea water on one side displaces a large portion of the fresh water on the other side because of the difference in weight.

The prototype gate leaf is about 84 ft long from miter end to axis of rotation. Neglecting the small area from the axis of rotation to the quoin end and substituting in Eq. 7, the total force on the gate leaf is computed as 141,000 lb. The moment arm of this force about the axis of rotation of the leaf is equal to half the length of the leaf. Therefore, the moment resisting opening of the leaf is $\frac{1}{2} \times 84 \times 141{,}000 = 5{,}920{,}000$ ft-lb.

Correction of Test Results for Slip in Driving Unit.—The model machine was driven by a relatively high-powered motor that produced a practically constant speed for the reduction gear and the operating crank. In the designed prototype machine, however, power is to be transmitted from motors to reduction gears through hydraulic couplings. Therefore the speed variations to be expected in the prototype machine must be taken into account in application of the model test results.

Although most of the model tests were conducted with an operating time representing 2 min in the prototype, the operating time later selected for the prototype was 2.25 min. A tentative selection was made of motors, hydraulic couplings, and reduction gears such that, with the motors operating at rated full-load speed through the entire operating cycle, and taking into account the slip of the couplings, an operating time of approximately 2.25 min would result. The motor and the hydraulic coupling were of standard design, and their slip characteristics were available from manufacturers. For the purpose under discussion, the two slip characteristics were combined. Fig. 10 shows the speed of the output shaft of the hydraulic coupling for the torque range from no load to the breakdown load of the coupling, with the slip of the motor included.

The travel of the gate leaf between recessed and mitered positions was divided for convenience into thirty parts corresponding to thirty equal divisions of the arc of crank movement. The relation of these divisions with respect to angular position of the leaf is shown by the vertical lines in Fig. 6(*a*).

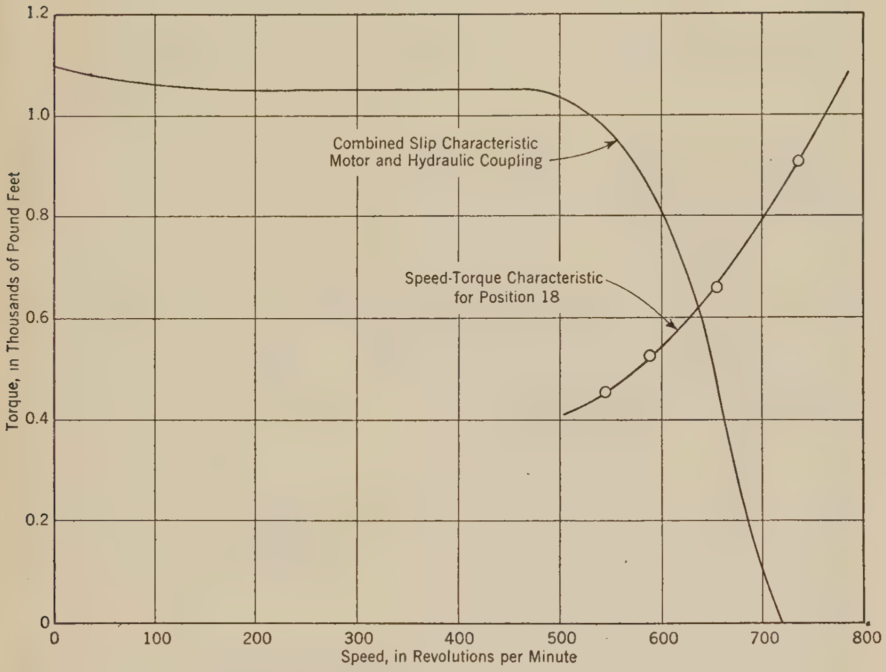

FIG. 10.—CORRECTION OF TEST DATA FOR SLIP IN DRIVING UNIT

Thus, for each position, the resisting torque about the axis of rotation of the leaf is indicated for five different operating times. On the assumption that the crank rotates at uniform speed throughout an operation, each operating time corresponds to a certain speed at the input shaft of the reduction gear. By computing trigonometrically the mechanical advantage of the crank-and-strut linkage for each position, taking into account the total gear reduction, and assuming a mechanical efficiency, the resisting torque at the input shaft of the reduction gear can be derived for each operating speed.

Leaf Position 18 will be taken as an illustration. For this position the mechanical advantage of the crank-and-strut linkage was calculated to be 1.92. The total gear reduction was 5,660 to 1, and the over-all mechanical efficiency, derived from assumed efficiencies for individual parts of the machine, was 89.4%. Therefore, the torque required at the gear input shaft to produce a given torque about the axis of rotation of the leaf was obtained by dividing by the factor (1.92 × 5,660 × 0.894 =) 9,715. With T_a representing the torque about the axis of rotation and T_g the corresponding required torque at the gear input shaft, the values in Table 1 were derived for the opening movement from the torque values shown in Fig. 6(*a*) for Position 18. The speed-torque relationships are plotted in Fig. 10 to the same coordinates as the hydraulic-coupling characteristic. Since the output torque of the hydraulic coupling must be the same as the resisting torque at the gear input shaft, the intersection of the curve for each leaf position with the hydraulic-coupling characteristic represents corrected torque and speed for that particular leaf position. Thus the corrected torque at the gear input shaft is 620 lb-ft, and the corrected speed is 637 rpm. The torque at the gear input shaft may be multiplied by the conversion factor 9,715 to obtain a corrected value of torque about the axis of rotation. This gives 6,020,000 lb-ft.

TABLE 1.—DATA FROM SPEED-TORQUE TESTS, OPENING MOVEMENT

No.	Description	OPERATING TIME, IN MINUTES				
		2.75	2.50	2.25	2.00	1.75
1	Speed at gear input shaft (rpm)	545	589	655	736	818
	Torque, in Pound-Feet:					
2	T_a, about axis of rotation (millions)	4.4	5.1	6.4	8.8	11.7
3	T_g, at the gear input shaft	453	525	659	905	1,205

This method was used to derive torque and speed values for each of the thirty positions for both the opening movement and the closing movement, and, from these values, crank-and-strut loads and motor horsepower were computed. The corrected values of torque about the axis of rotation for the opening movement are shown in Fig. 6(*a*) for comparison with the uncorrected model test results.

To determine the probable operating time, the average speed of the crank between each pair of consecutive positions was assumed to be equal to the average of the corrected speeds at the two positions. The total operating time calculated on this basis differed only a negligible amount from the desired 2.25 min, and the tentatively selected driving unit was adopted for the machine.

The correction method used is an approximate one, of course. The basic assumption was made that the speed-torque relationships indicated by the model test results for any given leaf position would hold true independently of speed variations at other positions. This assumption cannot lead to very accurate results, but the degree of accuracy probably is sufficient for the purpose of the computations.

Capacity of Machines.—All gates of the prototype will be operated by identical machines designed for the operating conditions at the gate with the greatest potential load. This load was assumed to be represented by the test results shown in Fig. 6(*a*). It was unnecessary to make additional allowances for salinity forces; at the gate where salinity is most likely to affect operation, the submergence is only about 70 ft, and, since the machines are designed to operate a gate submerged 82.5 ft, an ample reserve capacity is available (see Fig. 6(*b*)). The hydraulic coupling acts as a load-limiting feature, and, if salinity pressure exceeds expectations, the coupling slip will increase automatically, decelerating the opening movement until the salinity head has been dissipated by flow between the gate leaves. The operating strut is equipped with a shock absorber to dampen the effect of any transient loads such as waves. The shock absorber contains a limit switch that will stop the driving motors before the strut can be overloaded.

Application of Test Results to Other Miter Gates

The data obtained from the model tests probably could be applied to other miter gates having the same kinematic cycle. This would require correlation of scalar ratios with the relationships derived from the tests. The length of a gate leaf would determine the linear scale ratio with respect to the leaf of the test gate, which is 84 ft long. For example, if a gate leaf is 42 ft long, the linear scale would be 1 to 2. If the submergence is 30 ft, the curve in Fig. 6(*b*) representing a 60-ft submergence would be applicable with all torque values divided by 2^4, or 16. If the operating time is greater or less than 2 min, the appropriate curve of Fig. 6(*a*) is used and corrections are made for a number of leaf positions in accordance with the ratios in Fig. 6(*b*) between the torque values at a 60-ft submergence and those at an 82.5-ft submergence.

If it is necessary to correct for slip in the driving machine, new speed-torque curves should be derived from those of Fig. 6(*a*) on the basis of the scale relationships and the submergence ratio, and the correction method should be applied as outlined herein.

In this application, differences in chamber lengths are neglected. However, unless such differences are great, their effect may be relatively unimportant.

Acknowledgment

At the time of the tests described in this paper the Special Engineering Division of The Panama Canal was directed by T. B. Larkin, M. Am. Soc. C. E., supervising engineer. The investigation was conducted by the Hydraulic Section of the Division under the direction of F. W. Edwards, M. Am. Soc. C. E., senior hydraulic engineer, and later, E. Soucek, Assoc. M. Am. Soc. C. E., senior hydraulic engineer. The model operating mechanism was designed by G. D. Smith, engineer, of the Mechanical-Electrical Section. The writer was in charge of the investigation.

DISCUSSION

Edward Soucek,[3] Assoc. M. Am. Soc. C. E.—Prior to adoption of the test program so ably described by Mr. Amster, a study was made of the methods which had been used previously in design of miter gate moving machines. The usual basis for the hydraulic load is a differential head on the leaves acting in a direction opposing the motion. The magnitude of the head is commonly fixed by judgment—in some cases supplemented by observations at existing installations. The reliability of comparative studies for use in design is limited principally by uncertainty in allowing for differences in gate length, in submergence depth, and in kinematics of the gate motion; sill clearances are also believed to affect the hydraulic loads but probably to a lesser extent.

Some designers compute the varying differential head upon the leaves by consideration of the rates of change of the areas separated by the gates and the discharge past the gates. This method gives results that are much too small because the loads are principally due to water-level variations which are transient in character and local in extent—surges induced by the gate movement—and therefore not related in any simple manner to the adjacent water-surface areas.

During the search for design data, a paper that dealt with loads on moving miter gates was found (written in German). It appeared very promising because it contained many equations. Upon translation, however, all significant equations were found to contain that elusive term—the unknown and varying differential head—which had to be evaluated before the equations could be used in design. Owing to the lack of reliable design data, use of model tests was, as the author states, the only alternative to the use of extremely liberal safety factors for the design of a considerable number of large machines.

This situation not only gives Mr. Amster's paper a "scarcity value" which insures that it will be widely used, but it also requires that most careful consideration be given to the limitations stated by the author and to any other conditions that might affect the applicability of the test results to the design of gate moving machines in general. Operation of the model and interpretation of the test data in accordance with Froude's law are believed correct since the phenomena associated with the hydraulic loads are predominantly inertial in character. Elasticity of the gates, effect of flow through the lock culverts, and reduction in effective chamber length caused by the nearness of a large ship might be mentioned as factors not represented in the model additional to those listed by the author. Their effects are relatively small but should not always be considered negligible.

Under "Application of Test Results to Other Miter Gates," the author outlines a method for application of the test data to the design of dissimilar prototypes. The writer believes that the problem is not so simple as this section of the paper implies. If gate moving machines are not geometrically similar, the gate operating time is not a sufficient measure of the kinematic characteristics of the gate movement. If the model gates were operated at a uniform angular velocity, rather than with slow movement near the limits of travel, the hydraulic load for the same operating time would be increased many times. For this reason, it would be preferable to consider only the first 15 or 20 degrees of the movement for the critical opening operation rather than the entire opening period in some cases.

---

[3] Senior Civ. Engr., U. S. Engr. Office, Wilmington, N. C.

However, even dismissing the questions of kinematic characteristics (other than operating time), leaf angle when fully open, sill clearance, and other factors which were not investigated, it is not clear that the proposed adjustment for operating time is generally valid. As the author explains, the ratio of prototype leaf length to model leaf length establishes the scale ratio. Then from Fig. 6(*b*), a torque curve can be selected that is correct for a particular prototype operating time (determinable from the scale ratio and the model operating time). It may, but probably does not, correspond to that at which the prototype will operate. Fig. 6(*a*) shows the effect of varied operating time only for a gate with leaf length approximately equal to the submerged depth. The effect of operating time upon peak torque indicated by the curves is shown in Table 2. It does not follow from these data that Fig. 6(*a*) is a valid basis for adjustment of torque curves in terms of operating time when the leaf length is much greater than the submerged depth—a frequent case in barge locks. Pending the presentation of further data or a conclusive analysis, it would appear that the relationships suggested should be used only when the leaf length approximately equals the submerged depth.

TABLE 2.—EFFECT OF OPERATING TIME ON PEAK TORQUE

Description	TIME, IN MINUTES				
	1.75	2.00	2.25	2.50	2.75
Torque, in millions of foot-pounds	22.3	20.0	16.5	14.5	12.5
Percentage time increase	0.0	14.4	28.5	43.0	57.5
Percentage torque decrease	0.0	10.5	26.0	35.0	44.0

The treatment of the forces due to density differences covers the ideal case, a static condition with the plane separating fresh and salt water in a known position. In reality, determination of the elevation of this plane is quite difficult. It may be of interest to point out that a series of tests on the existing Panama locks, corroborated by a small transparent model, indicated that the excess closing force produced by difference in density cannot be eliminated by increasing the elevation of the culvert outlets. Consideration of this problem in detail is beyond the scope of this discussion. It may be suggested, however, that designers of miter gate moving machines should question the efficacy of elevated outlets in reducing the loads upon the machines.

In the Panama Canal Third Locks Project, the terminal gates which are most subject to the density effect will be less deeply submerged than most of the other gates so the machines of the terminal gates will have a substantial overload capacity. At all gates, the "overtravel" of water in the lock culverts produces a transient opening force which can be used to reduce the critical opening load, either by swinging the gates at or near the time of maximum overtravel or by closing the culvert valves and "trapping" the favorable water level differential. Of course a falling tide eliminates the latter possibility at the terminal gates.

The writer's remarks are intended solely to clarify certain design problems and to emphasize the limitations upon general applicability of the test data. Many significant conclusions can be drawn from the paper in addition to those modestly claimed by the author. His efforts would be justified if the paper did no more than call attention to the large reduction in operating forces and peak power loads which can be attained by reducing the operating speed of the gates and by nonsynchronous operation of the leaves. Since the gate operating time is a relatively small part of the time required to perform a lockage, these methods frequently can be adopted with scarcely noticeable adverse effects upon over-all lockage efficiency.

ISAAC DEYOUNG,[4] M. AM. SOC. C. E.—Tests for determining the force required to swing the mitering gates of the locks at St. Marys Falls Canal in Michigan were made in 1941. Although the method of testing was not highly refined, the results, in some respects, are similar to those determined by the more elaborate tests conducted with the model mechanism of the Panama Locks.

The gate engines were not tested as usual, because of the difficulty of inserting a measuring device for determining the power to move these gates. The gates tested are operated by cables reaved over spiral drums with the cables attached to the gates near the toe of the gates and close to the center of gravity of the mass of water through which the gates swing.

Power for swinging the gates was obtained from adjacent capstans, and the tension in the cable was measured on a hydraulic weighing machine.

One of the tests was made on the intermediate lower gates of the Davis Lock at St. Marys Falls Canal. The tests were made on a single-leaf operation with the other leaf fixed in its recess. The time of a complete swing of the leaf was 1½ min, about the usual time for actual operation. The operating speed of the capstan through which the power was applied was constant, resulting in a uniform intake of rope which was attached to the gate fastening. The depth of submergence was 34 ft.

The width of the Davis Lock is 80 ft. The leaves of all the operating gates are 44.56 ft wide, and the intermediate gates are about 52 ft high. The gate swings through an arc of 68° 12′, and the operating cable is attached to the leaf at 39.62 ft from the center of rotation. The weight of each leaf is about 173 tons.

The results of the tests are shown in Fig. 11, representing the average of three test runs, for the opening of gate only. The maximum pull is about 61° from the position of the gate in the recess and is in close agreement with that obtained in the model tests at this point. Since the opposing leaf is in its recess, the movement of water seems to be throttled between the sill and the sill cushion of the leaf tested. There should be liberal depths under the gate in the pit over which the gate swings, as well as in the gate recess in order to give a more effective path for the ingress and egress of the water back of the gate.

---

[4] Consultant to City Mgr., Sault Ste. Marie, Mich.

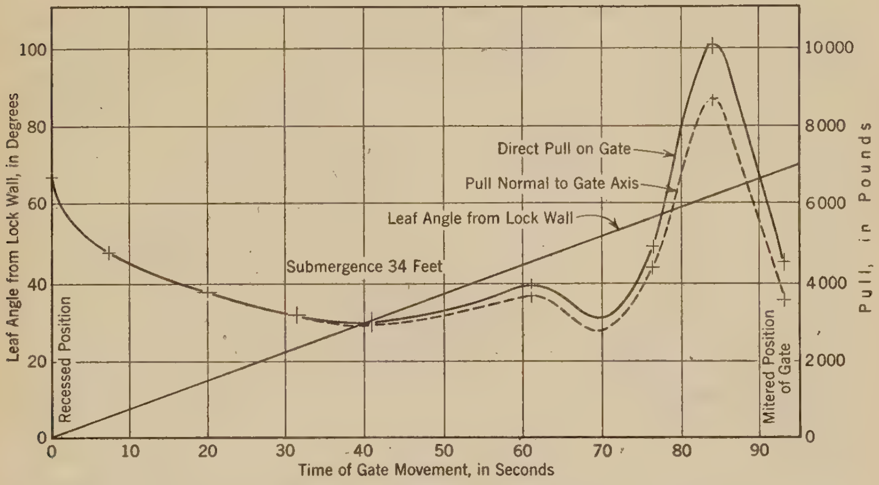

FIG. 11.—TYPICAL OPERATING GRAPH, DAVIS LOCK GATES, ST. MARYS FALLS CANAL

The clearance under the gate of the Davis Lock when in its recess is 3.5 ft and that between back of gate and recess wall is about 5 in. The operating graph of the Davis Lock gate shows that the force required to swing the gate from the open position is much larger than that required for the model tests. The low torque required in the model tests to start from the open position is surprisingly small and indicates an effective way for the water to reach the back of the gate in the recess.

Mr. Amster computed the mechanical advantage of the crank-and-strut linkage by trigonometry. The dead center positions of the crank coincide with the extreme positions of the gate, effecting theoretically an infinite mechanical advantage at those positions. The type of graph in Fig. 12 shows more clearly the relative torque applied to the gate at the different positions of its swing.

In the model and prototype the crank arm and the connecting rod form a straight line in both open and closed positions of the lock gate. With constant speed of gear input shaft, the rate of angular movement of the gate leaf swinging in either direction begins at zero, accelerating to a maximum at about 42° from the recessed position and then reduces to zero at the end of the swing. What is measured in the model tests is the torque required at the gate leaf which is taken as being directly proportional to the rate of swing, giving results of tests that would not apply if the gate were swung by an operating mechanism having different kinematic conditions between power input to shaft and force applied to the gate leaf.

The method used to measure the torque in the gate is applicable to model study of any lock gate of similar type. The results obtained, however, are applicable only to the model and prototype tested. For model tests of other lock gate installations, having different clearances between the gate leaf and sill, lock floor and recess, the model-driving mechanism would have to be redesigned to reproduce the kinematics of the prototype and model under the changed conditions.

Fig. 12.—Relative Torque Applied to Gate at Different Positions of Swing

It is interesting to note, from Fig. 2, that the seal between the gate and sill is near the upstream face of the gate leaf and that clearance between bottom of gate and top of seal is something less than 11 in. As a consequence, the gate in opening from the closed position is swinging over the sill with very little clearance for water to pass under the gate from the upstream to the downstream side. Consequently, water on the upstream side must be pushed into the lock chamber by the gate until the space between leaves at the miter end becomes large enough to equalize levels on upstream and downstream sides. This would account for the high peak torque at approximately 53° in the opening operation.

F. W. Edwards,[5] M. Am. Soc. C. E.—The use of an hydraulic model for the solution of a new type of problem is demonstrated in this paper. The data have been presented in a way which should be particularly valuable to designers. Mr. Amster deserves credit for his effort toward this end.

The curves in Fig. 6 are interesting from a design standpoint. An increase in gate operating time reduces greatly the peak torque near the mitered position, but has less effect on the peak near the recessed position. This is true for the smaller submergences as well as for the base test conditions. Where reduction in operating time is not an important factor, the time should be increased until the maximum torques near the recessed position and near the mitered position are equal. It is unfortunate that the tests were not extended to include gate operation for periods longer than 2.75 min. However, from extrapolation of data in Fig. 6(*a*), it appears that an operating time of about 4 min would reduce the peak torque to the practical minimum at both critical positions of the gate. This maximum torque for 4-min operation would be less than 10% of the peak for an operating time of 1.75 min and would have a pronounced effect on the required capacity of the gate operating machinery.

The curves in Fig. 7 illustrate a similar effect on the peak torque at the two positions for nonsynchronous operation. In this case, an increase in lead time causes a reduction of peak torque. However, it appears from the single-leaf operation that the peak torque near the mitered position could not be reduced to a value corresponding to the maximum obtained near the recessed position. Apparently, a 25-sec lead time, just outside the range of the tests, would reduce the torque to the practical minimum.

It is not entirely accurate to designate the prototype tests as verification tests. Prototype tests which are conducted specifically for verification of a model should be made with special care. Although the general conditions were indicated by the author, it should be emphasized that the tests on the existing lock gates were very rough. They were not intended originally for verification of the model. It is surprising that the results check as well as Fig. 8 indicates. The model, rather than the prototype, results are believed to represent the correct values.

The author states (see heading, "Conclusions from Tests"),

> "* * * but the best load distribution for simultaneous operation of the leaves, whether synchronized or not, can be obtained by the use of an operating cycle involving low speeds at the extremes of travel—* * *."

This part of conclusion 2 is not based entirely on the model results. In fact, the variation of the kinematic characteristics (except speed) of the gate operation was not tested. It would appear from the torque curves that, for the base operation time of 2 min, a faster movement of the gate could be used near the recessed position without affecting the required capacity of the gate operation machinery. This could be accomplished by establishing the end position of the crank arm away from dead center.

---

William A. Tripp,[6] Esq.—The model tests described by Mr. Amster do not include two factors, present in the actual operation of the locks of the Panama Canal, which have a substantial effect on the operating loads. These are: (1) The influence of the 200-ft chamber on the effective length, or free surface, of the chambers; and (2) the use of the culvert in equalizing water levels. Without proper evaluation of these factors, it is felt that the tests do not establish a sound criterion for predicting the forces on the prototype and are of doubtful value for application to other installations.

An analysis of the effect of these factors made by the writer indicates the factors to be much more important than has been recognized. According to this analysis, failure to introduce the 200-ft chamber properly into the problem appears to produce values of torque that are approximately 100% too large, and failure to include the effect of the culvert appears to produce values that are 50% too large. The combination of these two factors indicates that the tests may vary by as much as 200% from a correct prediction of the normal operating torques of the prototype. The method of analysis used by the writer is believed to be sound as it has been checked against sample cases taken from both the model and the prototype tests on the Panama Canal, yielding results which are reasonably close.

The basic conditions selected for the model tests include an upper chamber of 1,105 ft and a lower chamber of 200 ft. The 200-ft chamber is only an intermediate chamber between two 1,105-ft chambers; and the gates at both the upper and lower ends of this short chamber are operated simultaneously. This method of gate operation makes the short chamber act hydraulically much like a pool with an infinite free surface, and materially reduces the hydraulic resistance offered to the operation of each gate, at least during the opening cycle—the maximum duty cycle.

The free surface of the lock chambers has an important influence on the forces produced in the gate machinery. Evidence in support of this fact is presented in Fig. 8, in which the test curves for the opening cycle show progressively higher torques with shorter chamber lengths. Mr. Amster discusses this condition briefly under the heading, "Test Results." He states that increasing the length of the larger chamber beyond some 625 ft did not have a material effect on the torque. It should be noted, however, that the 200-ft chamber by then would be the dominating influence in the model. The torque required to move a gate is caused largely by the differential head produced by the movement of the gate. In effect, the gate is a wall between the two chambers on each side of it. Movement of the gate is equivalent to a change in the sizes of the two chambers, and, starting with a given quantity of water in each chamber, a differential head will be set up until sufficient water can flow to equalize the water levels. With a gate of a given size, a given movement will represent a definite volumetric change, which must be distributed over the free surface of the lock chambers, raising the water level in the chamber above the gate and lowering it in the chamber below the gate. The larger the free surface of each chamber, the smaller will be the differential head produced by the quantity of water involved. Thus, the chamber area will have a direct influence on the machinery torques for a given gate and gate drive. By the same reasoning, a gate at the other end of one of the chambers which follows the movement of the first gate, and causes a displacement of water compensating for the displacement of water caused by the first gate, will substantially prevent any change in the water level in the intermediate chamber. This is what takes place in the 200-ft chambers in the prototype at the Panama Canal.

---

[6] Elec. Engr., Chas. T. Main, Inc., Boston, Mass.; formerly Senior Engr., Mech.-Elec. Section, Special Eng. Div., The Panama Canal, Diablo Heights, Canal Zone.

Of course, the method of operation assumed for the model could be encountered in the prototype if something happened to prevent the "following" gate from operating, or if a gate were operated in this manner while being serviced. However, failure of the "following" gate to operate would be noted readily by the operator and, in any event, would impose only a short overload on the drive machinery. Such a failure would slow down the gate operation, thereby partly relieving the condition. Servicing operations could, and ordinarily would, be taken care of by nonsynchronous operation of the gate leaves. A substantial reduction in design requirements can thus be effected, by basing the size of the power unit on normal operation, and making the drive mechanism physically strong enough to take any momentary overloads that might be encountered with this smaller power unit.

With regard to the culvert, the operating practice at the Panama Canal is to keep the culvert valves open while swinging a set of gates. The importance of this procedure is evident from the discussion of the differential head produced by the movement of the gate. The significant fact is that the head is relieved by an equalizing flow of water between the chambers. Three channels are available for this flow—(*a*) the opening between the gate leaves, (*b*) the opening over the sill, and (*c*) the culvert. The first two start at zero for an opening cycle, whereas the third is constant. The importance of the culvert will depend upon its dimensions in relation to other geometrical features for the particular case. In the existing prototype at the Panama Canal, the culvert area is greater than the combined area of the other two channels for about the first 5% of the arc of gate swing in opening. It is understood that these relationships are about the same in the new locks. It is particularly significant, therefore, that the tests indicate that the peak of torque occurs within about the first 8% of the arc of swing. Of course, the rate of water flow per unit of cross-sectional area will be less for the culvert than for the gate opening, but the relative magnitude represents an important factor during a critical part of the cycle of operation. As is generally well known (and the model tests prove this), with lock gates following the kinematics of the Panama Canal type and with well-designed wall recesses, the torques determining the design of the gate machinery occur during this early part of the opening cycle. Anything that can be introduced to decrease torques during this period will have a substantial influence in reducing design requirements. Culverts of the relative size of those at the Panama Canal are of sufficient importance to warrant full and careful evaluation.

The magnitudes of the influences of the two factors discussed herein will vary for different physical relationships and operating conditions. They appear to be about the same for both the old and the new locks at the Panama Canal. Their relative importance indicates that these magnitudes should be introduced into any analysis or tests involving similar arrangements.

The writer wishes to acknowledge and express his appreciation of the interest and assistance of B. O. McCoy, Assoc. M. Am. Soc. C. E., in the study and analysis of this problem.

Maurice N. Amster,[7] Assoc. M. Am. Soc. C. E.—Quite appropriately, Mr. Soucek emphasizes the necessity for giving full consideration to the limitations involved in applying the test results to the design of other gate operating machines. More than one of the discussers overlooked the limiting nature of the writer's statement (see heading, "Application of Test Results to Other Miter Gates") that the test data "probably" could be applied to other miter gates having "the same kinematic cycle."

A specific limitation mentioned by Mr. Soucek is the fact that no tests were made of the effect of speed variation at low submergences. In the case of a miter gate of the same length, operated on the same kinematic cycle but with a submergence lower than that of the "base conditions," the only strictly applicable test results would be found in Fig. 6(*b*), and these would apply only for an operating time of 2 min. The effect of geometric disproportionality is small, however, and the speed-torque relations shown in Fig. 6(*a*) can be applied with reasonable reliability provided that the ratio of length of gate leaf to submergence is not too far from unity.

The test results presented by Mr. DeYoung in Fig. 11 are interesting and provide a basis for estimating loads on other gates operated with similar kinematic cycles. The angular position at which peak load occurs is close to that at which peak load was observed in the model tests of single-leaf operation. However, the kinematic cycle of the cable-and-drum mechanism described by Mr. DeYoung is so unlike that of the crank-and-strut mechanism used in the Panama Canal locks that the significance of the agreement between results in the two cases is doubtful. The diagram presented by Mr. DeYoung in Fig. 12 is quite convenient for some purposes.

Professor Edwards presents interesting extrapolations of the test results. The range of operating times tested with the model, like other phases of the model tests, was confined to the contemplated range of prototype values. It is regrettable that the model-test schedule could not be extended to cover more generalized studies.

As Professor Edwards states, the model study did not include any variation of the kinematic cycle except speed. The writer's conclusion that low speeds are best at the extremes of travel was based on the fact that peak loads occur near those positions. It is quite evident that a uniform speed throughout the leaf movement, for example, would produce even greater peak loads. The ideal load would be a uniform one, and this would be approached, not by increasing the relative speed near the recessed position, where a slight peak already exists, but by decreasing the relative speed near the mitered position. The degree to which this can be achieved in practice is limited by mechanical and structural design features and by space limitations. Dead-center recessed and mitered positions are desirable because they prevent gate-leaf overtravel in case of limit-switch failure.

[7] Engr., Air Products, Inc., Chattanooga, Tenn.

Mr. Tripp contends that the model-test results are substantially in error because of improper consideration of the chamber lengths and the influence of the lock culverts. Mr. Tripp's statements regarding the effect of gate movement show clearly that he has applied steady-flow formulas to transient phenomena, which fact alone invalidates his views. Mr. Soucek describes accurately the nature of the gate loads when he states that they "are principally due to water-level variations which are transient in character and local in extent—surges induced by the gate movement—and therefore not related in any simple manner to the adjacent water-surface areas." However, since Mr. Tripp obtains results differing so greatly from those reported, and in consideration of the danger that his method of computation might be adopted by others, a detailed examination of the differences and the reasons therefor appears advisable. Accordingly, it will be shown that:

1. The gate loading cannot be computed on the basis of surface areas;
2. The effect of the 200-ft downstream chamber length is relatively small;
3. The culverts have negligible effect upon the critical gate load;
4. The loads for the "base conditions," although somewhat severer than the normal operating loads, may occur frequently in the prototype locks; and
5. The "base conditions," as applied, are logical criteria for design of the prototype operating machines.

Fig. 13 shows the effect of variation in the upstream chamber length between the limits of 300 ft and 1,105 ft for both the opening operation and the closing operation. The peak torque reached in the opening operation is critical for design. In these tests, the downstream chamber length was held constant at 200 ft, but it is theoretically evident, and was shown by similar tests, that the effect of length changes is about the same for an upstream chamber as for a downstream chamber. These tests show clearly that changes in the chamber length had no significant effect for lengths exceeding 625 ft and therefore that the gate loading cannot be computed on the basis of surface area. The theoretical basis for this result is quite simple. The wave velocity is expressed by

$$c = \sqrt{g\,y} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

in which c is the wave velocity; g is the gravitational acceleration; and y is the depth. Thus, $c = \sqrt{32.2 \times 82.5}$, or about 50 ft per sec. The peak opening torque occurs about 20 sec after operation begins; therefore, in order for the peak torque to be affected by the waves generated at the instant operation begins, these waves must encounter a reflecting surface no farther than about 500 ft from the gate. Since the torque remains at or near its peak value for a few seconds, it was stated conservatively (and it was shown by the tests) that lengths exceeding 625 ft have no effect upon the peak torque.

The fallacy in computing the operating loads on the basis of surface area, as suggested by Mr. Tripp when he mentions "* * * a definite volumetric change, which must be distributed over the free surface of the lock chambers * * *," is evident when it is considered that consistent application of that theory would indicate zero loads in the operation of a gate separating two areas of infinite extent.

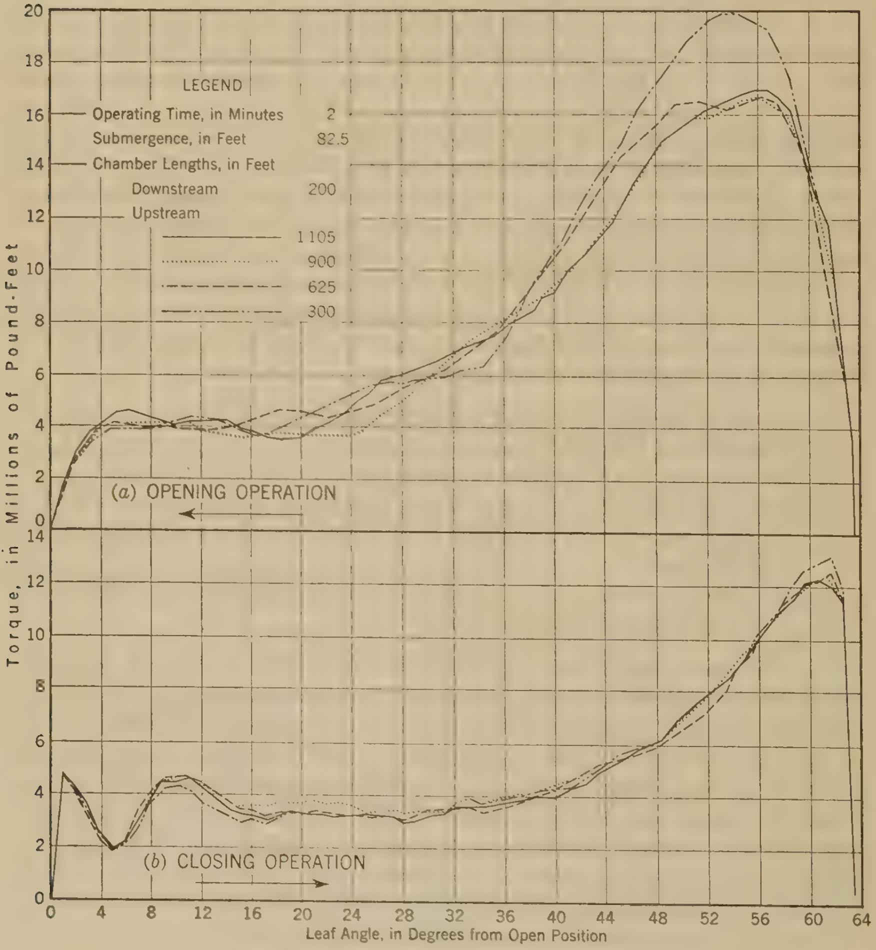

FIG. 13.—VARIATION OF CHAMBER LENGTH

As shown in Fig. 13, a reduction in upstream chamber length from 625 ft (the approximate limit of significant length effect) to 300 ft increased the peak opening torque from about 17,000,000 lb-ft to about 20,000,000 lb-ft; an increase of less than 10% in torque corresponds to a decrease of 52% in upstream chamber length within the effective range. Any reasonable method of extrapolating these results—even Mr. Tripp's computation procedure—would show that a decrease of 68% in chamber length would not increase the torque to the extent indicated by Mr. Tripp in his discussion. Even when one of the two chambers is only 200 ft long, it requires about 8 sec for a wave to travel the length of the short chamber and back. Thus, the reflected wave that is effective at the instant of peak torque originates from a slow gate movement occurring early in the cycle and produces a correspondingly small effect.

In making a substantial allowance for the effect of culvert discharge upon the gate operating load, Mr. Tripp again ignores a transient phenomenon that makes the effect of the culverts negligible. Tests of an intermediate gate at one of the existing locks showed that the duty cycle was absolutely unaffected by the position of the culvert valves (that is, whether they were closed or open). Since this result differs so greatly from Mr. Tripp's belief, some explanation of the reason is necessary. If a gate were operated under the base conditions—that is, with a 1,105-ft length of chamber upstream and a 200-ft length downstream—the throttling effect of the small port-and-lateral capacity in the short chamber would so restrict the culvert flow that little effect would be expected. Therefore, a condition more favorable to free flow through the culverts will be considered—opening of a single gate with chamber lengths of more than 1,000 ft both upstream and downstream and with culvert valves open. Since the gate leaves are accelerated continuously during the interval prior to occurrence of peak torque—a time of about 20 sec—the conditions will not be affected by reflections from the chamber ends and there will be an approximately uniform slope upward toward the gate from a point about 1,000 ft upstream and an approximately uniform slope downward toward the gate from a point about 1,000 ft downstream. At the instant of peak torque, the culvert discharge due to the average head on the system would be about 25% of that due to consideration of the head at the gate. However, the actual discharge is much smaller. It is impossible to determine the "equivalent unthrottled length" of the manifold system without considering the theory of hydraulic manifolds, but since only an approximate answer is sought, it will be assumed that the manifold system of the two 1,000-ft chambers has an "equivalent unthrottled length" of only 1,000 ft rather than the total culvert length of 2,000 ft. It is evident that the length cannot be assumed much shorter, because a shorter length would include so few ports and laterals that these rather than the culvert area would govern the rate of flow. With an "equivalent unthrottled length" of 1,000 ft, even if head losses that oppose the flow are ignored, the acceleration of the culvert flow would be approximately 0.016 ft per sec per sec at the instant of peak torque. The approximate mean acceleration from the start of gate operation to the instant of peak torque would be 0.008 ft per sec per sec, and the velocity of flow would be approximately 0.16 ft per sec. It appears that the velocity computed on the basis of steady flow corresponding to the head at the gate, disregarding friction losses, would be about 8.0 ft per sec—fifty times as great as the effect obtained by consideration of transient conditions. Of course, one simplifying assumption after another has been used in the preceding evaluation of the effect of the culverts for the transient conditions; however, any reasonable adjustment of these assumptions may be made without effect upon the principal conclusion—that the observed lack of appreciable effect of culvert discharge is consistent with theoretical considerations. A short loop culvert or an opening in the gate, of course, would have a pronounced effect.

It was not intended to convey the impression that the results for "base conditions" represent the average operating load. It is true that when two consecutive gates 200 ft apart are swung simultaneously the load is distributed to two sets of gate machines and is not critical. However, such operation will not be as general as would be inferred from Mr. Tripp's comments; it will occur only where it is desired to maintain two barriers against the upper pool. In other locations, it is contemplated that a single gate will be operated, with chamber lengths of more than 1,000 ft both upstream and downstream. Whether culverts are open or closed, the peak opening torque will be some 2,000,000 or 3,000,000 lb-ft less than the value obtained with the "base conditions" used in the model tests when no extraneous factors enter the problem. However, one normal condition, the presence of a large ship in either of the chambers between which the gate is located, will create a peak torque closely approximating that of the "base conditions." Occurrence of unexpected surges is another factor that makes it necessary that the design load exceed the usual operating load by a reasonable amount. Since the main purpose of the paper was to illustrate the application of model test data in design, it was not considered necessary to explain in detail all factors affecting selection of the base conditions, any more than it is felt necessary to defend the selection of a conservative unit stress in the design of an important structure subject to variable and uncertain loads. However, Mr. Tripp's claim that the base conditions were unduly conservative makes it clear that some of the additional factors considered in establishing the base conditions should have been explained for the benefit of those who are not familiar with the actual operating conditions.

The peak-torque values found in the model tests for "base conditions" were used as criteria for the design of the mechanical components of the gate operating machines because, as stated in the preceding paragraph, it is entirely possible and very likely that these values will occur in normal operation of the lock gates. However, the power of the driving motors was not controlled by the peak-torque requirements. During the part of the gate movement at which the peak torque occurs, the motors are loaded to approximately 180% of their full-load torque rating. It was also intended that, in the event of motor failure, one of the two motors for the machine of each gate leaf be capable of operating the gate leaf under otherwise favorable conditions, although the single motor would be considerably overloaded.

In conclusion, it is interesting to observe that transient conditions closely analogous to those affecting the peak opening torque exist in the field of electrical engineering. This is true not only of the wave conditions in the lock chambers but also of the inertial effects that make the discharge through the culverts insignificant.

The writer wishes to thank Messrs. Soucek and G. D. Smith for their assistance in the preparation of the text of this closure. The interest taken by all discussers is also appreciated.

SIMULTANEOUS CONSOLIDATION OF CONTIGUOUS LAYERS OF UNLIKE COMPRESSIBLE SOILS

By Hamilton Gray,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. Edward S. Barber, Jacob Feld, George W. Glick, and Hamilton Gray.

Synopsis

The results of an analysis of a condition which is sometimes encountered in foundation investigations—the consolidation of two contiguous layers of clay possessing different consolidation characteristics—are presented in this paper. A special case of such a phenomenon exists when one of two contiguous layers is relatively incompressible and functions merely to impede the outflow of water from the compressible stratum. When two adjoining compressible strata are made to consolidate under an applied load, the behavior of each stratum is influenced by the presence and action of the other. The extent of the mutual interference or influence of the layers depends on the physical properties (compressibility and permeability) of the materials comprising each layer. The analysis determines quantitatively how these physical properties govern the simultaneous consolidation of the two layers.

The details of the analysis have been placed on file for reference in Engineering Societies Library in New York, N. Y. They have been omitted from this paper, since they are long and do not influence the application of the results. The basic assumptions upon which the analysis is predicated are given in this paper, together with the appropriate differential equations and the final results. The user is thus able to apply these solutions with an understanding of the restrictions under which they have been secured. Graphs are presented illustrating the results secured for specific conditions. The nature of these solutions is in entire agreement with what "physical intuition" might anticipate, and a comparison is made between various approximations that have been made heretofore, and the "rigorous" solutions herein outlined.

Note.—Published in February, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Asst. Prof., Civ. Eng., New York Univ., New York, N. Y.

The results are purely theoretical and must be so considered until comparison with observed phenomena in the field confirms or denies their applicability to engineering problems. They are presented in the expectation that such comparisons may be more numerous if the nature of the theoretical approach is known.

INTRODUCTION

The original theory of the consolidation of clay deposits[2] was offered by Karl Terzaghi, M. Am. Soc. C. E., in 1925. Considerable interest has been shown recently in extensions of this theory to the more complicated practical problems involving three-dimensional flow and compression[3, 4, 5, 6] and stratified clay deposits.[7] Definite progress has been made in developing solutions for certain of these problems. A solution of the one-dimensional consolidation problem involving two contiguous layers of unlike clays has not appeared heretofore, although the technique required for obtaining it has been available for some years[8, 9] and somewhat analogous problems have been treated in the theory of heat flow.

The purpose of this paper is to draw attention to this solution and to indicate the nature of the results obtained. It must be realized that the application of these more recent developments would be justifiable only in the case of relatively large and expensive structures, since the analyses appear rather forbidding and at best necessitate considerable time and effort. Nonetheless, in connection with important structures it is frequently desirable to apply such advanced theories to secure one of perhaps a number of rough estimates of the possibilities inherent to the situation. Today engineers in increasing numbers are drawing extensively on the results of mathematical analysis as an aid in their work. In some cases the answer so obtained may be criticized as little better than a guess, but in any event it is a relatively "intelligent" or "conditioned" guess and, if actual behavior in the field is observed properly, one will ultimately be in a position to decide whether the "guess" was worth the effort or not. It is well to emphasize that experimental verification of the theories currently utilized for predicting the settlement of structures, perhaps by models, but more particularly by observing full-size structures, has not been as common as is desirable and that unwarranted confidence is sometimes placed in estimates that are based on theory unsubstantiated by field observation. Frequently actual conditions invalidate some of the assumptions on which a theory is based, and failure to consider this possibility may then result in large discrepancies between predicted and observed behavior. The following developments are offered as "tools," the accuracy of which remains to be determined, of which the engineer concerned with foundation design may avail himself at his discretion.

A Special Case of Impeded Drainage

By way of introduction the relatively simple problem of a compressible stratum with impeded drainage will be considered. This is actually a special case of the more general problem treated herein, but is introduced here because of the relative ease with which it can be analyzed. The method has long been known;[10] it represents an extension of the usual attack by means of differential equations and Fourier series. Two practical applications are found when one investigates (*a*) the error involved in the assumption of "free outflow" from the surface of a clay sample being compressed in the laboratory under known conditions, and (*b*) the case of a relatively thin but compressible soil layer overlain by a thick bed of incompressible and relatively impervious soil.

(*a*) TRUE DIMENSIONS (*b*) REDUCED DIMENSIONS

Fig. 1

The problem is shown schematically in Fig. 1, which serves also to define certain of the letter symbols introduced in the analysis. The remaining symbols are defined as they appear in the text and the complete list is presented, for the convenience of the reader, in the Appendix. The "reduced" dimensions of Fig. 1(*b*) were introduced for mathematical simplicity and are related to the true dimensions by the equations:

$$H_s = \frac{H}{1 + e} \quad \text{. . . . . (1a)}$$

and

$$z = \frac{h}{1 + e} \quad \text{. . . . . (1b)}$$

In accordance with the usual custom in dealing with the consolidation problem, it is assumed that the voids of both compressible and incompressible layers are completely filled with an incompressible liquid (water). It is further assumed that, before the consolidation process is initiated, the pressure, u_z, in the void liquid varies according to the law

---

[10] "An Elementary Treatise on Fourier's Series and Spherical, Cylindrical, and Ellipsoidal Harmonics," by W. E. Byerly, Ginn & Co., Boston, 1893, pp. 117–121.

$$u_z = \gamma\, z_d \quad \ldots\ldots (2)$$

in which γ is the density of the liquid, and that at all times the liquid pressure is atmospheric when $z_d = 0$. A normal stress of intensity, p, is abruptly applied to the surface S-S, resulting in an upward flow of water associated with the compression or void reduction of the lower layer under the influence of this added load. If u_d (commonly referred to as "hydrostatic excess pressure") denotes the fluid pressure, in excess of that given by Eq. 2, induced by p in the incompressible layer, the flow of liquid that occurs in this incompressible layer is governed by LaPlace's equation:[11]

$$\frac{\partial^2 u_d}{(\partial z_d)^2} = 0 \quad \ldots\ldots (3a)$$

Similarly, the excess fluid pressure, u, in the compressible layer varies in accordance with the formula[2]

$$c\,\frac{\partial^2 u}{\partial z^2} = \frac{\partial u}{\partial t} \quad \ldots\ldots (3b)$$

in which c, the coefficient of consolidation of the compressible material, is defined by the equation

$$c = \frac{k}{a\,\gamma\,(1 + e)} \quad \ldots\ldots (4)$$

$-\,a$ is the slope of the pressure, void-ratio curve; $+\,a$ is known as the coefficient of compressibility; and t is the time. The solution of the problem consists of two expressions—one for u_d, as a function of z_d and t, and the other for u, as a function of z and t. These expressions must satisfy the differential Eqs. 3 and, in addition, the following "boundary conditions":

When $z = 0$—

$$\frac{\partial u}{\partial z} = 0 \quad \ldots\ldots (5a)$$

when $t = 0$—

$$u = p \text{ (a constant)} \quad \ldots\ldots (5b)$$

when $z_d = 0$

$$u_d = 0 \quad \ldots\ldots (5c)$$

and, when $z_d = H_d$ and $h = H$—that is, at the common boundary—

$$u = u_d; \qquad \text{and} \qquad k\,\frac{\partial u}{\partial h} + k_d\,\frac{\partial u_d}{\partial z_d} = 0 \quad \ldots\ldots (5d)$$

Since $h = z\,(1 + e)$, Eq. 5d may be written

$$\left[k_s\,\frac{\partial u}{\partial z}\right]_{z=H_s} + \left[k_d\,\frac{\partial u_d}{\partial z_d}\right]_{z_d=H_d} = 0 \quad \ldots\ldots (6)$$

---

[11] "The Flow of Homogeneous Fluids Through Porous Media," by M. Muskat, 1st Ed., McGraw-Hill Book Co., Inc., New York, 1937.

in which $k_s = \frac{k}{1+e}$. By differentiation and substitution it is readily shown that—

$$u = 2\,p \sum_{n=1}^{n=\infty} \epsilon^{-TN} \left[\frac{\sin r_n \cos r_n \frac{z}{H_s}}{r_n + \frac{1}{2}\sin 2\,r_n}\right] \qquad (7a)$$

and

$$u_d = p\,\frac{z_d}{H_d} \sum_{n=1}^{n=\infty} \epsilon^{-TN} \left(\frac{\sin 2\,r_n}{r_n + \frac{1}{2}\sin 2\,r_n}\right) \qquad (7b)$$

—are two functions which, respectively, satisfy the differential Eqs. 3 and the prescribed boundary conditions, provided r_n is a root of the equation—

$$r \tan r = \frac{H_s}{H_d}\frac{k_d}{k_s} = R \qquad (8a)$$

In Eqs. 7, ϵ is the base of natural logarithms and the symbols in the exponent

$$N = (r_n)^2 \qquad (8b)$$

and

$$T = \frac{c\,t}{(H_s)^2} \qquad (8c)$$

are used solely to simplify typography. In Eq. 8*c* the symbol T is a dimensionless quantity commonly termed a "time factor."

The degree of consolidation at any point in the compressible stratum is defined as

$$U_p = 1 - \frac{u}{p} \qquad (9)$$

and the average degree of consolidation for the entire stratum is then given by

$$U = \frac{1}{H_s}\int_0^{H_s} U_p\,dz = 1 - \frac{1}{p\,H_s}\int_0^{H_s} u\,dz \qquad (10)$$

The degree of consolidation, U, equals the ratio of current subsidence or compression to the ultimate values of these quantities under the existing pressure provided the relation between void ratio and intergranular pressures in the soil is linear. Substituting the expression Eq. 7*a* for u under the integral sign in Eq. 10, and evaluating:

$$U = 1 - 2\sum_{n=1}^{n=\infty} \frac{\epsilon^{-TN}}{r_n}\,\frac{\sin^2 r_n}{r_n + \frac{1}{2}\sin 2\,r_n} \qquad (11)$$

The degree of consolidation is frequently expressed as a percentage and written as $U\%$. The values of $U\%$ then are one hundred times the magnitudes of U given by Eq. 11. As k_d approaches infinity (corresponding to unimpeded or free outflow from the upper surface of the compressible layer), R likewise becomes infinite and the roots of Eq. 8*a* become simply odd multiples of $\frac{\pi}{2}$, and may be represented by

$$r_n = (2\,m + 1)\,\frac{\pi}{2} \qquad (12)$$

in which m takes on successive integer values beginning with $m = 0$. The corresponding equation for U is

$$U = 1 - \frac{8}{\pi^2} \sum_{m=0}^{m=\infty} \frac{1}{(2\,m + 1)^2}\,\epsilon^{-TN'} \qquad (13)$$

which coincides with the familiar solution obtained when the boundary condition Eq. 5*d* for the compressible layer is $u = 0$ when $z = H_s$. In Eq. 13, the exponent N' is substituted for

$$N' = \frac{(2\,m + 1)^2\,\pi^2}{4} \qquad (14)$$

to simplify typography. For fixed values of H_s, H_d, k_s, and k_d, R is determined, and the roots of Eq. 8*a* may be found by the method of successive approximations. Typical curves such as those illustrated in Fig. 2, showing the variation of U with T for different values of R, may then be plotted.

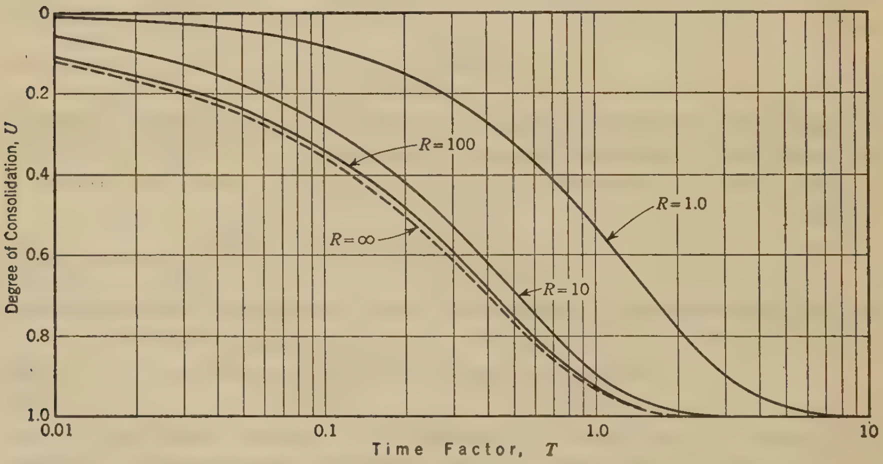

FIG. 2.—CURVES OF U VERSUS T

For large values of T, only one term of the series for U is needed for sufficient accuracy in plotting the curves. Hence, to find the approximate value of $T > 0.5$ required for a given value of $U > 0.76$ when R is known, it is sufficient to use the equation:

$$U = 1 - \frac{2\,\sin^2 r_1}{r_1 + \frac{1}{2}\sin 2\,r_1}\,\frac{\epsilon^{-NT}}{r_1} \qquad (15)$$

Solving for T (as in Eqs. 7, $N = (r_n)^2$, the value of n being 1 in this case):

$$T = \frac{1}{(r_1)^2} \log \frac{2\,\sin^2 r_1}{(1 - U)\,r_1\,(r_1 + \frac{1}{2}\sin 2\,r_1)} \qquad (16)$$

in which r_1 is the smallest root of $r \tan r = R$ (see Eq. 8*a*).

In determining the value of k from the results of a consolidation test it is necessary to utilize the relationships:

$$c = (H_s)^2 \frac{T}{t} \qquad (17a)$$

and

$$k = a \gamma c (1 + e) \qquad (17b)$$

Eq. 17b may also be written

$$k_s = a \gamma c = a \gamma (H_s)^2 \frac{T}{t} \qquad (17c)$$

In these formulas a is determined from the pressure, void-ratio diagram, and H_s by actual measurements. It is customary to compare the shape of an empirical time-consolidation curve of the tested soil with that of the theoretical curve, $R = \infty$, of Fig. 2. These two curves are usually rather similar in shape, but the empirical curve is plotted to scales of elapsed time, t, and measured compression of the soil sample, whereas the curve, $R = \infty$, of Fig. 2 is plotted to the scales of the dimensionless quantities T and U. It is generally possible to determine, for most empirical curves, the approximate value of elapsed time, t, which is required to attain some specified portion, say 60% or 90%, of the ultimate compression under the prevailing load.[12, 13] To be specific, the elapsed time required to reach 90% of the ultimate compression, when drainage is unobstructed, will be denoted by t_9. The corresponding value of U is 0.9, and of T, 0.848. Then

$$k_s = a \gamma (H_s)^2 \frac{0.848}{t_9} \qquad (18a)$$

and

$$k = k_s (1 + e) \qquad (18b)$$

in which e is the average void ratio under the load increment which resulted in the empirical time-consolidation curve, and a is determined from the pressure, void-ratio diagram.

This value of k will be accurate only if the actual value of R is infinite. If $R \neq \infty$, consolidation will occur in accordance with Eq. 11 rather than Eq. 13. The empirical curve should then be compared with a theoretical curve for $R \neq \infty$ rather than with the theoretical curve for $R = \infty$. However, the correct value of R is unknown since it depends upon the value of k to be determined.

It is possible to avoid this dilemma as follows: Assuming that $R \neq \infty$, let t_a denote the observed time which corresponds to 90% of the ultimate compression given by the empirical curve. Since drainage is impeded, $t_a > t_9$. Computing as before by using $T = 0.848$:

$$k_{sa} = a \gamma (H_s)^2 \frac{0.848}{t_a} \qquad (19)$$

in which k_{sa} is the "apparent" permeability of the soil. Since $t_a > t_9$,

---

[12] "Principles of Final Soil Classification," by Charles Terzaghi, *Public Roads*, Vol. 8, May, 1927, p. 41.

[13] "Improved Soil Testing Methods," by G. Gilboy, *Engineering News-Record*, May 21, 1936, p. 732.

$k_{sa} < k_s$. Had the actual value of R been known, a magnitude of T greater than 0.848 could have been used, this magnitude being found by means of Eq. 16, in which $U = 0.9$. Use of this correct value of T (denoted by T_a) would have given the result, k_s, at once. Since $\frac{T_a}{0.848}$ may be determined as a function of R, when $U = 0.9$, by means of Eq. 16, the ratios $\frac{k_s}{k_{sa}} = \frac{t_a}{t_9} = \frac{T_a}{0.848}$ may also be found in terms of R (Eq. 8a). If $M = \frac{H_s}{H_d} k_d$, $\frac{M}{k_{sa}} = R \frac{t_a}{t_9}$. For any chosen value of R, the ratios $\frac{t_a}{t_9}$ and $\frac{k_s}{k_{sa}}$ can be found, and thence, $\frac{M}{k_{sa}}$. A plot of corresponding values of $\frac{k_s}{k_{sa}}$ versus $\frac{M}{k_{sa}}$ is shown in Fig. 3.

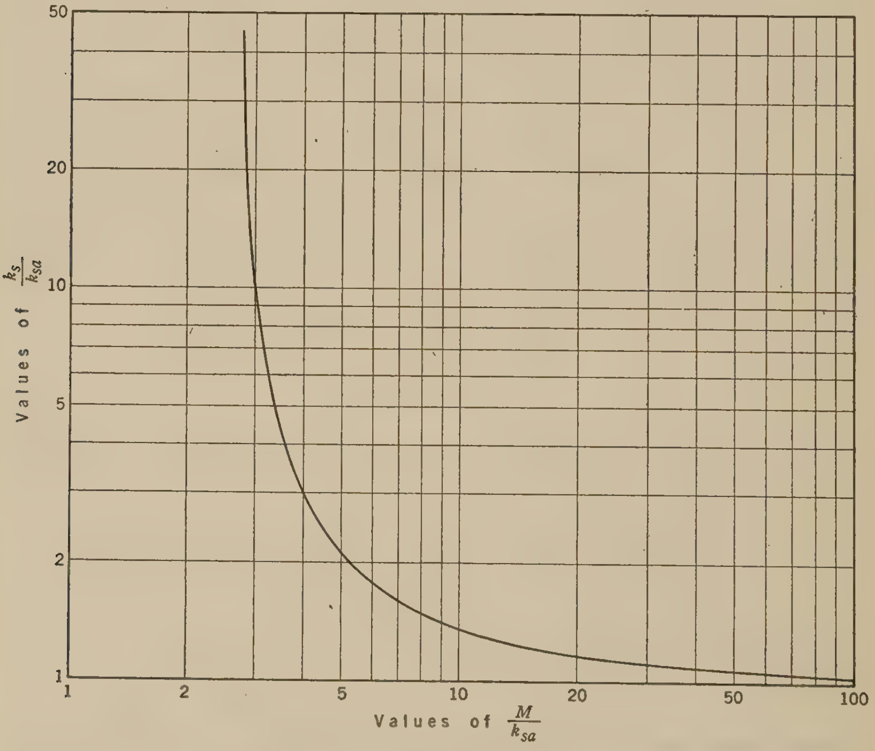

FIG. 3.—THE RATIO OF TRUE PERMEABILITY TO APPARENT PERMEABILITY AS A FUNCTION OF $\frac{M}{k_{sa}}$ (FOR $U = 0.9$)

From this curve it appears that, when $R = 100$, the ratio of $\frac{k_s}{k_{sa}}$ is only 1.025 so that it may be concluded that the drainage medium exercises a negligible influence if the value of R exceeds 100. Ordinarily the drainage media used in laboratory testing are of such a nature that R is of the order of magnitude of 10^5. If, in any instance, the value of R should fall below 100, the curve of Fig. 3 would permit proper correction to be made in determining the value of k_s.

Another application of the results expressed in Eqs. 8*a* and 9 is involved in the subsidence of a load placed upon a bed of relatively incompressible soil of low permeability, such as a cohesionless silt, which overlies a stratum of compressible clay. It is assumed that the load exerts a uniform pressure on the soil and that its lateral extent is so great as to afford no appreciable reduction in pressure increase between the upper surface of the silt and the bottom of the clay, which is assumed to rest on impervious rock; that is, a load of 1 ton per sq ft applied at the ground surface creates an additional pressure of nearly the same magnitude at the rock surface, and at all intermediate elevations.

FIG. 4

The consolidation phenomenon then is one-dimensional for all practical purposes. Suppose that subsoil and laboratory investigations have established data shown in Fig. 4. Eq. 8*a* yields

$$R = \frac{k_d}{k_s}\frac{H_s}{H_d} = \frac{80 \times 10^{-9}}{8.33 \times 10^{-9}}\frac{4.16}{40.0} = 1.0.$$

The time required to reach any fraction of the ultimate subsidence of approximately 4 in. may be secured by means of the curve $R = 1.0$ in Fig. 2. For example, 3 in. of settlement corresponds to $U = 75\%$ and $T = 1.85$ according to this curve. The time in years is obtained from

$$t = T\frac{(H_s)^2}{c} \times \frac{1}{3.16 \times 10^7} \qquad (20)$$

in which 3.16×10^7 is the number of seconds in a year. Thus,

$$t = 1.85\frac{(30.48 \times 4.16)^2}{10 \times 10^{-5}} \times \frac{1}{3.16 \times 10^7} = \frac{1.85}{3.16}(3.048 \times 4.16)^2 = 9.5 \text{ yr.}$$

Had the permeability of the silt been of the order of 10^{-4} cm per sec the value of R would have been

$$\frac{10^{-4}}{8.33 \times 10^{-9}} \frac{4.16}{44} = \frac{41.6}{44} \times \frac{10}{8.33} \times 10^{3} = 1.137 \times 10^{3} = 1{,}137.$$

Using the curve $R = \infty$ in Fig. 2, the value $T = 0.48$ corresponds to $U = 75\%$; whence $t = 9.5 \times \frac{0.48}{1.85} = 2.46$ yr.

It should be realized that the drainage conditions affect only the time rate of compression and have no influence on the total amount of compression. Therefore consideration of the drainage conditions is required only when the settlement rate is of importance.

Another application of the solution given by Eq. 7*a* consists of the computation of the variation, brought about by consolidation, of the shearing strength of a clay. In some instances it is feasible to schedule construction operations for earth dams or embankments in such a manner that a weak foundation, originally incapable of supporting the finished structure, may be gradually loaded and compressed during the construction period so that its strength is never exceeded, but gradually increases as the void ratio is reduced. Thus, ultimately, it is able to support the finished structure safely. In such circumstances it is necessary to know not only the shearing, but also the consolidation characteristics of the foundation material. If the soil, which is to be strengthened by consolidation, does not have free drainage, the usual consolidation theory based on the assumption of unimpeded drainage will yield results that are on the unsafe side.

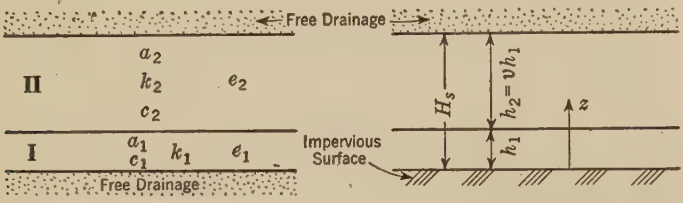
In considering the variation in shearing strength one may deal with the average strength of the weak stratum, in which case curves similar to those of Fig. 2 are useful, or one may deal with the weakest zone in the consolidating stratum. The shearing resistance at any point is a function primarily of the void ratio which may be found by means of the pressure, void-ratio diagram used in conjunction with Eq. 7*a*. At any instant of time the value of u is greatest at the bottom of the consolidating stratum, see Fig. 1, where $z = 0$. At this elevation the void ratio is greater and the shearing strength is less than for values of $z > 0$. Setting $z = 0$, Eq. 7*a* becomes

$$u = 2\,p \sum_{n=1}^{n=\infty} \frac{\sin r_n}{r_n + \frac{1}{2} \sin 2\, r_n}\, \epsilon^{-TN} \quad \text{.................} \quad (21)$$

If the thickness and the coefficient of consolidation of the consolidating stratum are known, $T = \frac{c\,t}{(H_s)^2}$ (Eq. 8*b*), and u may be expressed as a function of the time lapse following the application of a load increment, p. Therefore, one is in a position to determine the variation of shear strength with the passage of time at the elevation where the stratum is weakest. In this connection it is convenient to plot u as a function of T in accordance with Eq. 21.

THE GENERAL CASE OF TWO ADJACENT COMPRESSIBLE STRATA

In analyzing the problem of two contiguous layers of consolidating soils, it is expedient to consider the layers in a manner similar to that in the preceding text. This problem is depicted in Fig. 5, there being two distinct cases to consider—(*a*) free drainage top and bottom, and (*b*) drainage at top only, as shown. In Fig. 5 all the dimensions shown are "reduced." The layers of soil are numbered I and II, and the corresponding soil coefficients are identified by appropriate subscripts, 1 and 2. For each material,



(*a*) FREE DRAINAGE AT TOP AND BOTTOM

(*b*) FREE DRAINAGE AT TOP ONLY

FIG. 5

$$k = a\,c\,\gamma\,(1 + e) \qquad (22)$$

In addition, the following transformations are convenient:

$$k_{s1} = \frac{k_1}{1 + e_1} \qquad (23a)$$

$$k_{s2} = \frac{k_2}{1 + e_2} \qquad (23b)$$

and the introduction of four dimensionless numbers—

$$\mu^2 = \frac{c_1}{c_2}; \qquad \sigma = \frac{1}{\mu}\frac{k_{s1}}{k_{s2}}; \qquad \nu = \frac{h_2}{h_1}; \qquad \text{and} \qquad T = \frac{c_1}{(h_1)^2}\,t \qquad (24)$$

—is useful. The last (T) is the "time factor" for this case.

It is possible to solve the two basic cases simultaneously, and, in summarizing, the boundary conditions have been arranged in Table 1 so as to emphasize the similarity. For the lower layer the law of fluid flow may be expressed by

$$c_1\,\frac{\partial^2 u_1}{\partial z^2} = \frac{\partial u_1}{\partial t} \qquad (25a)$$

and for the upper layer the corresponding equation is

$$c_2\,\frac{\partial^2 u_2}{\partial z^2} = \frac{\partial u_2}{\partial t} \qquad (25b)$$

in which u_1 and u_2 denote the fluid pressures in excess of hydrostatic in the lower and upper layers, respectively.

Boundary condition 5, Table 1, is more restrictive than is necessary, since solutions can be obtained in cases where u is any function of z when $t = 0$. It may be shown by direct substitution that, for the case of drainage at both top

TABLE 1.—BOUNDARY CONDITIONS

No.	Boundary	Drainage top and bottom	Drainage top only
1	$z = 0$	$u_1 = 0$	$\frac{\partial u_1}{\partial z} = 0$
2	$z = H$	$u_2 = 0$	$u_2 = 0$
3	$z = h_1$	$u_1 = u_2$	$u_1 = u_2$
4	$z = h_1$	$k_{s1} \frac{\partial u_1}{\partial z} = k_{s2} \frac{\partial u_2}{\partial z}$	$k_{s1} \frac{\partial u_1}{\partial z} = k_{s2} \frac{\partial u_2}{\partial z}$
5	$t = 0$	$u = p$ (a constant)	$u = p$ (a constant)

and bottom, the two functions,

$$u_1 = \sum_1^\infty C_n \, \epsilon^{-TN''} \sin A_n \frac{z}{h_1} \sin \mu \, \nu \, A_n \ldots\ldots\ldots\ldots (26a)$$

for the lower layer, and

$$u_2 = \sum_1^\infty C_n \, \epsilon^{-TN''} \sin A_n \sin \left(1 + \nu - \frac{z}{h_1}\right) \mu \, A_n \ldots\ldots (26b)$$

for the upper layer, satisfy the respective differential equations and boundary conditions if A_n is a root of the equation—

$$F(A) = \sigma \cos A \sin \mu \, \nu \, A + \sin A \cos \mu \, \nu \, A = 0 \ldots\ldots\ldots (27)$$

and if

$$C_n = 2 \, p \, \frac{\sigma \sin \mu \, \nu \, A_n + \sin A_n}{\sigma \, A_n \sin^2 \mu \, \nu \, A_n + \mu \, \nu \, A_n \sin^2 A_n} \ldots\ldots\ldots\ldots (28)$$

In Eqs. 26, $N'' = (A_n)^2$ is used to simplify typography. The corresponding expressions for the average degree of consolidation in the lower and upper layers are

$$U_1 = 1 - 2 \sum_1^\infty \frac{\sin \mu \, \nu \, A_n \, (\sigma \sin \mu \, \nu \, A_n + \sin A_n)}{(A_n)^2 \, (\sigma \sin^2 \mu \, \nu \, A_n + \mu \, \nu \sin^2 A_n)} (1 - \cos A_n) \, \epsilon^{-TN''} \ldots (29a)$$

and $U_2 =$

$$1 - \frac{2}{\mu \, \nu} \sum_1^\infty \frac{\sin A_n \, (\sigma \sin \mu \, \nu \, A_n + \sin A_n)}{(A_n)^2 \, (\sigma \sin^2 \mu \, \nu \, A_n + \mu \, \nu \sin^2 A_n)} (1 - \cos \mu \, \nu \, A_n) \, \epsilon^{-TN''} \ldots (29b)$$

For the case of drainage at the top only, the equations for hydrostatic excess pressure are:

$$u_1 = \sum_1^\infty C_n \, \epsilon^{-TN''} \cos A_n \frac{z}{h_1} \sin \mu \, \nu \, A_n \ldots\ldots\ldots\ldots (30a)$$

and

$$u_2 = \sum_1^\infty C_n \, \epsilon^{-TN''} \cos A_n \sin \mu \, A_n \left(1 + \nu - \frac{z}{h_1}\right) \ldots\ldots (30b)$$

in which A must be a root of the equation—

$$G(A) = \sigma \sin A \sin \mu \nu A - \cos A \cos \mu \nu A = 0 \quad \ldots\ldots\ldots (31)$$

—and,

$$C_n = \frac{2\, p \cos A_n}{\sigma A_n \sin^2 \mu \nu A_n + \mu \nu A_n \cos^2 A_n} \quad \ldots\ldots\ldots\ldots\ldots (32)$$

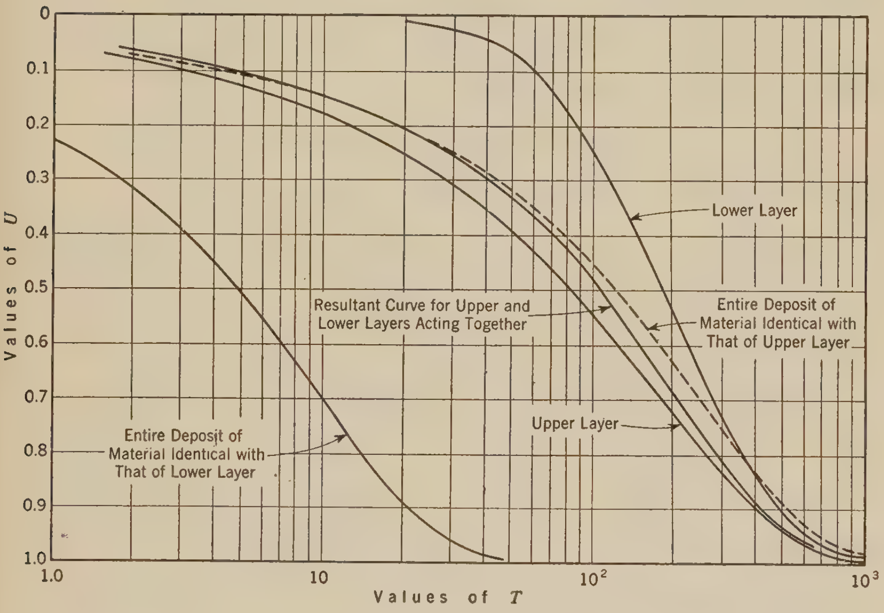


FIG. 6

The corresponding degrees of consolidation are:

$$U_1 = 1 - 2 \sum_{1}^{\infty} \frac{\sin A_n \cos A_n \sin \mu \nu A_n}{(A_n)^2 (\sigma \sin^2 \mu \nu A_n + \mu \nu \cos^2 A_n)} \epsilon^{-TN''} \quad \ldots (33a)$$

and

$$U_2 = 1 - \frac{2}{\mu \nu} \sum_{1}^{\infty} \frac{\cos^2 A_n (1 - \cos \mu \nu A_n)}{(A_n)^2 (\sigma \sin^2 \mu \nu A_n + \mu \nu \cos^2 A_n)} \epsilon^{-TN''} \quad \ldots (33b)$$

A convenient key to the application of these formulas is presented in Table 2. Results such as these are most readily comprehended if illustrated by graphical means, and the results of a particular case are shown in Fig. 6. In this situation it is assumed that there is drainage at the top only, with the following relationships between the coefficients and dimensions: $\nu = 4$; $e_1 = e_2$; $k_{s1}/k_{s2} = 10$; $a_1/a_2 = 0.4$; $\frac{c_1}{c_2} = \frac{k_{s1}}{k_{s2}} \frac{a_2}{a_1} = 25$; $\mu = \sqrt{\frac{c_1}{c_2}} = 5$; $\sigma = \frac{k_{s1}}{k_{s2}} \frac{1}{\mu} = 2$;

TABLE 2.—KEY TO DESIGN EQUATIONS

Definition	Upper Layer		Lower Layer

8	A_8	63° 41⅔′	1.1117

Fig. 7 shows the distributions of excess fluid pressures, u, in the soil layers at two different times corresponding to $T = 100$ and $T = 200$. As is to be expected from the assumed relation between the soil coefficients, the lower layer consolidates as rapidly as the upper will permit, the variation in u through the lower layer at any instant being very small. In the upper layer the variation is similar to that found in the case of a layer of homogeneous material with free drainage at one surface. In Fig. 6 the curves of U versus T are plotted for the upper and lower layers, together with a "resultant" curve computed from

$$U_r = \frac{U_1\,h_1 + U_2\,h_2}{h_1 + h_2} = \frac{4\,U_2 + U_1}{5} \quad \text{(35)}$$

Also shown are curves of U versus T which would result if the entire deposit of compressible soil were of material identical with that of (1) the upper layer, and (2) the lower layer.

Fig. 8 shows the "resultant" curve of Fig. 6, together with a curve obtained by averaging the coefficients of the two layers in the following manner, as suggested by Professor Terzaghi:[14]

$$a_{\text{aver}} = \frac{a_1\,h_1 + a_2\,h_2}{h_1 + h_2} = \frac{a_1\,h_1 + 2\tfrac{1}{2}\,a_1\,4\,h_1}{h_1 + 4\,h_1} = \frac{11}{5}\,a_1 = 2.2\,a_1 \quad \text{(36a)}$$

$$k_{\text{aver}} = \frac{h_1 + h_2}{\dfrac{h_1}{k_{s1}} + \dfrac{h_2}{k_{s2}}} = \frac{h_1 + 4\,h_1}{\dfrac{h_1}{k_{s1}} + \dfrac{4\,h_1}{k_{s1}}\,10} = \frac{5\,h_1}{\dfrac{41\,h_1}{k_{s1}}} = 0.122\,k_{s1} \quad \text{(36b)}$$

FIG. 7

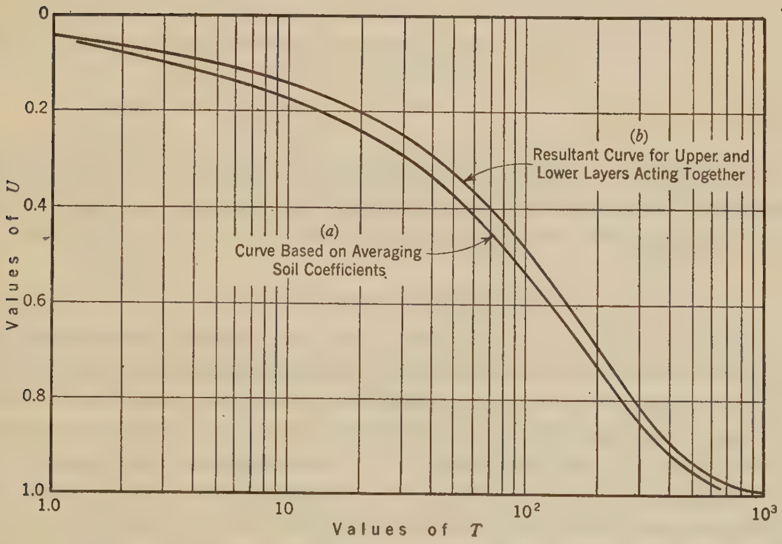

FIG. 8

Naturally, curve (a), Fig. 8, secured by the method of averaging, is obtained with far less effort than the theoretically correct "resultant" curve which it approximates. It is evident from Fig. 8 that the discrepancy between the two is not excessive. Fig. 9 shows these two curves plotted with T on an arithmetic scale. The difference between the two at any given value of T does not exceed 5% of the ultimate theoretical subsidence (that is, $U = 0.05$). The difference in T for a given value of U does not appear to exceed 20%. It is thought that the indicated agreement is adequate for practical purposes. Whether the agreement will be appreciably less close for other probable conditions can only be ascertained by "cut-and-try" methods. Such trials are time consuming, but, once values have been established, the degree of accuracy of the simpler method can be determined. This degree of accuracy need not be large, inasmuch as other variables, which enter the problem from sampling operation to estimates of the increase in load on the soil, all tend to influence the results in a more or less erratic manner.

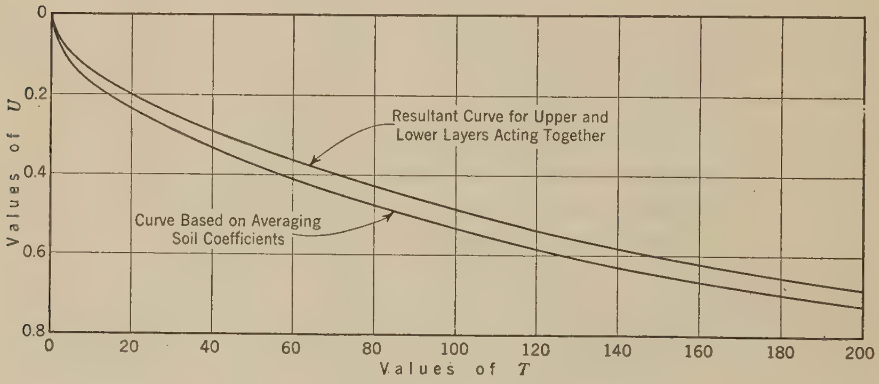

FIG. 9

For the case just considered, it is interesting to note that the theoretically correct curve lies between the curve secured by averaging, and that obtained by assuming the entire deposit to have the properties of the upper layer.

ACKNOWLEDGMENT

In times past the writer has had numerous interesting discussions with George W. Glick of the firm of Moran, Proctor, Freeman and Mueser, New York, N. Y., relative to various technical subjects, among them the consolidation of clay deposits. These discussions prompted the writer to investigate matters further and led ultimately to the preparation of this paper. The writer is indebted to Mr. Glick for the stimulation derived from these conversations and for pointing out the existence of the solution[10] used in analyzing the influence of the incompressible drainage medium. This solution and a part of that pertaining to two consolidating clay beds was developed while the writer was in the employ of the firm, Moran, Proctor, Freeman and Mueser, which has consented to the use of Figs. 2 and 3.

APPENDIX

NOTATION

The letter symbols used in this paper conform, in so far as possible, with those listed in "Soil Mechanics Nomenclature."[15] The units of the quantity represented by each symbol are given herein, in terms of force (F), length (L), and time (T). Subscripts 1 and 2 are used to indicate when a symbol refers to soil layers designated respectively by I and II.

Symbol	Definition	Unit
A	= dimensionless number in Eqs. 27 and 31: A_n denotes a root of Eqs. 27 and 31;	....
a	= coefficient of compressibility of soil;	$L^2 F^{-1}$
C_n	= dimensionless coefficient defined by Eqs. 28 and 32;	....
c	= coefficient of consolidation of soil;	$L^2 T^{-1}$
e	= void ratio of soil;	....
F	= "function of";	....
G	= "function of";	....
H	= thickness of soil layer:	L
	H_d = thickness of drainage layer;	
	H_s = reduced thickness as defined by Eq. 1*a*;	
h	= a vertical dimension in Fig. 1(*a*);	L
k	= coefficient of permeability of soil:	$L T^{-1}$
	k_a = "apparent" coefficient;	
	k_d = coefficient for the drainage layer;	
	k_s = reduced coefficient (Eq. 6);	
M	= a substitution constant = $\frac{H_s}{H_d} k_d$ (see Fig. 3);	$L T^{-1}$
m	= an integer indicating a succession of values (Eq. 14) beginning with $m = 0$;	....
N	= a substitute exponent (see Eq. 8*b*), equal to $(r_n)^2$, used in formulas to simplify typography;	....
N'	= a substitute exponent (see Eq. 14) used in formulas to simplify typography;	....
N''	= a substitute exponent (see Eqs. 26), equal to $(A_n)^2$, used in formulas to simplify typography;	....
n	= an integer indicating a succession of values (Eq. 9);	....
p	= pressure intensity;	$F L^{-2}$
R	= a ratio (Eqs. 8) = $\frac{H_s}{H_d} \frac{k_d}{k_s}$	....
r	= a ratio: r_n denotes a root of Eqs. 8;	....
T	= time factor: T_a = a correct value of T to determine a given value of k_s;	....

ν =	a dimensionless ratio (Eq. 24).	....

DISCUSSION

Edward S. Barber,[16] Esq.—A timely analysis of the consolidation of contiguous layers of foundation soils having different consolidation characteristics is offered in this paper. The mathematically correct approach provides opportunity to evaluate the results furnished by the less laborious but approximate methods. An approximation that provides a reasonably simple solution for the consolidation of any number of contiguous layers and takes into account an influencing factor not considered in the author's method of average coefficients—namely, the relative position of the consolidating soil layers and the drainage faces—is outlined in this discussion. This approximation produces results that agree more closely with the exact theoretical analysis than do those by the method of average coefficients.

By considering the average gradient in the incompressible layer, H_d, shown in Fig. 1(a), required to carry away the water squeezed out of the consolidating layer, H, at any degree of consolidation, U, an approximate formula is obtained for the curves in Fig. 2, as follows:

$$U_R = \frac{U_\infty}{1 + \frac{U_\infty}{T\,R}} \qquad \text{(37)}$$

in which U_R = the value of U for a particular value of R, and U_∞ = the value of U when R is infinite, a theoretical condition assumed if it were possible to have the coefficient of permeability of the drainage layer, k_d, large enough to provide unrestricted flow.[17] The results furnished by Eq. 37 are good except for the combination of large values of T and small values of R.

The dimensionless coefficients, R, σ, μ, ν, and c used in Professor Gray's formulas may be simplified by expressing them in terms of the strain per unit increase in pressure, s, rather than a. The strain, s $\left(\text{which equals } \frac{a}{1+e}\right)$, can be obtained directly from the dial readings in a consolidation test. Actual thicknesses and permeabilities may be used instead of their reduced values and the void ratio becomes unnecessary.

Thus:

$$R = \frac{H/k}{H_d/k_d} \qquad \text{(38a)}$$

$$\sigma = \sqrt{\frac{k_1\,s_1}{k_2\,s_2}} \qquad \text{(38b)}$$

$$\mu\,\nu = \frac{H_2/k_2}{H_1/k_1}\,\frac{1}{\sigma} \qquad \text{(38c)}$$

---

[16] Associate Highway Engr., Public Roads Administration, Washington, D. C.

[17] "The Theory of Soil Consolidation and Testing of Foundation Soils," by L. A. Palmer and E. S. Barber, *Public Roads*, March, 1937, p. 15.

and

$$c_v = \frac{H^2\,T}{t} = \frac{k}{\gamma\,s} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (38d)$$

Reference is now made to the comparison between the results furnished by the method of average coefficients and those by the exact analysis.

TABLE 4.—Properties of Layers in Illustrative Example

Layer	s	H	k	H/k	$s\,H$
II	1	1	1	1	1
I	0.4	5	10	0.5	2
Total	....	6	....	1.5	3

It appears that the consolidation of several layers should be averaged on the basis of the settlements rather than the thicknesses, as shown in Eq. 35. In such case, the agreement between the exact and average methods would be even closer than that shown in Fig. 8. The agreement of the two methods discussed by the author may not always be as close as that indicated in Fig. 8. To illustrate, assume two contiguous consolidating layers with one drainage face and properties as given in Table 4.

Using the method of average soil coefficients outlined by Eqs. 36 and taking $\gamma = 1$: $k = \frac{\sum H}{\sum H/k} = 4$; $s = \frac{\sum s\,H}{\sum H} = 0.5$; $c_v = \frac{k}{\gamma\,s} = 8$; and $t = \frac{H^2}{c_v}\,T = 4.5\,T$

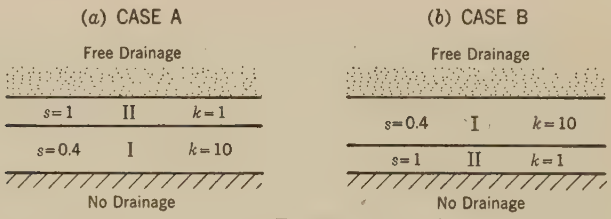

Fig. 10

Using Professor Gray's exact method, there are two cases (see Fig. 10): Case A, impervious face next to layer I, and case B, impervious face next to layer II. The constants are:

Constant	Case A	Case B
c_v	25	1
t/T	1	1
σ	2	0.5
$\mu\,\nu$	1	1

The time-consolidation curves resulting from these two methods of calculation are shown in Fig. 11. Also, in Fig. 11 are shown the curves obtained by means of the approximation introduced by the writer (which modifies the method of average coefficients to take into account the effect of the relative position of the boundaries and thus agrees more closely with the exact method).

The effect of this approximation is illustrated by the example for three contiguous layers outlined in Table 5. The time is computed as in the method of average coefficients. Thus, using the relationship,

$$s\,H = \frac{\delta}{p} \qquad (39)$$

the elapsed time t is expressed by

$$t = T \sum \frac{\delta}{p} \sum \frac{H}{k} \qquad (40)$$

which becomes 10 T for $p = 1$. However, the actual layers are replaced by their "equivalent thicknesses" H/k (Col. 4, Table 5) and, instead of using the same percentage load transfer in each layer, the part of the load transfer in each part of the total thickness[18] is used as shown in Fig. 12 and Table 6.

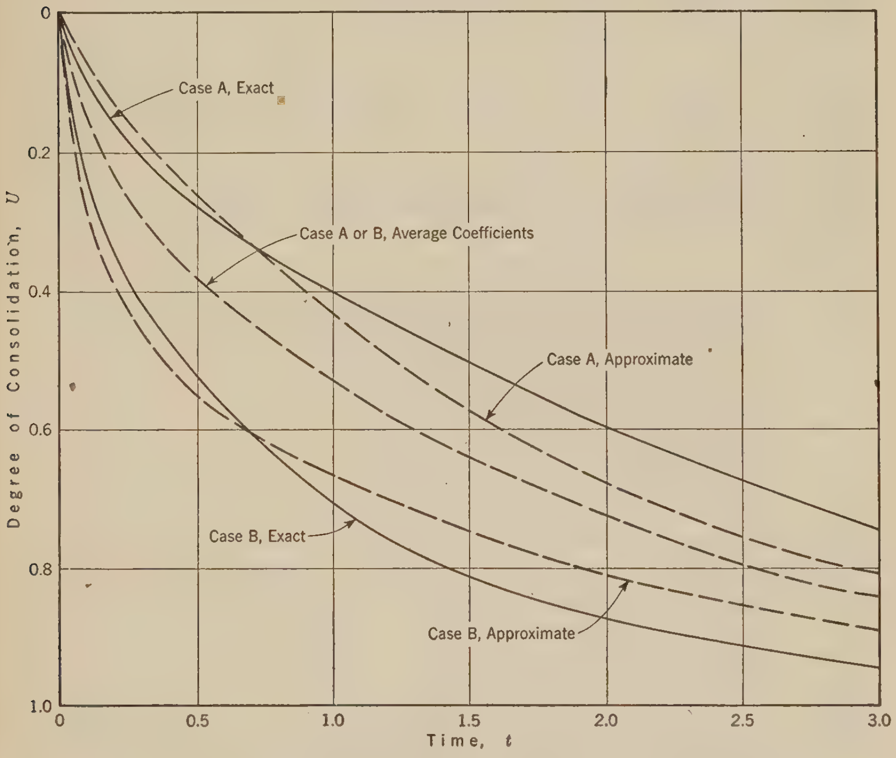

FIG. 11.—COMPARISON OF COMPUTATIONS OF TIME-CONSOLIDATION IN COMBINED LAYERS

In Table 5, Cols. 8 to 11, the settlement in a layer is computed by

$$\delta_p = \delta \frac{\Delta U_p}{H_p} \qquad (41)$$

---

[18] "Notes on Analytic Soil Mechanics," by J. R. Bruggeman, C. N. Zangar, and J. H. A. Brahtz, *Technical Memorandum No. 592*, Bureau of Reclamation, U. S. Dept. of the Interior, 1939, Fig. 34.

in which values of ΔU_p are taken from Table 5 as the difference between the U_p-values at the limits of the layer. Thus, for layer 2 (see Col. 10, Table 5), when $U = 0.60$ the value of ΔU_p (for $H_p = 0.30$ to 0.80) is equal to $0.440 - 0.210 = 0.230$ and δ_p (see Eq. 41) is equal to $1 \times \frac{0.23}{0.50} = 0.46$.

TABLE 5.—EXAMPLE OF THREE CONTIGUOUS LAYERS

Given				Computation				Inches of Settlement in Layer (Eq. 41) for the Following Degrees of Load Transfer U			
Layer No.	Final settlement δ (in.)	Thickness of layer H (ft)	Coefficient of permeability k	Equivalent thickness H/k	Equivalent part of total thickness H_p	Limits of Layer (Total H_p) From:	Limits of Layer (Total H_p) To:	0.20	0.40	0.60	0.80
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)

....	6	38	....	20	1.00[a]	....	....	1.87	3.24	4.16	5.04

[a] This is for drainage above and below. For an impervious lower boundary make this value 0.50.

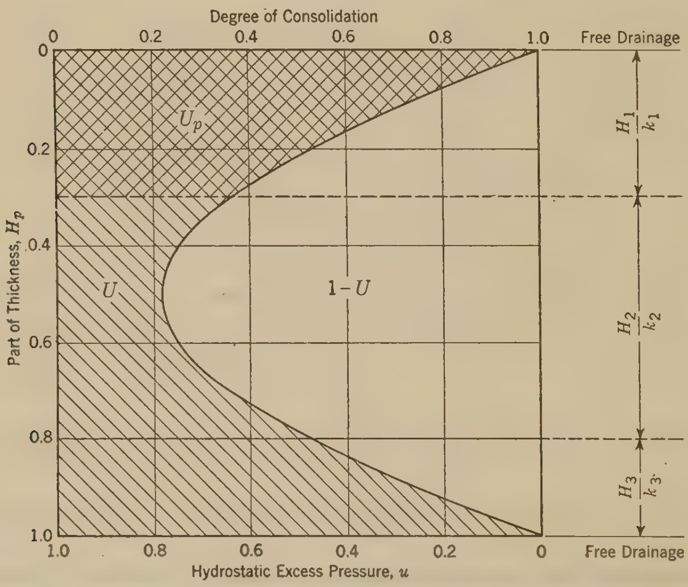

FIG. 12.—APPROXIMATE ANALYSIS OF TIME-CONSOLIDATION IN COMBINED LAYERS

The writer has assumed that the increase in pressure applied to the consolidating layers is uniform throughout their total thickness. To include the effect of a trapezoidal distribution of the initial excess pressure, values of T may be taken from Table 7, which is based on the following interpolation formula:[19]

$$U = U_1 + \frac{f-1}{f+1}(U_1 - U_0) \qquad (42)$$

in which T is constant and the subscripts are values of f.

[a] Pressure at drainage face divided by pressure at impervious face = f. [b] Values of time factor for two drainage faces.

JACOB FELD,[20] M. AM. SOC. C. E.—By clearly indicating how the limitation of actual field conditions affects the theoretical solutions, the author has provided a valuable method for determining the range of values, not only in magnitude but also in rate of occurrence. This procedure will not mislead the engineer who looks to such tools for guidance in the determination of expected consolidation in soil fills and under foundations. All theoretical solutions are based on assumed end and surface conditions. Unless such ideal conditions occur, the formulas can only approximate true values and probably only give a range within which results may be expected. Only when a prophecy of consolidation, both as to extent and rate, is made on the basis of theoretical conditions alone, is no correlation found between actual occurrence and expected values, and one loses faith in all quantitative soil studies.

---

[19] "The Theory of Soil Consolidation and Testing of Foundation Soils," by L. A. Palmer and E. S. Barber, *Public Roads*, March, 1937, p. 18, Eqs. 53, 54, and 55.

[20] Cons. Engr., New York, N. Y.

Sudden clear-cut changes in soil layers are not often encountered in nature —even in rock formations. There is usually a conglomerate, mixed skin separating unlike soil layers. Such a condition is difficult to evaluate in theoretical solutions, and thus subjects of this nature fall in the class of the practical art rather than in that of the theoretical science.

The same problem occurs in building up road and airport surfaces on sub-base materials. When a layer of pervious material is placed directly on a clay subgrade, apparently the ideal condition of contact in soil layers occurs. Actually, experience indicates that the two materials mix and form an intervening skin, which is similar to neither of the parent layers. An accelerated field demonstration of this phenomenon (probably not new) occurred during the construction of some twenty-five miles of pavements on extremely fine and impervious Seneca County (New York) clays in 1942. An examination of all existing roads in that area, and experience on other projects built in the previous year, showed that the fine clay worked up through the run-of-bank gravel sub-base, through penetration macadam, and even through bituminous mix surfacing. In one year, under rather light traffic, the clay had come through a total thickness of 8 in. of gravel sub-base, 4 in. of crushed dolomite base, and a penetration surfacing.

However, inspections, after almost two years of use, on the roads built under the writer's supervision showed no vertical intrusion of the clay into the road construction. In these cases, a fine bank sand containing leachings from limestone deposits had been placed about 2 in. deep on the excavated roadbed. Over the sand 6 in. to 8 in. of run-of-bank gravel, 4 in. of crushed stone base, and 2½ in. of tar mix surfacing were then placed. Similarly, some test roads built directly on top of a 2-in. or 3-in. weathered clay "topsoil" containing some grass roots were also satisfactory. Apparently the introduction of a fine sand screen, rolled into the clay and forming a conglomerate skin, changes all the consolidation characteristics normally encountered in the clay.

A consolidation forecast of filled materials must also take into account the possible altering of the exposed surface with the formation of a crust which will entirely change the expected free drainage surface conditions. In the construction of a large airport, grading operations included the removal of glacial till hills and the filling in of valleys to depths of almost 60 ft. The expected shrinkage and consolidation did not occur. When the paving was placed, about a year later, it was found necessary to remove about 1 ft of the fills to bring the surface to subgrade elevations. This top crust was very hard and of high density, but was floating on an almost liquid material which had not consolidated. The result could be prophesied by the author's methods if it had been assumed that there was practically no surface evaporation. However, if that assumption is not made, an erroneous result is found from the use of any consolidation formula.

In placing fills over completed subway and similar structures in densely populated areas, the most important requirement is rapid consolidation. Otherwise, there is not sufficient time to replace the subsurface utility structures in such a manner that failures will not occur after the streets are repaved. Too little has been done in experimenting with artificially treated backfill materials, when ideal porous filling materials are not available. The necessity for such treatment can be determined from the methods developed by the author, and by proper assumptions the relative depths of treated and untreated fills can also be obtained. In one personal experience, the use of river silt taken from a subaqueous tunnel operation was found unsatisfactory because of the slow drainage characteristics. However, when the tunnel operation ran into some difficulties and an appreciable amount of hay was used for "mudding up" the heading of the tunnel, the silt material became excellent backfill material and consolidated very rapidly. Once it was consolidated there was little danger of future volume changes because of the restrictions of subsurface structures, foundations, and impervious street paving. Of course, this idea is ancient in origin, dating back to biblical, or earlier, days when bricks were manufactured by the addition of straw to clay.

The author is to be congratulated for the presentation of workable formulas which can be checked in the field and which will give consistent and true results if, and only if, consistent and true field conditions are evaluated (as he so carefully explains) before using these formulas.

GEORGE W. GLICK,[21] ESQ.—The analysis by Professor Gray of consolidation in a two-layer system gives the answer to a most difficult problem and is a very worth-while contribution to the study of soil mechanics. As has been shown, the application of the formulas is long and tedious; yet, within limits, certain approximations can be used.

The problem of drainage through an incompressible porous medium is related to the problem of consolidation of a two-layer system with single drainage. This can be seen readily when the thickness of the outer layer becomes very thin, as the solutions for the consolidation of the inner layers become identical.

This type of problem was presented first a number of years ago during the testing of silty soils in the usual consolidation devices. At that time, it was realized that stones of high permeability were desirable, but the magnitude of the error that could occur from improperly chosen drainage stones was unknown until Professor Gray solved the problem in 1938.[22]

The author's remarks on the influence of the drainage medium on the shearing strength of consolidating soils are most pertinent.

---

[21] Staff Engr., Moran, Proctor, Freeman & Mueser, New York, N. Y.

[22] "Research on Consolidation of Fine-Grained Soils," by Hamilton Gray, thesis presented to the faculty of the Graduate School of Eng., Harvard Univ., Cambridge, Mass., in partial fulfilment of the requirements for the degree of Doctor of Science in the field of Soil Mechanics, April, 1938.

The solution of the problem of the two-layer system with double drainage is most interesting and raises some unusual speculations. When one considers the solution as applied to two layers of homogeneous soil, it can be concluded that this is a solution of the familiar single-layer problem with the time factor referenced to the thickness of one of the two layers. In other words, the time factor for a single-layer system is multiplied by the square of the ratio of the total thickness to one of the layers to secure the time factor for that layer.

For homogeneous layers, the values of both σ and μ are unity. When only σ has the value of unity, the system might be considered pseudo-homogeneous as a stretching transformation can be applied to one of the layers to make a homogeneous system. In this manner, the time-consolidation coefficients for a single-layered homogeneous system can be used, thereby saving the labor of solving the equations for the two-layer system. When σ is unity, any number of layers can be combined by using their transformed thicknesses. The same type of reasoning can be applied to the two-layer system with single drainage.

From the solution of the two-layer system with double drainage, a solution for a single layer having one side with restricted drainage and one side with free drainage can be deduced by assuming one layer to be very thin.

When the value of σ differs from unity, the use of a stretching transformation introduces an error of unknown magnitude. It is a safe assumption that, when σ is less than 2, the error will be less than that for the author's case in which the time factor is about 13% too small at 90% consolidation. It would be interesting to know whether the writer's suggested transformation is applicable to other stress distributions.

The author is to be congratulated for his efforts in solving one of the most common, yet annoying, problems in this new science.

HAMILTON GRAY,[23] ASSOC. M. AM. SOC. C. E.—The discussions may be classified into two types. Those in type 1 suggest certain approximate solutions that can be applied with less expenditure of time than the rigorous solutions and for which the degree of approximation may be fairly high, at least within certain limits. Type 2 involves the application of the solutions to various foundation problems. Both types of discussion are valuable contributions to the subject.

There is no reason for applying involved and time-consuming analyses to engineering problems unless no simpler mode of attack will suffice. Exact methods of analysis may be useful from either of two standpoints: (*a*) As the only available rational attack on a problem, or (*b*) as a check on the degree of approximation in simpler methods of analysis.

Mr. Barber illustrates that, if preferred, compressions may be expressed in terms of strain rather than in terms of void-ratio changes. This is wholly a matter of personal taste since some engineers prefer pressure, void-ratio curves whereas others favor curves showing percentages of compression as functions of the pressure. In either case the results of the analysis are identical.

Mr. Barber's statement regarding the computation of the resultant consolidation on the basis of compressions rather than of thicknesses merits comment. Computation on the basis of thicknesses requires the use of the formula:

---

[23] Asst. Prof., Civ. Eng., New York Univ., New York, N. Y.

$$U_r = \frac{U_1 + \nu\, U_2}{1 + \nu} \quad \text{(43a)}$$

which indicates the extent to which the transfer of stress from fluid to solid phase has occurred. Eq. 43*a* may be termed the "resultant degree of consolidation" by virtue of the definition of "degree of consolidation" given in Eqs. 9 and 10. Computation on the basis of compressions utilizes the expression:

$$U_r = \frac{U_1 + \frac{\mu\,\nu}{\sigma} U_2}{1 + \frac{\mu\,\nu}{\sigma}} \quad \text{(43b)}$$

Eq. 43*b* indicates what portion of the resultant ultimate compression has occurred, based on the assumption that the pressure, void-ratio curves are linear in the pertinent pressure range. This may be called the "resultant relative compression." From a practical standpoint, Eq. 43*b* is required for estimating the actual settlements. Only if $\frac{\mu}{\sigma} = \frac{a_2}{a_1} = 1.0$ will Eqs. 43*a* and 43*b* give identical results. The distinction between these two formulas should have been treated in the paper. For the example in the paper Eqs. 43 do not give very different results. This is illustrated in Fig. 13 which also reveals that, if the compressibility of layer I were to be ignored completely, a fairly close approximation to the exact result would be obtained.

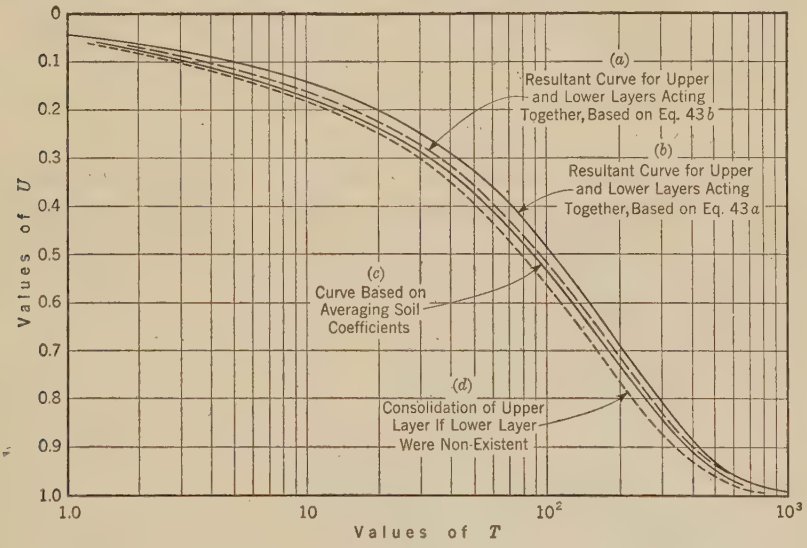

FIG. 13

Fig. 14 illustrates the situation in which the positions of the two layers which were considered in the paper are interchanged. Under these conditions, the agreement between Eq. 43*a* and Eq. 43*b* is less close, and neither of the two approximate solutions suggested in connection with Fig. 13 seems to yield as reliable results. Table 8 is included to clarify the differences that are reflected by the curves in Figs. 13 and 14. Fig. 15, based on case D, is analogous to Fig. 5 which is based on case C.

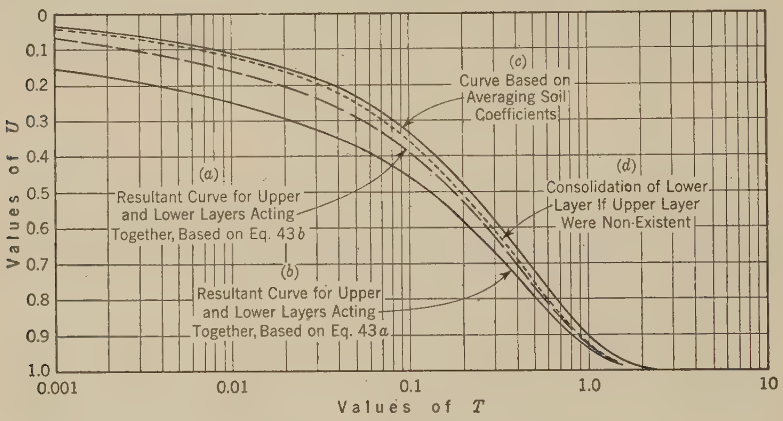

Fig. 14

Table 8 also illustrates typical numerical values for the pertinent physical constants. In this connection, it is of interest to note that the actual time required to achieve 50% of the ultimate resultant consolidation or settlement

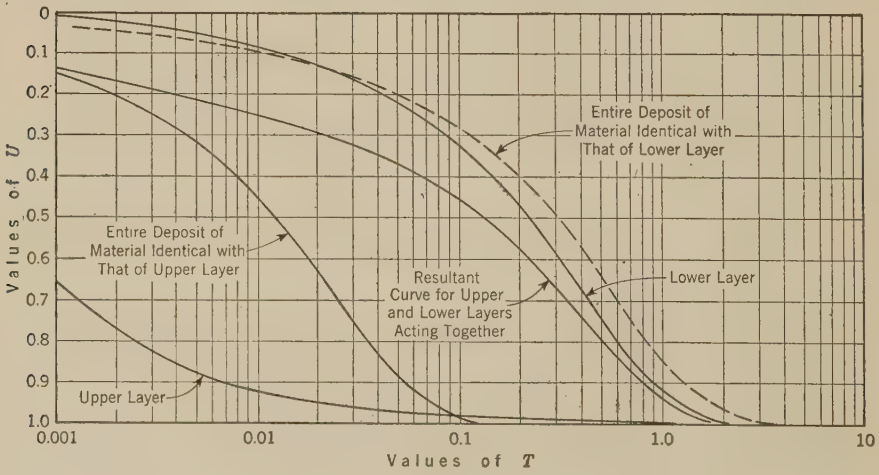

Fig. 15

is greater for case C than for case D—in case C consolidation of layer I is retarded by layer II as indicated in Fig. 7, whereas in case D layer II drains relatively rapidly and in addition exerts only a minor influence on layer I. If the thinner layer in each case is neglected, a moderately close approximation to the actual behavior of the two layers is obtained. This phenomenon seems to be due to the great difference in the consolidation characteristics of the two layers. In cases A and B discussed by Mr. Barber, layers I and II would each consolidate at the same rate if they were not contiguous, since the ratio, t/T, is the same for each. Consequently, ignoring one or the other of these layers will not give a close approximation of the exact behavior when the layers are contiguous.

TABLE 8.—TYPICAL VALUES OF PHYSICAL CONSTANTS

Description	Case C	Case D	Key
Layer II—			
k_{s2} (cm per sec)	1×10^{-8}	1×10^{-7}	 Free Drainage k_{s2} e_2 a_2 c_2 II h_2 I k_{s1} e_1 a_1 c_1 h_1 CASE C

As Mr. Glick states, when $\sigma = 1$ it can be shown that, if the thickness, h_2, of layer II be multiplied by $\mu = \sqrt{\frac{c_1}{c_2}}$ so as to yield $(h_2)' = \mu\, \nu\, h_1$, it is possible to obtain the following expressions for the resultant consolidation:

$$U_r = \frac{U_1 + \mu\,\nu\,U_2}{1 + \mu\,\nu} = 1 - \frac{8}{\pi^2} \sum_{n=0}^{n=\infty} \frac{1}{(2\,n + 1)^2}\, \epsilon^{-N'T'} \quad \ldots\ldots\ldots (44a)$$

and

$$U_r = \frac{U_1 + \mu\,\nu\,U_2}{1 + \mu\,\nu} = 1 - \frac{8}{\pi^2} \sum_{n=0}^{n=\infty} \frac{1}{(2\,n + 1)^2}\, \epsilon^{-N'''T'} \quad \ldots\ldots\ldots (44b)$$

in which

$$N'''_{\,} = (2\,n + 1)^2\,\pi^2 \qquad (45a)$$

and

$$T' = \frac{c_1\,t}{(1 + \mu\,\nu)^2\,(h_1)^2} \qquad (45b)$$

and N' is given by Eq. 14. Since the right-hand sides of Eq. 44*a* and Eq. 44*b*, respectively, are identical with the expressions for the degree of consolidation of homogeneous layers (thickness, $h_1\,(1 + \mu\,\nu)$, consolidation coefficient, c_1, and drained, respectively, at one face and at both faces), the transformation, $z' = \mu\,z$, applied to dimensions, Z, in layer II makes it possible to consider the two layers as a single homogeneous stratum. When μ is equal to unity, there does not appear to be any analogous transformation that may lead to a simplification of the general problem.

For practical applications, the various approximate solutions or modifications outlined by Messrs. Barber and Glick are very valuable, provided one knows the extent to which the approximate results differ from those which are theoretically exact. In some cases two or more approximate approaches are suggested, and it then becomes important to know which method is best—from the standpoint of accuracy as well as from that of time. In many cases an inspection of the relative consolidation characteristics of the pertinent strata will give some indication of the reliability to be expected from one or another of the suggested methods of approach.

Mr. Feld has described numerous cases, both natural and man made, to which the methods outlined in the paper may be applied. It is of great help to the engineer to be able to analyze actual field conditions in terms of an idealized situation, especially if, at the same time, he does not lose sight of the differences between actual conditions and assumed conditions. Mr. Feld emphasizes this fact, which the writer had in mind when he suggested that the results obtained in the paper should be verified by observations before being used with confidence. In many instances it is possible to explain discrepancies between a theoretical approach and the observed behavior on the basis of differences between actual and assumed conditions. The writer would disagree with one of Mr. Feld's statements since he believes that the influence of surface evaporation upon the consolidation of a soil deposit can be analyzed by appropriate methods.

The writer wishes to express his thanks to the discussers for their worthwhile comments on this paper.

LOCK MANIFOLD EXPERIMENTS

BY EDWARD SOUCEK,[1] ASSOC. M. AM. SOC. C. E., AND
E. W. ZELNICK,[2] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. J. PIETRKOWSKI, JOHN S. MCNOWN, F. W. EDWARDS, W. M. LANSFORD, ROBERT F. KREISS, RALPH G. BERK, RALPH W. POWELL, AND EDWARD SOUCEK AND E. W. ZELNICK.

SYNOPSIS

In connection with the design of the Third Locks of the Panama Canal, a series of experiments dealing with the hydraulics of manifolds was performed in The Panama Canal Hydraulics Laboratory during 1939 and 1940. This paper presents a summary of the test results. Certain introductory and theoretical material which appeared desirable has been included. A method of predicting the performance of a manifold by the use of single port test data is presented and the method is checked by comparison with manifold tests. Some of the data are presented in abridged form but transcripts of original and more complete records have been filed with the Engineering Societies Library.

INTRODUCTION

Manifolds are important elements in the design of side-filling or bottom-filling locks. There is no generally accepted basis for their design, however. Discussions of a paper presented in 1940 by R. D. Gladding,[3] M. Am. Soc. C. E., and the absence of the subject from hydraulics textbooks are noteworthy in this connection. With few exceptions model tests used in the design of most recently built locks have been limited[4] to models of the entire lock. Consequently, there is little basis for designing the hydraulic system of locks that must meet special requirements or operate under unusual conditions. The size and importance of the new Panama Canal locks seemed to justify more fundamental treatment. The tests described herein were adopted to this end.

NOTE.—Published in October, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

Howland, R. W. Powell, W. M. Langsford, and the author, *ibid.*, January 16, 1941, p. 78; April 10, 1941, p. 522; and May 22, 1941, p. 801.

[4] "The Manifold Problem in Lock Design," by Martin E. Nelson, *Bulletin 20, Proceedings of Hydraulics Conference*, Studies in Engineering, Univ. of Iowa, Iowa City, March, 1940, p. 160.

It is not easy to predict the time required to fill or empty a lock through a manifold system. It is customary to use a differential equation based on the orifice formula with an estimated coefficient, to compute the time required to fill or empty a lock under a falling head. Owing in part to complications resulting from inertial effects and to difficulty in allowing for time consumed by valve operations, but principally to lack of a satisfactory theory of manifold hydraulics, these attempts at simplification often have been unsuccessful.

Inequality in port discharges tends to defeat the purpose of a lock manifold.[5] These differences in discharge are produced by changes in pressure and velocity along the manifold tube. Elimination of the differences, or compensation for the differences, is possible by various methods, discussion of which is beyond the scope of this paper. It is evident that the use of such expedients as tapered culverts, varied port sizes, and varied port spacing is highly speculative without a specific model test of each design or some knowledge of what takes place within a manifold.

Purpose

The purpose of the tests was to provide data that would expedite the design of lock manifolds. Specifically, it was desired to give mathematical expression to the phenomenon of manifold flow in order to facilitate the original design and the modification of model manifolds. Since a single port can be built and tested quite easily and quickly, determination of a means of predicting the performance of a manifold on the basis of single port tests and verification of the technique by tests of a manifold were the principal phases of the program.

Outline

The first part of the study, "Theoretical Considerations," describes the mathematical approach adopted for the analysis. It is perhaps regrettable that several simplifying assumptions were necessary in order to obtain tangible results without unduly extending the test program. Substantial correctness for design purposes rather than precision was the reason for simplifying the theory to the greatest possible extent. Since disturbances within a lock chamber during emptying operations are usually (perhaps always) negligible in comparison with those that occur during filling, more attention was given to the discharge ports. The difference between filling and emptying conditions is due to the lower head-to-depth ratio which prevails during emptying operations and to the absence of what might be called jet action. The basic discussions deal with what will be called "discharge manifolds," "intake manifolds" being covered by brief supplementary statements.

The second part of the study, "Single Port Tests," covers the results of tests of seven different ports, each attached to a 6-in. square conduit. The ports were tested as both "discharge ports" and as "intake ports."

The third and final part of the study, "Verification Tests," describes tests of a manifold containing five identical ports which were duplicates of one of those tested as a single port. A 6-in. square conduit again served as the manifold tube. Observations are compared with calculations based on single port characteristics which had been determined previously.

NOTATION

The following letter symbols, adopted for use in this paper, conform essentially to American Standard Letter Symbols for Hydraulics,[6] prepared by a Committee of the American Standards Association, with Society participation, and approved by the Association in 1942:

A = area:
  A_c = cross-sectional area of conduit, in square feet;
  A_p = throat area of the port, in square feet;
C = discharge coefficient in orifice formula with subscript d or i denoting discharge ports or inlet ports, respectively;
g = gravitational acceleration, in feet per second per second;
H = effective head on a given port, in feet, with subscript d or i denoting discharge ports or inlet ports, respectively;
k = a dimensionless coefficient to be studied experimentally, with subscript d or i denoting discharge ports or inlet ports, respectively;
n = Manning's roughness coefficient;
P = a ratio of discharges:
  $P_d = Q_3/Q_1$;
  $P_i = Q_3/Q_2$;
Q = discharge, in cubic feet per second:
  Q_1, in the conduit upstream from a port;
  Q_2, in the conduit downstream from a port;
  Q_3, through a port;
V = mean conduit velocity, in feet per second:
  V_1, upstream from port;
  V_2, downstream from port;
Z = elevation of the hydraulic gradient in feet; Z_1 = upstream elevation and Z_2 = downstream elevation; ΔZ = difference between upstream and downstream elevations;
γ = specific weight of water, in pounds per cubic foot.

THEORETICAL CONSIDERATIONS

It is evident that any fundamental study of the hydraulics of manifolds must be based upon an analysis of the behavior and effects of a single lateral port attached to a tube. Preliminary study made it clear that two problems were of primary importance—namely, (*a*) the pressure change which occurs in a tube in the vicinity of a lateral port and (*b*) the discharge through a lateral port and the factors that modify it. Solution of these two problems permits analysis of the hydraulics of a manifold by a simple computation procedure which resembles somewhat the calculation of a backwater curve. Mutual interference between closely-spaced consecutive ports is the principal limitation on the applicability of this procedure which otherwise appears quite general.

(*a*) *Pressure Changes.*—Consider a horizontal frictionless tube to which a discharging lateral port is attached. The port outlet is submerged in still water. The elevation of the water surface over the port outlet is called the

---

[6] ASA—Z10.2—1942.

"submergence level." The tube is connected to a source of supply which is at some elevation greater than the submergence level. Downstream from the port, the tube is throttled in such a manner that the hydraulic gradient past the port is above the submergence level. The port is of such a length that the discharge through it occurs substantially at right angles to the axis of the manifold tube. Since the tube is frictionless, the pressure gradients both upstream and downstream from the port are horizontal but at different elevations. In the immediate vicinity of the port, there is an abrupt pressure rise in the direction of flow.

Consider the rate of change of momentum that occurs between two sections on the horizontal pressure gradients upstream and downstream, respectively, from the port. Neglecting nonuniform velocity distribution, the rate of change of momentum has the value $\frac{Q_2}{g} \gamma (V_1 - V_2) + \frac{Q_3}{g} \gamma V_1$. The forces producing this effect are the pressure rise in the conduit and the resultant of unbalanced pressures within the port. The latter force is unknown and undeterminable in any practical manner except as a residual. The unbalanced port pressure is intimately related to the momentum change of Q_3 and, therefore, it seems likely that any allowance for its effect can be applied to the term representing that momentum change.

It is considered that k_d is that fraction of the momentum change of Q_3 which is produced by a pressure rise in the conduit. Conversely, $(1 - k_d)$ is that fraction of the momentum change of Q_3 which is produced by unbalanced pressure within the port. This line of reasoning leads to an expression involving the pressure rise, an equation which is not obtainable without some simplifying assumption similar to the one which has been explained. The equation obtained is:

$$\gamma A_c (Z_2 - Z_1) = \frac{Q_2}{g} \gamma (V_1 - V_2) + \frac{k_d (Q_3 \gamma V_1)}{g} \dots\dots\dots (1)$$

By use of the law of continuity and some algebraic manipulation, Eq. 1 may be reduced to the form,

$$\frac{\Delta Z}{(V_1)^2/2 g} = 2 P_d (1 + k_d) - 2 (P_d)^2 \dots\dots\dots\dots\dots (2)$$

Certain published data indicate that, for a given port and conduit, the ratio on the left side of Eq. 2 is a function of P_d only. For this to be true, k_d must be either a constant or a function of P_d only. Fig. 1(*a*) is a comparison of tests by the U. S. Bureau of Reclamation[7] as interpreted by R. W. Powell,[8] M. Am. Soc. C. E., tests by John A. Oakey,[9] Assoc. M. Am. Soc. C. E., and the conclusions, supported by tests, of M. L. Enger, M. Am. Soc. C. E., and M. I. Levy.[10] The approximate diameter ratios, lateral to conduit, for the

tests in Fig. 1(a) are as follows:

Series (see Fig. 1)	Diameter ratios
A	1:4.24
B	1:2.82
C	1:1.82
D	1:1.21
Enger and Levy	1:5.3
Bureau of Reclamation	1:2.3

In Fig. 1(b) are plotted graphs of Eq. 2 with various constant values assigned to k_d. It is evident that this comparison tends to support the analysis.

The published data exhibit a maximum relative pressure rise in the vicinity of P_d equal to 0.7, corresponding in that respect to the theoretical curve for k_d equal to 0.4. However, the relative pressure rises are of lower magnitude than those indicated by the theoretical curve for k_d equal to 0.4.

It should be noted that the graphs of relative pressure rise plotted against P_d are simply a convenient means of evaluating the effect of a residual unknown —the resultant of unbalanced port pressures. The graphical method could have been evolved by some other line of reasoning. However, the method appears to represent an approximately correct interpretation of the mechanics of pressure changes in manifolds. Of course, the effects of nonuniform approach velocity distribution and of angularity of port discharge are reflected in the relations between the relative pressure rise and P_d.

Since no real conduit is frictionless, a method had to be devised for measuring the pressure rise for a real manifold so as to minimize the effect of friction. The gradients in a real manifold are not level but, beyond the immediate effects of the port, they are straight lines. In analysis and application of pressure rise data, it is considered that the pressure change is sudden and occurs opposite the port center line. In practice then, the upstream gradient is extended downstream and the downstream gradient is extended upstream, both at their respective friction slopes, until they intersect a vertical erected at the center of the port. The intercept on this vertical, between the extended gradients, is considered to represent the pressure rise. As a matter of fact, the pressure rise is exceedingly abrupt. The described method of interpreting the pressure rise makes the calculated gradient for a manifold consist of a series of sloping lines with a step at each port. Fig. 2 illustrates these relations, the discharges, in cubic feet per second, being as follows:

Flow	Discharge Port	Intake Port
Q_1	2.631	1.844
Q_2	2.222	2.245
Q_3	0.409	0.401

An intake port is analyzed similarly. For an intake port, the elevation of the water surface over the port inlet is called the "submergence level." The conduit pressure gradient is below, instead of above, the submergence level. The port discharges into the conduit rather than out of it. A drop in pressure, in place of a rise, occurs in the direction of flow. The result of reasoning identical to that used for a discharge port is a similar equation,

$$\frac{\Delta Z}{(V_2)^2/2\,g} = 2\,P_i\,(1 + k_i) - 2\,(P_i)^2 \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

It is evident from physical considerations that k_i will be larger than k_d. Since water enters the port from a quiescent pool, the unbalanced port pressure is much smaller in an intake port. Accordingly, the pressure change in the conduit (in this case a drop) must account for substantially all the momentum change.

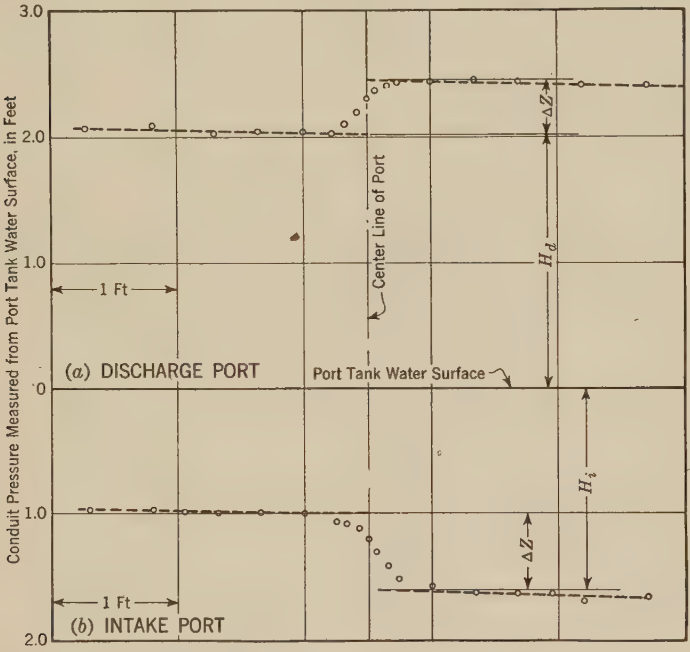

FIG. 2.—TYPICAL GRADIENTS; SINGLE PORT TESTS

Certain similarities exist between the equations derived and the formulas used for obtaining gradients in side channel spillways. If k_d in Eq. 2 or k_i in Eq. 3 is taken as unity (this is equivalent to considering that the unbalanced port pressure is zero), the value of pressure change obtained—actual, not relative—will equal twice the difference between the velocity heads upstream and downstream from the port. It is evident, of course, that Bernoulli's theorem is not applicable to the phenomenon under consideration, although a modified energy equation might be used.

(b) *Port Discharge.*—After considering various methods, it was decided to attempt to relate the port discharge to some head measurement by the use of the simple orifice equation ($Q_3 = C\,A_p\,\sqrt{2\,g\,H}$), and then to study variations in the resulting "discharge coefficient." Although it could not have been predicted definitely that this approach would be successful, study of published data[4,9,10] indicated that it was promising.

(a) PLAN

(b) ELEVATION

Fig. 3.—Single Port Test Apparatus

The hydraulic gradient in the vicinity of a port changes so rapidly that there is no natural method of defining the "head on the port." Since the choice is arbitrary, the head is defined in a manner which seems definite, convenient, and logical. The elevation difference between the submergence level and the intersection of the upstream gradient with a vertical line erected opposite the center of the port (the same intersection previously used in evaluating pressure change) is defined as the effective head, H_d, on a discharge port. This relationship is illustrated in Fig. 2.

For an intake port, the effective head, H_i, is defined as the elevation difference between the submergence level and the intersection of the downstream gradient with the intersection of a vertical line erected opposite the center of the port. This relationship is also shown in Fig. 2.

It might appear desirable to add the head corresponding to the mean velocity of approach to the effective head for a discharge port and to make a corresponding adjustment to the effective head for an intake port. This was not done for several reasons. The method of measuring the effective head and the discharge equations are rather arbitrary so it seemed desirable to use simple definitions. The principal effect of high conduit velocity approaching the port, considering now a discharge port, would appear to be such as to reduce the port discharge. Accordingly, it seemed illogical to insert a velocity term into the discharge equation in a manner that would indicate the contrary. The effect of conduit velocity is considered separately in studying the variation in discharge coefficients. Certain minor complications which are due to the manner in which the effective head is defined are discussed in another section of the paper.

SINGLE PORT TESTS

Apparatus.—The arrangement of test apparatus is shown in Fig. 3. The equipment was designed to simulate the range of heads, velocities, and port and culvert areas which ordinarily occur in lock manifolds. Port VII, shown in Fig. 4, was placed in the conduit with square corner vertical and the large radius opposite the square corner on the upstream side of the port for the discharge tests. The large radius was on the downstream side of the port for the intake tests. All verification tests were made with Port VII. Radii that are not shown in Fig. 4 are 0.36 in.

[a] Radius of edge fillet, in inches.

In order to obtain parallel flow upstream from the port, a set of vanes was placed in the conduit as shown in Fig. 3. To simulate a discharge port, all the flow was supplied by the 10-in. line. To simulate an intake port, the port discharge was supplied by the 3-in. auxiliary line. Discharges and pressures were controlled by the valve on the 10-in. pipe, the valve on the 3-in. swing pipe, the butterfly valve on the port tank outlet, and the butterfly valve at the end of the conduit.

Particular care was taken in the construction of the pyralin conduit to prevent bulging under pressure. All piezometers except those in the port tank were placed in the pyralin sections where greater care in installation and maintenance was possible.

Flow patterns were observed by injecting dye through the piezometer connections. For some of the tests, velocities at various cross sections were obtained with a pitot tube, inserted through special openings provided for that purpose.

The level in the port tank was determined from the piezometers connected to the bottom of the tank at several points. The baffle shown in Fig. 5 was placed in the port tank to prevent excessive turbulence and entrainment of air during the intake tests. Port discharge measurements were made by diverting the flow into a 50-gal weighing tank. Conduit discharges were measured with a calibrated 90° V-notch weir.

Test Procedure.—For each port, intake and discharge tests were made with effective heads, previously defined, ranging from 0.3 to 3.0 ft. In addition to the variations in head, the conduit discharges were varied from zero to 2.5 cu ft per sec downstream from the port.

The hydraulic gradient in the culvert, the level in the tank, and the pressures in the port were obtained by reading forty-five manometers ten times during the course of each test and averaging the results for each manometer. In discharge port tests, discharge measurements for the port and the culvert were made at the beginning of each test, during the test, and at the conclusion of the test. For the intake port tests, discharge measurements were made

Fig. 5.—Manifold Test Apparatus

only at the beginning and at the end of each test, since the port discharge had to be diverted for measurement, thus disturbing the test conditions.

Several tests were made at various times to determine and check the roughness of the pyralin conduit. With undisturbed flow, friction slopes could be approximated closely by using an n of 0.009 in Manning's formula.

Analysis.—It proved possible to reduce the data, along the lines suggested under "Theoretical Considerations," to four characteristic curves for each port. Fig. 6 shows the characteristic curves for Ports I to VI, inclusive. To save space, these curves are shown to a very small scale and observation points are omitted. The complete data for Ports I to VII, to be used by interested investigators in plotting the complete set, are filed with the Engineering Societies Library. Fig. 7 shows the characteristic curves for Port VII to a larger scale with observations indicated. The curves for Port VII are indicative of the agreement between curves and observation points for Ports I to VI, inclusive. Since each observation point represents a ratio of two observed quantities—some of which are very small—considerable "scatter" is to be expected.

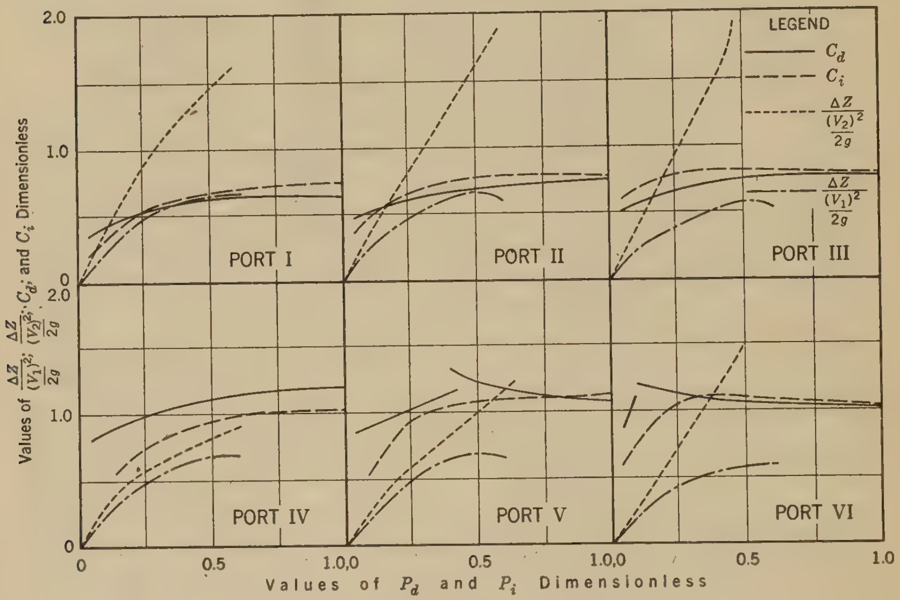

FIG. 6.—PORT CHARACTERISTICS, PORTS I TO VI, INCLUSIVE

This method of analysis was adopted for a number of reasons. The tentative nature of the theory did not justify a complex treatment. The relative pressure changes and discharge coefficients showed no significant dependence upon variables other than P_d and P_i. The time available for testing was limited; the need for tangible results great. The amount of data required for the method of analysis adopted was relatively small. The range of conditions under which lock manifolds operate makes certain compromises

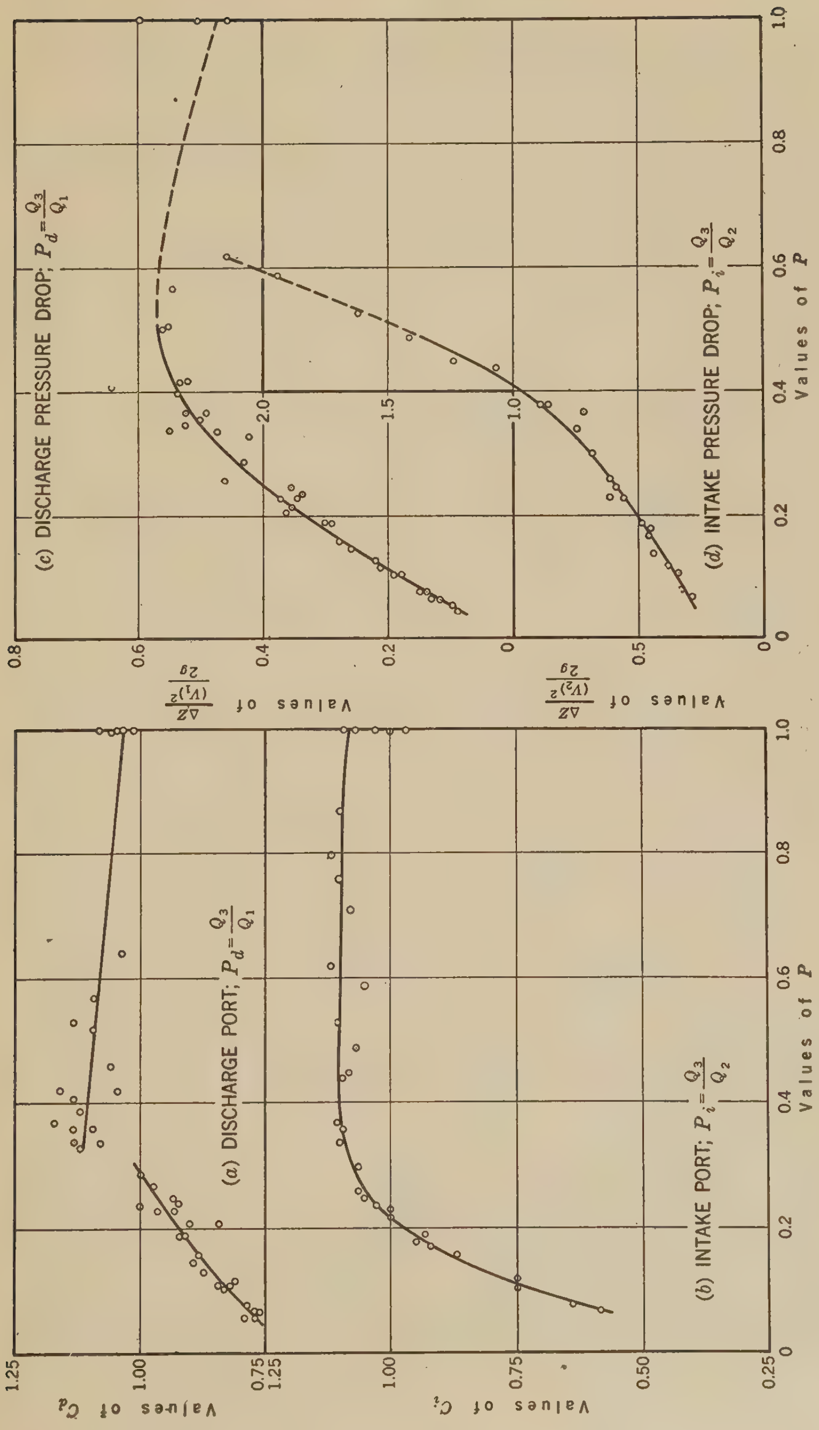

Fig. 7.—Port Characteristics, Port VII

in design inevitable. Inertial effects make real precision nearly impossible to attain. The dimensionless treatment makes it possible to solve many problems by proportion and simplifies model-prototype ratios. Finally, and most important, there is a reasonable physical basis for the relations used. Similar flow patterns and, therefore, similar relations between physical quantities might be expected to prevail at given values of P_d and P_i for a particular port, regardless of the absolute magnitude of the quantities involved.

The port discharge is a factor that occurs to the first power in both coordinates of the coefficient curves. Therefore, some other combination of variables, omitting the port discharge as a factor, could have been used. This apparent simplification did not prove advantageous so the more significant combinations were retained.

Discussion of Results.—The limitations of the apparatus made it impossible to obtain large values of ΔZ simultaneously with large values of P_d or P_i. Only the farthest downstream port in a discharge manifold and the farthest upstream port in an intake manifold have values of P_d and P_i, respectively, exceeding about 0.5. The pressure in the closed end is not required in analysis. It was not justifiable, therefore, to build the apparatus so as to reduce observational error in the pressure change when P_d or P_i exceeded about 0.5. The observed values in the unreliable range are only a few hundredths of a foot in magnitude and large percentage errors are inevitable. The use of ratios in the graphs does not show the absolute magnitude of the pressure changes and, when the pressure change itself is small, a very small observational error produces a large effect on the relative pressure change. For this reason, the pressure-change curves are not considered to be established beyond P_d and P_i exceeding 0.6. However, the data filed with the Engineering Societies Library show the observations beyond the range of the curves.

The rounded ports, particularly the smaller sizes, exhibit a discontinuity in the relations between C_d and P_d. The largest rounded port (Port IV) probably has a similar but minor discontinuity at a value of P_d equal to about 0.75. From observation of dye streams, the discontinuity is believed to mark the value of P_d at which a change in the character of the flow through the discharge port occurs. An eddy which existed along the upstream side of the port for values of P_d less than that corresponding to the discontinuity was not evident for higher values. Tests in the vicinity of the discontinuity were difficult to establish and conditions tended to be unstable. Fortunately, the magnitude of the break in the relation was not sufficient to produce serious error in the calculations.

With the exceptions to which attention has been called, the characteristics of the data are fairly consistent and regular. Although the tests are evenly divided between effective heads of 0.3, 0.6, 1.0, 1.5, 2.0, 2.5, and 3.0 ft, the data for each port were found to be represented with fair accuracy by the dimensionless curves. The effect of rounded port entrances is evident and as expected. The effect of port size or, by inference, port area to culvert area ratio is reasonably well established over a large range and probably can be extrapolated somewhat.

Limitations.—Before explaining the application of the data to manifold calculations, it seems desirable to call attention specifically to certain limitations. All characteristic curves for the seven ports are based on single port observations. Approach conditions were normal for a smooth conduit. Downstream from the port, the velocity distribution was irregular. Although the pressure change was abrupt, as shown by the typical gradients of Fig. 2, the velocity distribution remains irregular for some distance downstream from a port. The slope of the hydraulic gradient was found, in the single port tests, to reach a value which was normal for the mean velocity within a very short distance from the port. This condition does not necessarily indicate a normal velocity distribution. A gradual reduction in the velocity head coefficient might obscure a tendency toward a greater than normal slope produced by the abnormal flow pattern. Although it is frequently assumed that the excess energy due to a distorted velocity distribution is not recoverable, the implication of a normal friction slope cannot be accepted without reservations. Accordingly, although it is believed that the observed pressure changes correctly represent the displacement between upstream and downstream gradients for values of P_d and P_i below about 0.5, it is not claimed that the disturbed flow pattern may not affect the performance of an adjacent port. On the other hand, the relatively small rate of change in discharge coefficient with P_d or P_i indicates that the effect of velocity distribution upon port discharges will not be large.

It has been observed that some discharge may occur through a port when the head, as defined, is negative. Negative heads could have been avoided by introducing a velocity head term into the effective head and this may ultimately prove to be the best solution. The discharges accompanying negative heads, as herein defined, tend to be irregular and of small magnitude. In general, it is felt that this condition can and should be avoided in design. For very low values of P_d and P_i, however—below the range covered by the tests—the method of analysis would cause the coefficient curves to rise rapidly as the zero value of P_d or P_i is approached. The curve of discharge coefficients should not be extrapolated to low values of P_d or P_i.

The data are based on tests of ports of particular sizes, shapes, and lengths—attached to a conduit of a particular size and shape. In view of the absence of data on other shapes and sizes, it is likely that some extrapolation from these tests will be attempted. If done carefully, such extrapolation should give better results than a guess or empirical rule. Strictly, however, the results are applicable only to geometrically similar designs. Any other application should be made with the realization that substantial errors are possible.

Application.—The design of a manifold is an indirect process. Characteristic curves for the ports used must be established by single port tests or otherwise. A manifold is assumed and analyzed. If the result is unsatisfactory, the design must be modified. This procedure is repeated until the required relations are obtained. Only the analysis of a manifold with a series of identical ports will be considered. Other applications are obvious.

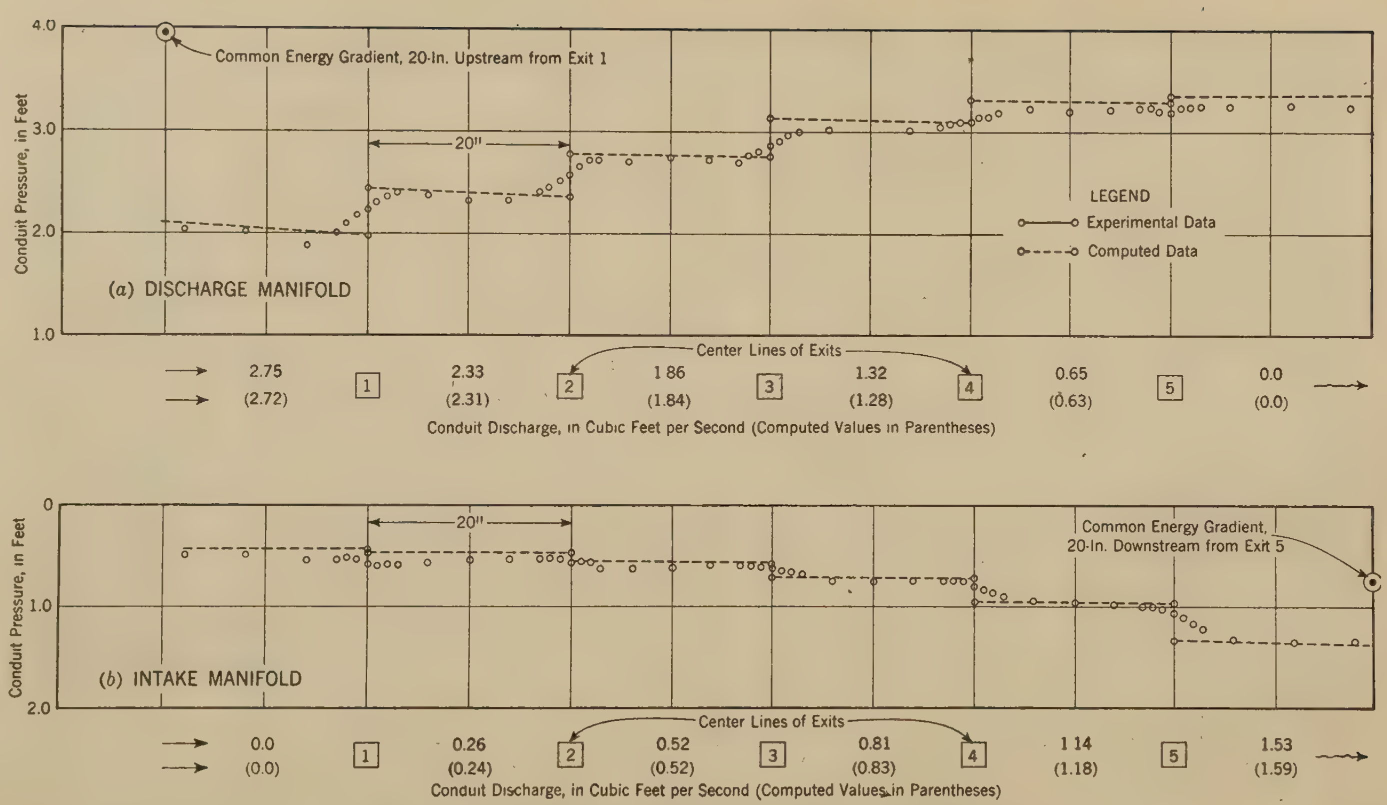

Fig. 8.—Comparison of Conduit Pressures and Discharges, Port VII
(Pressure Measured from the Water Surface in the Port Tank)

Assume a discharging manifold. The farthest downstream port has a value of P_d equal to unity. Any convenient discharge through this port may be assumed and the head calculated, the value of C_d being known. The friction loss to the next port can be calculated, since the discharge is known, and added to the previously determined head, the result being the head immediately downstream from the next port. The discharge through the second port from the downstream end is then assumed and the heads upstream and downstream are calculated, P_d being determinable for any assumed discharge. Only one discharge can be found which is consistent with the established discharge through the end port and the resulting gradient. The calculation proceeds up the manifold by trial until the farthest upstream port is passed. Since friction losses may be considered to vary with the square of the mean velocity, the distribution of the total discharge is the same, regardless of the port discharge originally assumed. Accordingly, the calculation made for one discharge may be adjusted to any other head or discharge by the following rules: (1) All heads vary in proportion to the over-all head applied to the manifold; and (2) all discharges and velocities vary as the square root of the applied head. An example of this adjustment is shown under "Verification Tests."

If the calculation indicates a negative head upstream from any port, the method fails. However, this result indicates that the port area is too great for good distribution. This may be corrected by reducing the size, number, or efficiency of the ports or by increasing the size of the conduit. The choice between these adjustments is governed by the desired relation between the applied head and the corresponding discharge and by the required distribution.

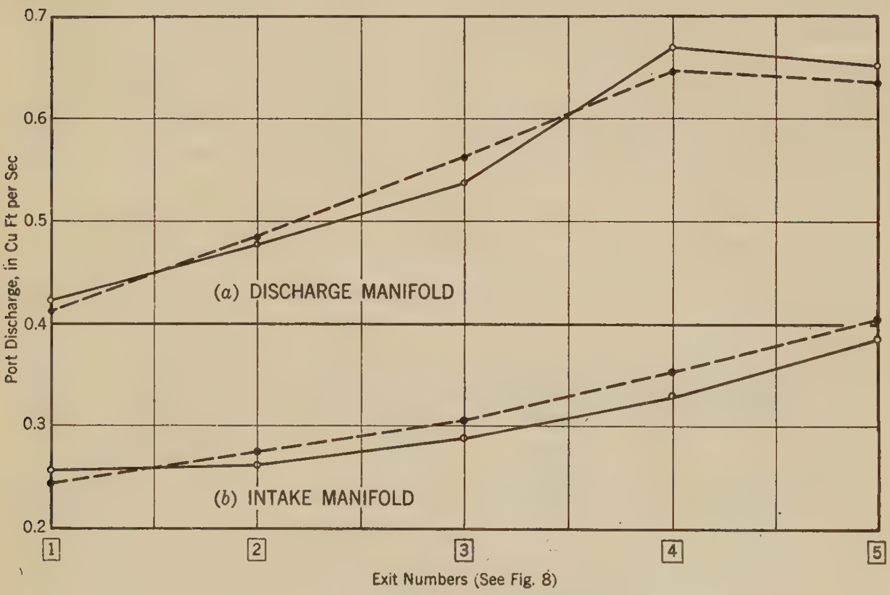

FIG. 9.—COMPARISON OF PORT DISCHARGE, PORT VII (SOLID LINES DENOTE EXPERIMENTAL DATA)

Methods of adjusting the distribution of discharge along the length of the manifold by varied port size or spacing are obvious.

For an intake manifold, the procedure is similar to that which has been explained. The calculations begin with the port at the upstream end of the manifold and proceed downstream.

It is possible to make the calculation without assigning a numerical value to the port discharges but this method has not been found advantageous. Examples of the calculations are presented under "Verification Tests."

VERIFICATION TESTS

Apparatus, Tests, and Procedure.—The apparatus used for the verification tests is shown in Fig. 5. Ports type VII were connected to the conduit at five points at a 20-in. spacing, each port leading to a separate tank. The water levels in the tanks were equalized by adjustment of slide valves for discharge tests and by regulating the inflow for intake tests. A small 90° V-notch weir was used to measure port discharges. For the intake tests, each port was supplied by a 3-in. swing pipe connected to a 6-in. auxiliary line. The test procedure was substantially as described for the single port tests.

Results.—Figs. 8 and 9 show typical comparisons of experimental pressures and discharges with calculated values. The basis of comparison is a common energy gradient 20 in. upstream from the farthest upstream port—for the discharge manifold—and 20 in. downstream from the farthest downstream port for the intake manifold. The number of significant figures used in the tabular calculations is not justified by the nature of the data and is used merely to illustrate better the method of making friction adjustments. Table 2 shows the calculations for the discharge manifold, based on a port discharge of 0.5 cu ft per sec for the farthest downstream port. The energy head calculated for this case—$H_1 + \frac{(V_1)^2}{2\,g} + H_f$—was $1.25 + 1.15 + 0.07 = 2.47$ ft. In Figs. 8(*a*) and 9(*a*), the tabulated results have been adjusted to an energy head of 3.95 ft, which is the experimental value. For the intake manifold the computed energy head—$H_2 - \frac{(V_2)^2}{2\,g} + H_f$—was $1.43 - 0.66 + 0.04 = 0.80$.

[a] When the value in Col. 11 of any row substantially corresponds with the value in Col. 10 of the preceding row, the assumed discharges are verified.

As before, Figs. 8(*b*) and 9(*b*) show the tabulated results adjusted to an energy head of 0.78 ft, to agree with the experimental value. For this case Table 3, contains the corresponding computations, starting with a discharge of 0.25 cu ft per sec for the extreme upstream port. Since the theory indicates constant distribution of total discharge between the ports for any applied head and, as all experiments confirmed this result, tests at other heads are compared with calculated values only on the basis of total discharges and energy heads. These comparisons are shown, for the discharge and intake manifolds, in Fig. 10.

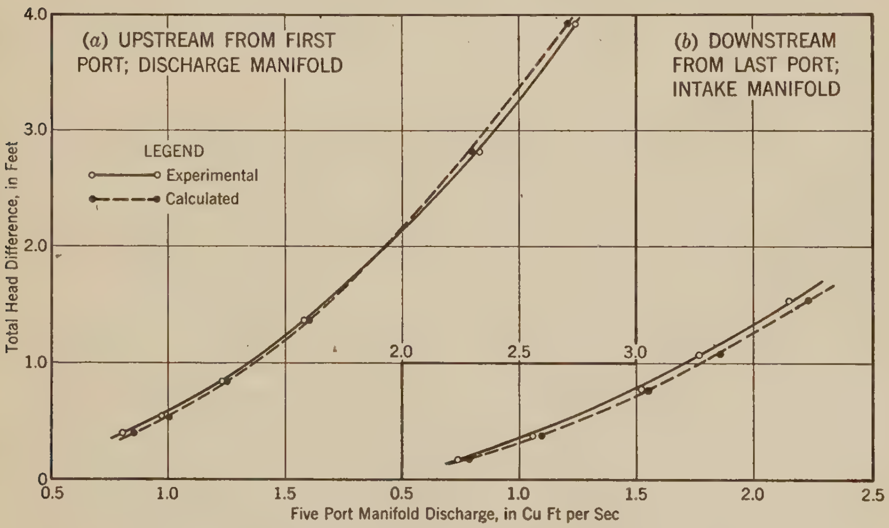

FIG. 10.—COMPARISON OF COMPUTED AND OBSERVED MANIFOLD DISCHARGES

CONCLUSION

The tests indicate that the application of single port test data to the design of manifolds for lock hydraulic systems is feasible. The use of dimensionless characteristic curves is a convenient generalization which expedites the analysis and application of single port test data. The theory presented appears to provide a reasonably correct basis for the analysis of problems in manifold hydraulics; its imperfections and its merits are due largely to its simplicity.

ACKNOWLEDGMENT

F. W. Edwards, M. Am. Soc. C. E., preceded the senior writer as Chief of the Hydraulic Section of the Special Engineering Division. He initiated the manifold tests, took an active interest in the work, and reviewed the text of this paper. S. O. Steinborn, Jun. Am. Soc. C. E., conducted the verification tests. P. S. O'Shaughnessy reviewed the text. Several other members of the Hydraulic Section were employed on the tests and calculations. The cooperation of all is gratefully acknowledged.

The Special Engineering Division was directed by Maj. Gen. T. B. Larkin, Supervising Engineer, and Brig. Gen. Hans Kramer, Assistant Supervising Engineer, Members, Am. Soc. C. E. E. E. Abbott, Designing Engineer, and J. E. Reeves, Assoc. M. Am. Soc. C. E., Assistant Designing Engineer, were in charge of design.

DISCUSSION

J. PIETRKOWSKI,[11] ESQ.—Elsewhere[12] the writer has developed equations for open channel flow, with $k_d = 1$, which were based on the same logic as Eq. 1. The water surface was found to rise in downstream direction corresponding to the pressure increase in the closed conduit treated by the authors.

Experience has shown that the water surface in the channel in the region of the side spillway is not horizontal but that it slopes toward the outlet. The effect of this phenomenon cannot be computed theoretically but must be appraised by the experimental determination of coefficients such as C_d in the conduit treated by the authors. Both the investigation reported by the authors for closed conduits and that reported by the writer for open channels can be interpreted best by instruction sheets, outlining steps in a computation, rather than by formulas.

Two differences between open channel flow and conduit flow should be emphasized:

(1) To be of any value, the spillway crest must be much longer than the corresponding dimension of the port; therefore the friction loss in the channel along the weir must be considered.

(2) The critical depth $d_c = \frac{V^2}{g}$ may occur in the channel, adjacent to the side spillway, with important consequent results upon the discharge over the weir.

It is noteworthy that the authors report the pressure change with $k_d = 1$, would be twice the difference between velocity heads upstream and downstream from the port. They conclude that Bernoulli's theorem is not applicable to problems of this kind. Similarly, the writer could show that the slope of the energy line in an open channel, computed by the momentum equation, is twice as great as the slope computed by the energy equation. Again Bernoulli's theorem is not applicable.

Incidentally, Bernoulli was the last man to expect too much from his famous theorem; he was the first to understand that conditions at the outlet of a vessel, or conduit, can be described adequately only by considering momentum.[13] L. Föppl has contributed a valuable statement[14] regarding Bernoulli's theorem —namely, that this theorem is valid either along a streamline even if curl occurs or between different streamlines when the curl is zero. The lock manifold and the side spillway are surely phenomena involving different streamlines with curl.

JOHN S. MCNOWN,[15] JUN. AM. SOC. C. E.—There are two general methods of approach to a design problem of the type outlined in this paper—the use of model studies and the application of a fundamental analysis or comprehensive research study. Only the first method can be applied in the absence of a general treatment, but this method possesses the disadvantages both of being more expensive and of furnishing results that may be of little use in related studies. In other words, the lock manifold study presented by the authors is an excellent example of specific model testing, but will not greatly reduce the work necessary for the design of a dissimilar lock port except in so far as it completely defines the experimental procedure to be followed. It is unfortunate, therefore, that the experimental work could not have been extended to include an investigation of the theory presented. The continued absence of a basic study is surprising because such a basic study would have many applications in the field of hydraulic engineering.

An attempt has been made herein to describe the general aspects of the problem and to present a specific analysis of the flow conditions at a point of lateral discharge or intake. Consideration has been given to the dimensional aspects of the problem and to the rôle of the energy and momentum equations. The analysis represents in part an extension of that given by the authors under the heading, "Theoretical Considerations," and in part an alternate approach to a general solution. Parallel developments have been carried out based on the momentum and energy principles. These are compared and combined in an attempt to obtain as much information from the analysis as possible.

Experiments have indicated that the effective area in a lateral may be considerably less than the total area of the lateral for large conduit velocities, and also that the lateral velocity is dependent upon the piezometric head within the conduit rather than upon the total head. Thus, the variation of the discharges from successive openings depends upon (*a*) the magnitudes of the velocities, and (*b*) the magnitude of the friction head between openings as compared to the increase in piezometric head at the openings. As a result, the characteristics of multiple lateral flow from a conduit vary markedly as the relative size and spacing of the lateral openings are changed.

For a conduit with closely spaced, relatively small openings, the velocity and friction heads in the conduit are negligible, and the pressure along the pipe and the discharge through the various openings are practically constant. For somewhat larger openings the velocity head becomes significant, but for close spacing the pressure recovery at the openings more than compensates for friction loss in the conduit. Consequently, the pressure and lateral discharge increase in the direction of flow, as in the lock manifold. The friction head and pressure recovery may compensate for some intermediate condition of outlet spacing and relative diameters, and the pressure and discharge may again be relatively constant for a few adjacent openings. As the spacing is further increased, pipe friction becomes predominant, and the pressure and lateral discharge then decrease in the direction of flow.

---

[15] Research Engr., Iowa Inst. of Hydr. Research, and Asst. Prof., Dept. of Mechanics and Hydraulics, State Univ. of Iowa, Iowa City, Iowa.

Throughout the entire range, the flow conditions in the vicinity of the opening and those between the openings make up two independent parts of the problem. The pipe friction on the one hand and the pressure recovery and efflux on the other are essentially unrelated unless by an effect of close spacing of the openings. Thus, it should be possible to obtain a systematic representation of the flow at the openings over the entire range of discharge without regard to friction losses in the conduit. As the authors have shown, tests on a single opening can then be applied to a multiple system, once the component parts of the problem have been separated.

A single tube in the side of a circular pipe is perhaps the simplest case of a conduit with lateral discharge, and an analysis of this case should indicate the basic relationships involved in the general problem. These relationships might then be adjusted to describe additional effects such as changes in geometrical form and close spacing of the openings. Although the orifice or port in the side of a conduit discussed by the authors is somewhat simpler because the jet is unconfined, the uncertainty regarding the conditions in the direction of the jet complicates the application of the momentum equation to the extent of an additional variable.

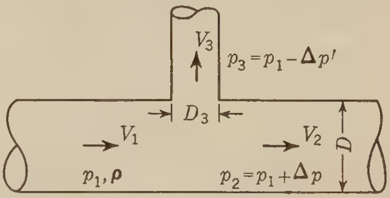

FIG. 11.—DEFINITION SKETCH FOR A SINGLE MANIFOLD PORT

The variables involved in the simple case, indicated in Fig. 11, are the pressures and velocities at the three points in question, the diameters of the pipe and opening, and the density of the liquid. Before investigating the proper grouping of these terms, it should be noted that the three pressures can be replaced by two pressure differences—say, $p_2 - p_1$ and $p_1 - p_3$—since the absolute magnitude of the pressures has no effect on the flow. Thus, the number of variables is reduced by one. The nomenclature may also be simplified somewhat by representing these two pressure differences as Δp and $\Delta p'$, respectively. Once the two diameters and fluid density have been established, only two of the flow variables can be determined arbitrarily; that is, if the two velocities, V_1 and V_2, are established by manipulation of the controls, the remaining variables, V_3, Δp, and $\Delta p'$, are also determined. Thus, five of the eight variables are independent, whereas the remaining three are dependent. Although practical considerations limit the dependent variables to the pressure and velocity terms, any three of these may be selected. Functionally, three independent equations are indicated, each expressing one of the dependent variables in terms of the five independent variables. Arbitrarily selecting V_1 and V_2 as independent variables, the dimensionless form of one such set of equations is as follows:

$$\frac{\Delta p}{0.5\,\rho\,(V_1)^2} = \phi_1\left(\frac{V_2}{V_1}, \frac{D_3}{D}\right) \qquad \text{(4a)}$$

$$\frac{V_3}{V_1} = \phi_2\left(\frac{V_2}{V_1}, \frac{D_3}{D}\right) \qquad \text{(4b)}$$

and

$$\frac{\Delta p'}{0.5\,\rho\,(V_1)^2} = \phi_3\left(\frac{V_2}{V_1}, \frac{D_3}{D}\right) \qquad (4c)$$

Eq. 4*a* describes the flow within the pipe, Eq. 4*b* reduces to the equation of continuity, and Eq. 4*c* expresses the pressure drop experienced by the water as it passes into the lateral tube. This particular set of functional relationships was selected because Eq. 4*a* has the form of Eq. 2. The independent dimensionless ratio V_2/V_1 in Eq. 4 is related to the discharge ratio P_d in Eq. 2 by the simple expression,

$$P_d = 1 - \frac{V_2}{V_1} \qquad (5)$$

Relationships of the type indicated by Eq. 4*a* can be obtained by the application of either the momentum or the energy equation between sections 1 and 2. In a manner similar to the authors' procedure, the momentum equation can be obtained in either of the following forms:

$$\frac{\Delta p}{0.5\,\rho\,(V_1)^2} = 2\left[1 - \left(\frac{V_2}{V_1}\right)^2\right] - \frac{2\,F}{\rho\,Q_1\,V_1} \qquad (6a)$$

or

$$\frac{\Delta Z}{(V_1)^2/2\,g} = 4\,P_d - 2\,(P_d)^2 - \frac{2\,F}{\rho\,Q_1\,V_1} \qquad (6b)$$

in which F is the residual force exerted on the water in this region. Eq. 6*b* differs from Eq. 2 only in that F has been used rather than k_d. A comparison of the two equations yields the relationship,

$$1 - k_d = \frac{1}{P_d}\,\frac{F}{\rho\,Q_1\,V_1} = \frac{F}{\rho\,Q_3\,V_1} \qquad (7)$$

which is in agreement with the authors' description of the ratio k_d. It should be noted that the effect of the velocity distribution on the momentum at the downstream section may be appreciable, and the neglect of this fact implies that k_d or F includes the effect of the velocity distribution as well as that of the unbalanced pressures. Also of interest is the fact that Eq. 4*a* indicates that $\frac{\Delta p}{0.5\,(V_1)^2}\left(\text{or } \frac{\Delta Z}{(V_1)^2/2\,g}\right)$ is a function of $\frac{V_1}{V_2}$ (or P_d) and of boundary conditions only, thus bearing out the authors' assumption that k_d was either a constant or a function of P_d for the particular geometrical form studied.

The energy equation written between sections 1 and 2 may take the form,

$$\frac{\Delta Z}{(V_1)^2/2\,g} = 2\,P_d - (P_d)^2 - \frac{H_f}{(V_1)^2/2\,g} \qquad (8)$$

A comparison of Eqs. 2, 6*b*, and 8 yields the following expressions for the head-loss term:

$$\frac{H_f}{(V_1)^2/2\,g} = (P_d)^2 - 2\,k_d\,P_d = (P_d)^2 - 2\,P_d + \frac{2\,F}{\rho\,Q_1\,V_1} \qquad (9)$$

For the special case of zero head loss, k_d has the value of 0.5 P_d. At the other extreme, $k_d = 0$, and the corresponding maximum value of the head loss is $\frac{(V_1 - V_2)^2}{2g}$, significantly identical to the loss for an abrupt enlargement. With these two limits as guides, it appears logical to substitute curves of $c = k_d/P_d =$ constant $(0 \leqq c \leqq 0.5)$ for the k_d (= constant)-curves in Fig. 1. This set of curves, defined by the formula,

$$\frac{\Delta Z}{(V_1)^2/2g} = 2P_d - 2(P_d)^2(1 - c) \quad \ldots . (10)$$

makes up part of the family of curves in Fig. 12, the remainder of which is obtained from the analysis of inflow manifolds.

As the upper limit for k_d has been shown to be 0.5 P_d and, as P_d varies from 0 to 1, k_d cannot exceed 0.5. If k_d were to exceed 0.5 P_d, an increase in unit energy in the direction of flow would be indicated—obviously an impossible situation. The authors' mention of the case $k_d = 1.0$, therefore, has no practical significance. It follows that an unbalanced force exists for all cases of lateral discharge. The authors' subsequent statement regarding the inapplicability of Bernoulli's equation needs clarification. For a discharge port it is possible to write an energy equation along a streamline or tube which may either continue along the conduit or pass out through the port, and each of the resulting equations has the essential characteristics of Bernoulli's theorem. For the intake port, the energy relationship may well be more complicated. The authors' remarks concerning the Bernoulli theorem and a "modified energy

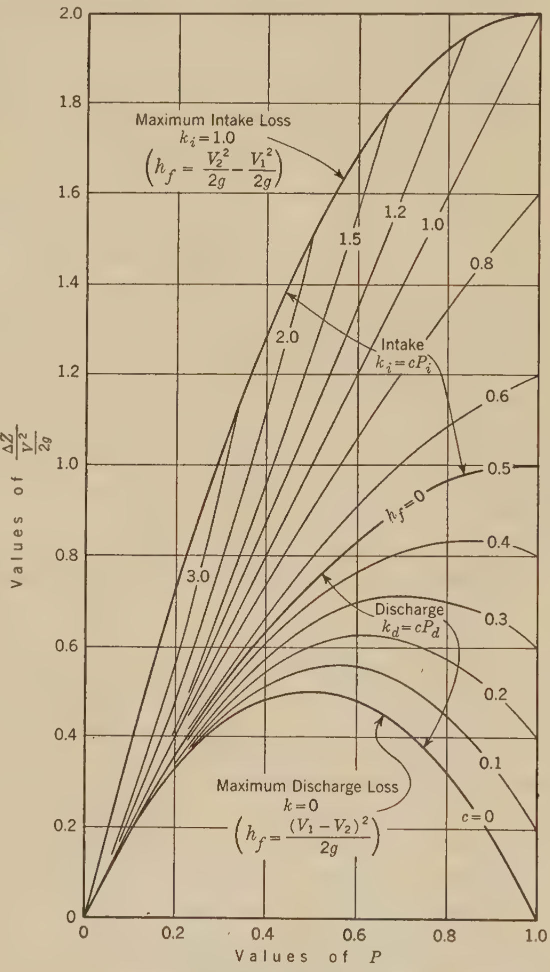

FIG. 12.—THEORETICAL CURVES FOR DISCHARGE AND INTAKE MANIFOLDS: $c = k/P =$ CONSTANT

equation" might be construed to refute the existence of Eq. 6, which to the writer is an unmodified energy equation, or Bernoulli's equation with a head-loss term. It is hoped that the closing discussion will amplify the brief statement in the paper.

The value of the energy approach lies in the determination and interpretation of the limiting curves for P plotted against $\frac{\Delta Z}{(V_1)^2/2\,g}$ as in Figs. 1 and 12. The Enger-Levy data coincide almost exactly with Eq. 6 for $H_f = 0$, or for $k_d = P_d/2$, and the substitution of $c\,P_d$ for k_d in Eq. 2 ($c < 0.5$) is equivalent to assigning a value to the friction head term as

$$\frac{H_f}{(V_1)^2/2\,g} = (P_d)^2\,(1 - 2\,c) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

A comparison of the c (= constant)-curves with the experimental data in Fig. 1 shows good agreement not only with the Enger-Levy curve at the upper limit, but with three of the curves from the Oakey series as well. The writer is unable to explain the discrepancy indicated by the position of the A-curve from the Oakey series above the upper theoretical limit of $c = 0.5$. Although the curves presented by the authors are not defined over a wide enough range to compare with the c (= constant)-curves, it is noteworthy that they tend to fall between the aforementioned limits.

The case of zero head loss for this type of flow perhaps can be visualized more easily for a special condition in which the tubes are extended into the flow, as shown in Fig. 13. If the tubes were closely spaced and carefully streamlined to prevent eddy formation at the downstream side, the friction losses might well be negligible, and the unbalanced force F would be the force exerted on a given tube. In this special case, the origin of the force is more easily visualized than in the case of a flush entrance. For the flush entrance, the unbalanced force must result from local pressure effects in the region of the tube—that is, nonuniform pressure distribution on either side of the opening, probably caused by eddy formations.

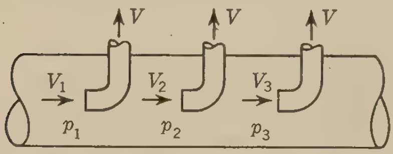

FIG. 13.—IDEALIZED MANIFOLD FOR ZERO ENERGY LOSS

The energy equation, applied in the case of the inward projecting tubes, shows that the efflux velocity would be the same for all tubes since

$$\frac{V^2}{2\,g} = \frac{(V_1)^2}{2\,g} + \frac{p_1}{\gamma} = \frac{(V_2)^2}{2\,g} + \frac{p_2}{\gamma} = \cdots \ldots\ldots\ldots\ldots\ldots (12)$$

This result is expected to differ from that for a tube with a flush entrance, since, even if the flow within the pipe for the latter case occurs with negligible head loss, the efflux could not be expected to do so. The effect of a high velocity in the pipe is to decrease the rate of lateral discharge because of larger losses and reduced effective area rather than to increase the flow because of the additional kinetic energy.

The foregoing remarks have been restricted to the case of a discharging lateral or manifold. To complete the analysis it is necessary to compare and contrast the foregoing conclusions with those for an intake system. The derivation and results in the two cases have a marked similarity. The values of k_i and P_i are implicitly different from those of k_d and P_d; that is:

$$k_d = 1 - \frac{F}{\rho\, Q_3\, V_1} \quad \text{(13a)}$$

and

$$k_i = 1 - \frac{F}{\rho\, Q_3\, V_2} \quad \text{(13b)}$$

and, also,

$$P_d = \frac{Q_3}{Q_1} = 1 - \frac{V_2}{V_1} \quad \text{(14a)}$$

and

$$P_i = \frac{Q_3}{Q_2} = 1 - \frac{V_1}{V_2} \quad \text{(14b)}$$

With these logical changes the momentum equation for intake flow is

$$\frac{\Delta Z}{(V_2)^2/2\,g} = 4\,P_i - 2\,(P_i)^2 - \frac{2\,F}{\rho\, Q_2\, V_2} \quad \text{(15a)}$$

corresponding to Eq. 3, and the energy equation is

$$\frac{\Delta Z}{(V_2)^2/2\,g} = 2\,P_i - (P_i)^2 + \frac{H_f}{(V_2)^2/2\,g} \quad \text{(15b)}$$

The head loss may again be expressed in terms of P_i and k_i or c:

$$\frac{H_f}{(V_2)^2/2\,g} = P_i\,(2\,k_i - P_i) = (P_i)^2\,(2\,c - 1) \quad \text{(16)}$$

With the proper substitutions, Eqs. 15 reduce to the intake counterpart of Eq. 10, and, for the special case of zero head loss, $k_i = 0.5\,P_i$, just as $k_d = 0.5\,P_d$ for outflow under the ideal condition. The upper limit for inflow is given by $k_i = 1.0$, which yields a maximum value for the head loss of $\frac{(V_2)^2 - (V_1)^2}{2\,g}$.

Because of the similarities indicated in the foregoing paragraph, it is possible to represent both discharge and inflow conditions on a single dimensionless plot, as shown in Fig. 12. The curves for inflow are a part of the same family of c (= constant)-curves which characterize the discharge manifold. The family is bounded by the practical limits of $k_d = 0$ and $k_i = 1.0$, these values representing conditions of maximum loss for the two different cases. The curve for zero head loss ($c = 0.5$) is the same for both types of flow, as indeed it must be for the ideal condition. With a redefinition of the principal variables, both types of flow could be represented by a single relationship. However, the foregoing analysis and the curves of Fig. 12 have been based, in so far as possible, on the terminology presented by the authors.

The agreement of the curves $c \leqq 0.5$ with experimental data for discharging flow has already been discussed. The curves $c \geqq 0.5$ are similar to those presented by the authors for the various inflow manifolds, although the agreement between individual curves is only fair. It is to be expected that the system of curves in Fig. 12 is only one step toward a complete solution of the general problem of lateral flow. Many uncertainties remain, and modifications doubtless will be necessary as more information is obtained. Much systematic experimental work will be required before the problem is solved adequately.

Throughout this discussion the effect of nonuniform velocity distribution has been neglected although it has been stated that the unbalanced force term may include this effect if appreciable. The distribution immediately downstream from a tube is certain to be irregular, but this irregularity is probably relatively unimportant unless the spacing of the outlet tubes is quite small. However, the upstream velocity distribution may affect the flow in a quite different and significant manner. The lateral discharge undoubtedly comes from a region of the pipe in which the velocity is below average, particularly for relatively small values of the lateral discharge. Hence, the subtraction of this quantity of water possessing below-average kinetic energy increases the average kinetic energy of the quantity continuing in the pipe. In this way it is possible to explain the tendency of several of the curves, aside from the Oakey A-curve, to exceed slightly the upper limit of zero head loss for small values of P_d.

Although the foregoing remarks have for the most part applied to the flow within the pipe or manifold, the lateral discharge is of primary importance in many problems. For the elementary case herein analyzed, the discharge is immediately determined from the value of V_2/V_1 by the equation of continuity, which can be written in the form of Eq. 4b:

$$\frac{V_3}{V_1} = \left(\frac{D}{D_3}\right)^2 \left(1 - \frac{V_2}{V_1}\right) = P_d \left(\frac{D}{D_3}\right) \ldots\ldots\ldots\ldots (17a)$$

for outflow, and

$$\frac{V_3}{V_2} = \left(\frac{D}{D_3}\right)^2 \left(1 - \frac{V_1}{V_2}\right) = P_i \left(\frac{D}{D_3}\right)^2 \ldots\ldots\ldots\ldots (17b)$$

for inflow. However, the functional relationship, Eq. 4c, between the pressure difference $\Delta p' = (p_1 - p_3)$ and the independent variables can be determined only by experiment. The method used by the authors is one of several that might be followed. Although $\Delta p'$ and V_3 do not occur in any one of the three relationships in Eqs. 4, the complete determination of the form of Eq. 4*b* permits the use of Eq. 4*b* in combination with Eq. 4*c* so that a simple discharge equation such as that proposed by the authors could be utilized. It should be emphasized, however, that, for an orifice or port, Eq. 17*a* is complicated by a contraction coefficient which is likely to be a function of D_3/D as well as of P. The variation of the coefficient with the velocity and diameter ratios and the outlet spacing must also be determined by experiment.

In conclusion, it is hoped that these remarks will serve to clarify the analytical background of multiple lateral flow, and at the same time will be of specific assistance in an experimental investigation of any phase of the problem. The effectiveness of dimensional analysis has been demonstrated through the determination of the number of independent equations which can be written and the functional form of each. The seeming contradiction between the momentum and energy equations has been examined in some detail, and an explanation presented. In this analysis, as in investigations of the sudden expansion of a pipe line, the Borda re-entrant tube, and the hydraulic jump, the simultaneous application of these two basic equations yields more information than would either equation used alone. The question as to which equation is applicable to a given problem is of no significance. In some cases, one is more easily applied than the other, and hence more useful; but both are applicable to all such problems.

F. W. EDWARDS,[16] M. AM. SOC. C. E.—Results of a successful effort to develop a method for designing lock manifolds are presented in this paper. The authors have prepared an excellent summary of the investigation and analysis and have called attention to the limitations of the procedure. These limitations, however, do not detract from the study because the results justify the method.

Although greater refinement was not necessary for the specific purpose of the experiments described in the paper, further studies based on the authors' method should yield valuable results for other fields as well as for lock design. Several factors require further investigation:

(1) A discrepancy in the discharge from a port under negative head (negative according to the definition adopted for head) is not important in designing lock manifolds, but it does show that the definition for head on the port is not precise. Although it does not appear logical to add the full velocity head to the pressure head to obtain the total head on the port, it might be more accurate to add all or part of the pressure rise to the head (as defined) for the discharging port. Using the same reasoning, all or part of the pressure drop would need to be subtracted from the head for an intake port. A trial plotting of discharge coefficients against P_d was prepared on this basis, but no significant change in design results was indicated.

(2) The relation between the coefficient of discharge and the head on the port should be studied. The tests gave a slight indication that separate curves

---

[16] Associate Prof., Dept. of Civ. Eng., The Pennsylvania State College, State College, Pa.

of C_d versus P_d might be drawn for each head. However, many more tests would have been required to define such curves. An average curve which permitted simplification, while keeping the error for lock design within narrow limits, was used for all heads.

Fig. 14.—Ports VIII and VIIIA

(3) The sudden change in the relationship of C_d and P_d for the ports with rounded entrance probably depends on several factors, including radius of curvature on the upstream edge of the port, shape of the port cross section, length of the port, and ratio of port area to conduit area. The authors present the test points for Port VII as being representative of the agreement between curves and observation points for Ports I to VI, inclusive. However, the test points for Ports I to III, inclusive (square-cornered ports), show less scatter than do those for Port VII. In general, the curve for a square-cornered port and the portion of the curve on the left of the discontinuity point for a round-cornered port are similar. This fact supports the belief that eddies along the upstream edge of the port entrance cause the discontinuity, as eddies always exist in the entrance of a square-cornered port.

It should be emphasized that the experiments described in the paper were made before the lock hydraulic system was designed and before the complete system was tested by hydraulic models. This study not only furnished a method of designing the manifold systems for the Third Locks, but also greatly reduced the revisions required on the large, more expensive models of the complete system. It is the writer's belief that many useless model tests are made because of inadequate preliminary studies and analyses.

The equipment described in the paper was used to test several types of ports before the final design was determined. In addition, tests of connections between the main tunnels in the lock walls and the laterals in the lock floor were conducted and analyzed by the authors' method.

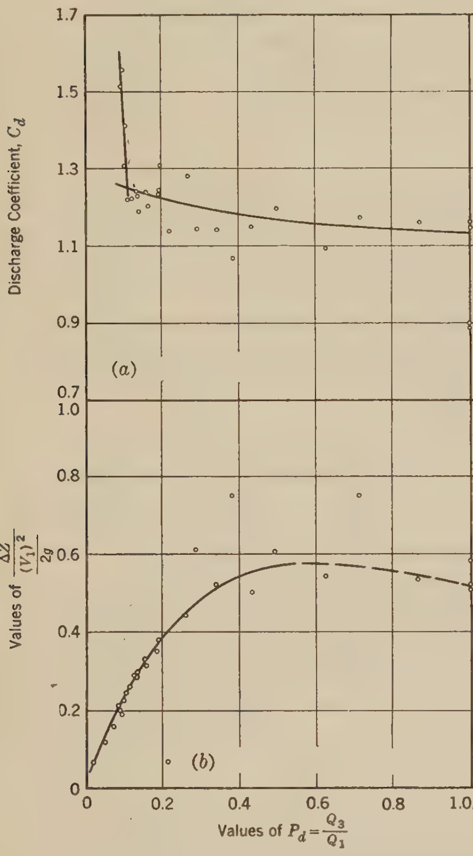

Fig. 15.—Port Characteristics, Port VIII

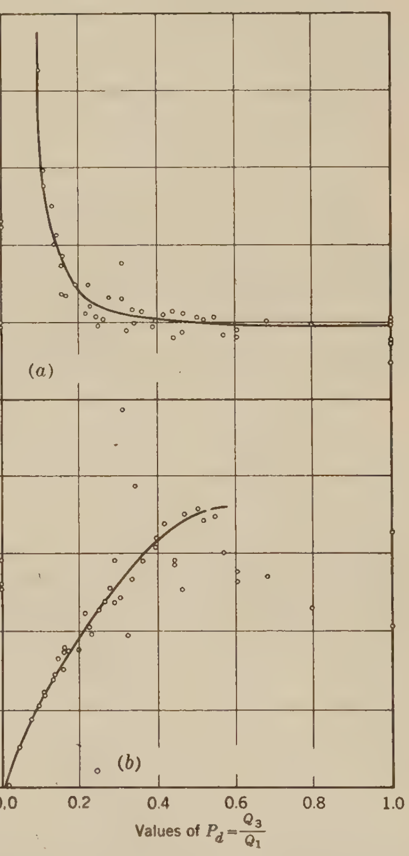

Fig. 16.—Port Characteristics, Port VIIIA

The test port developed for the design of the Third Locks (see Fig. 14) has several special characteristics. The port throat is long and narrow. The long dimension is perpendicular to the direction of flow in the conduit. The shape caused the flow to emerge from the port very nearly at right angles to the direction of flow in the conduit. The port was designed so that a grid could be used at the outlet to prevent objects from entering the hydraulic system.

The long dimension of the port is flared from the throat to the lock floor. The flare serves two purposes:

(*a*) It increases the area of the port so that the grid obstructs the flow as little as possible, and makes the operation of the hydraulic system practicable either with or without the grids in place; and
(*b*) It spreads the flow along the length of the lock.

The characteristic curves for this special port, with and without grid, are shown in Figs. 15 and 16. Curves for discharge tests only are shown. It is interesting to note that the Panama tests furnished the basis for the adoption of a similar port, without grid, in the MacArthur Lock at Sault Sainte Marie, Mich.

W. M. LANSFORD,[17] M. AM. SOC. C. E.—A problem that is difficult to analyze, not only as applied to canal locks but also as applied to piping systems such as those used in sand filters and sprinkling systems, is presented in this instructive paper.

In 1932–1933 the writer made a study of two manifold orifices in the side of a 3-in. brass pipe. The arrangement of the pipe and orifices is shown in Fig. 17. Both orifices had the same diameter for each series of tests. Four series of tests were made using orifices, 1/4 in., 3/8 in., 1/2 in., and 3/4 in. in diameter. The head on the orifices, as measured by the manometer upstream from each orifice, varied from 5.97 ft to 0.50 ft.

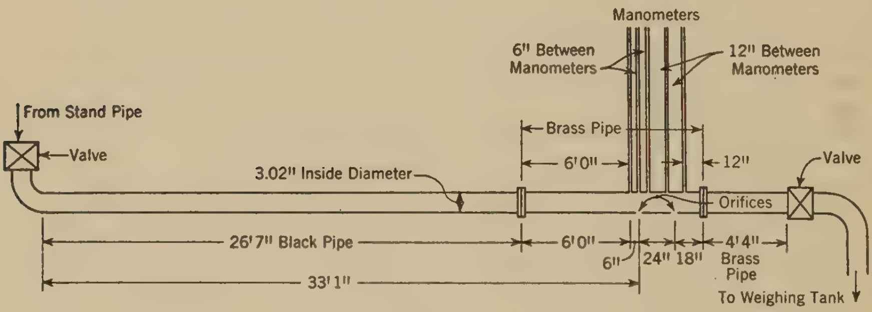

FIG. 17.—SKETCH OF APPARATUS

The water was taken from a constant level standpipe which maintained a static head of approximately 60 ft at the upstream valve in the supply line. The quantity of water discharged from each orifice and from the pipe was determined by simultaneous weighing operations. The maximum velocity obtained in the pipe preceding the upstream orifice was about 16.25 ft per sec.

---

[17] Associate Prof., Theoretical and Applied Mechanics, Univ. of Illinois, Urbana, Ill.

By adjusting the two valves in Fig. 17, it was easy to obtain several widely different velocities in the pipe while maintaining a constant head on the orifice. During early preliminary tests, an approach pipe shorter than the one in Fig. 17 was used. The shorter pipe caused the upstream valve to affect the flow from the orifice. The approach pipe, shown in Fig. 17, which was longer than 132 diameters, placed the valve far enough upstream that no disturbance from the valve was noticed at the orifice.

While the data presented by the authors seem to be in agreement with results obtained by the use of Eq. 2, the data herein presented by the writer are of such values that other means of analyzing and presenting the data had to be used.

The rise in the hydraulic gradient, ΔZ, could not be used as a criterion of the orifice flow in the analysis of these tests because of the very small value of ΔZ. The results of some of these tests are shown graphically in Fig. 18 by a relation between $\frac{(V_1)^2/(2\,g)}{Z_1}$ and $\frac{Q_3}{Q_1}$, in which $\frac{(V_1)^2}{2\,g}$ is the kinetic energy in the pipe; Z_1 is the potential energy in the pipe at a point preceding the orifice; Q_3 is the quantity discharged from the orifice; and Q_1 is the quantity flowing in the pipe preceding the orifice. The curves in Fig. 18 indicate the great effect the ratio of the kinetic energy to the potential energy has upon the flow through a manifold orifice in a pipe.

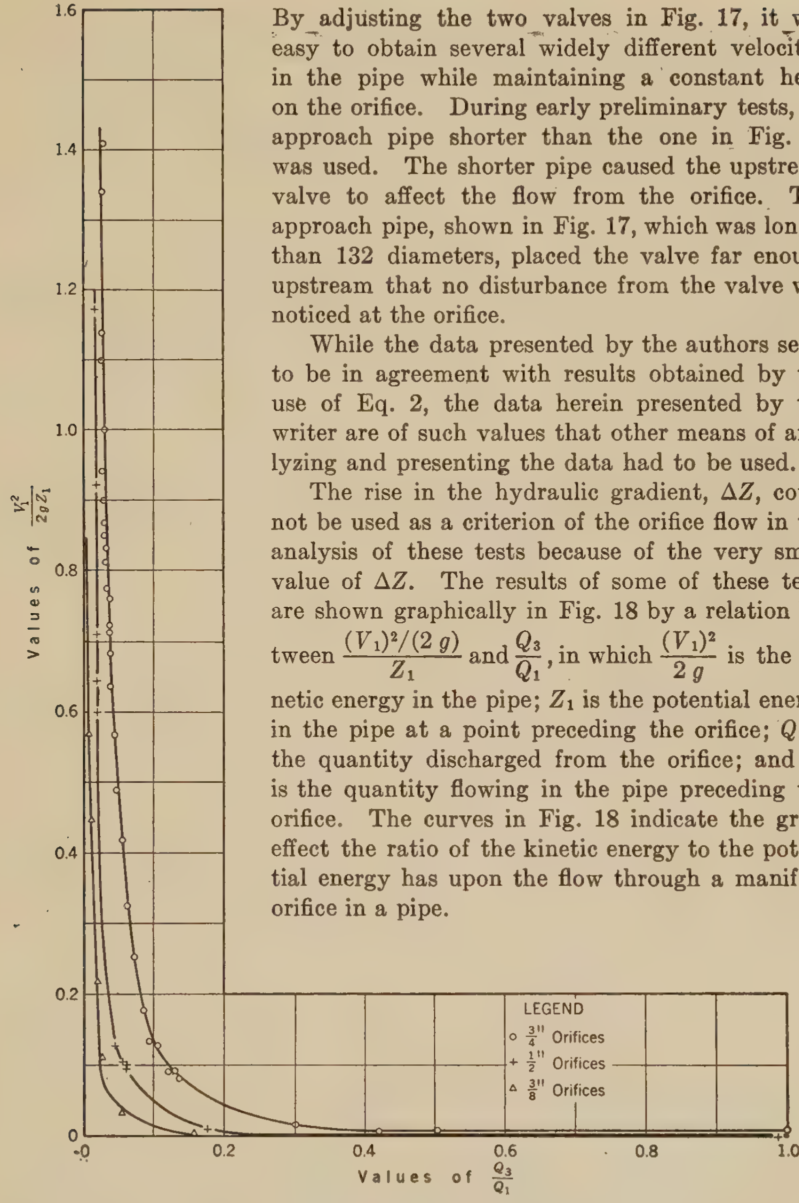

Fig. 18.—Relation Between $\frac{(V_1)^2}{2\,g\,Z_1}$ and $\frac{Q_3}{Q_1}$

Robert F. Kreiss,[18] Jun. Am. Soc. C. E.—Manifold tests whose results are in good agreement with the discharge distribution and with the over-all coefficients computed from calibrations of a single port confirm the usefulness of

port calibrations. Inspection of the coefficient curves of Fig. 6 suggests that a plot of port coefficients against the ratio of average port velocity to conduit velocity would be significant in interpolating test results to ports of other sizes. Rather than present graphs of such relations, the writer has computed the characteristics of discharging manifolds from the calibrations on Ports I to VII. Two characteristics are shown as functions of the ratio of cumulative port area to conduit area in the semilogarithmic plots of Fig. 19. The results, which are the practical objectives of the single port calibrations, indicate that for ports of similar design the relative distribution of discharge and the over-all coefficients for manifolds are nearly single valued functions of the area ratio (compare results for Ports I to III and for Ports IV to VI). The discontinuity in the coefficients of the single port calibrations is apparent in the coefficients for the manifold, the discontinuity for Ports IV to VI occurring at an area ratio of about 0.4.

The computations for the manifold have been made essentially as outlined by the authors. The over-all coefficients assume a manifold acting as a unit such that the head producing discharge Q_1 through N ports of area A_3 is $H_d + \frac{(V_1)^2}{2\,g}$, or

$$C = \frac{Q_1}{N\,A_3\,\sqrt{2\,g}\sqrt{H_d + \frac{(V_1)^2}{2\,g}}} \quad \text{(18)}$$

the discharge, velocity, and head being those immediately upstream from the most upstream port. The results in Fig. 19 represent characteristics for a frictionless conduit. The discharge distribution in Fig. 19(*b*) refers to a unit discharge either at an area ratio approaching zero as a limit (Ports I to III) or at the downstream port (Ports IV to X).

An additional observation, worthy of note, is that the over-all coefficients, shown in Fig. 19(*a*), bear a relation to the area ratio as follows:

$$C = \frac{C'}{10^a} \quad \text{(19)}$$

in which, to simplify typography:

$$a = C''\,\frac{N\,A_3}{A_1} \quad \text{(20)}$$

In Eqs. 19 and 20, C' and C'' are constants dependent on the port design and on the two types of discharge mentioned by the authors. Computed manifold characteristics for ports of four other designs further check the validity of Eq. 19. Results for Ports IX and X are shown in Fig. 19. The values of the coefficients C' and C'', the range of area ratios to which the coefficients apply, and the type of discharge from the ports are given in Table 4 for Ports I to X. The tabulated values are subject to the limitations given by the authors (see heading, "Single Port Tests: Limitations"). It is evident that the discharge distribution and the efficiency of the manifold are dependent on the type of ports in the manifold.

Port IX is similar to Port VII (see Fig. 4) except that the dimensions of the opening are 1.52 in. (parallel to the conduit center line) by 2.97 in. Port X is a tapered flow-line port with one face extending from the floor of the conduit. Ports XI and XII extend downward from the conduit floor and then horizontally, the horizontal leg being of constant shape in Port XI and divergent in Port XII. (Details of design and port calibrations have been presented by Sydney O. Steinborn,[19] Jun. Am. Soc. C. E., and are on file in the Engineering Societies Library.)

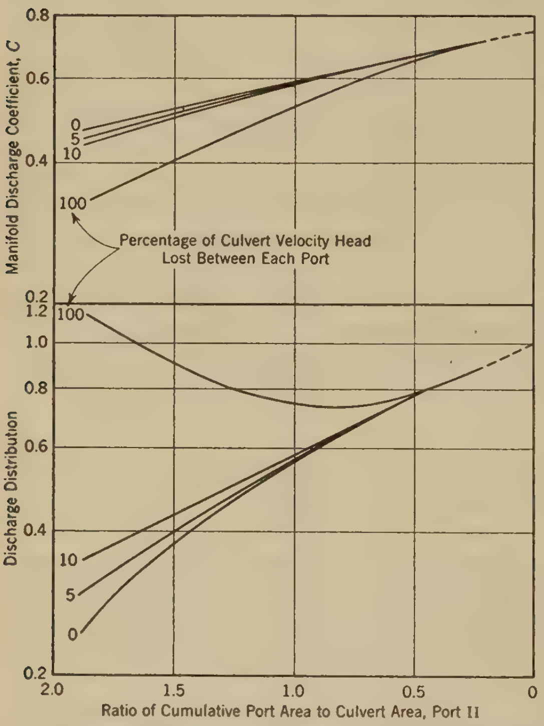

FIG. 20.—EFFECT OF FRICTIONAL LOSSES IN A CULVERT ON THE HYDRAULIC CHARACTERISTICS IN A MANIFOLD

An exponential equation was reported in 1937[20] for filling and emptying operations in lock models having port designs similar to Port X. In more recent (1944) tests on another lock model, the exponential equation was found applicable to steady flow calibrations and to varied flow operations as the number of lateral culverts (containing ports and connected to a main conduit) was varied. These results provide additional evidence of the relation that exists between single port calibrations and discharging manifolds.

The conduit friction has an appreciable effect on the characteristics of a discharge manifold when ports are widely spaced. An example for Port II is shown in Fig. 20. The conduit friction between each port is assumed as 0, 0.05, 0.10, and 1.00 of the velocity head immediately upstream of each port. (In Manning's equation these frictional values represent port spacings of roughly 0 ft, 1 ft, 2 ft, and 20 ft in a 6-in. square conduit with $n = 0.10$.)

The methods of testing and analysis presented by the authors are suitable for such designs as lock manifolds, storm sewers, sprinkler systems, and penstocks from a feeder line. With the graphs in Fig. 19 the design of manifolds, when ports are closely spaced, is further simplified and clarified.

[20] "Laboratory Tests on Hydraulic Model of Filling and Emptying System for Proposed Watts Bar Project Lock," U. S. Engr. Sub-Office, Iowa City, Iowa, December, 1937.

Ralph G. Berk.[21]—A valuable method of predicting the hydraulic performance of lock manifolds is presented in this paper. The method can be applied to other types of manifolds, such as filter, bottom-lateral systems, sprinkling filter underdrain systems, irrigation piping distribution systems, and orange orchard, smudge-pot fuel-supply piping.

The authors' procedure is similar to the method employed for the calculation of backwater curves in open channels. Orifice coefficients are used for calculating the flow through each port in the manifold. These orifice coefficients are derived from data obtained in testing single port models. The test results are expressed by curves showing the variation of the orifice coefficient C with changes in the value of P (ratio of flow through the port to flow in the conduit).

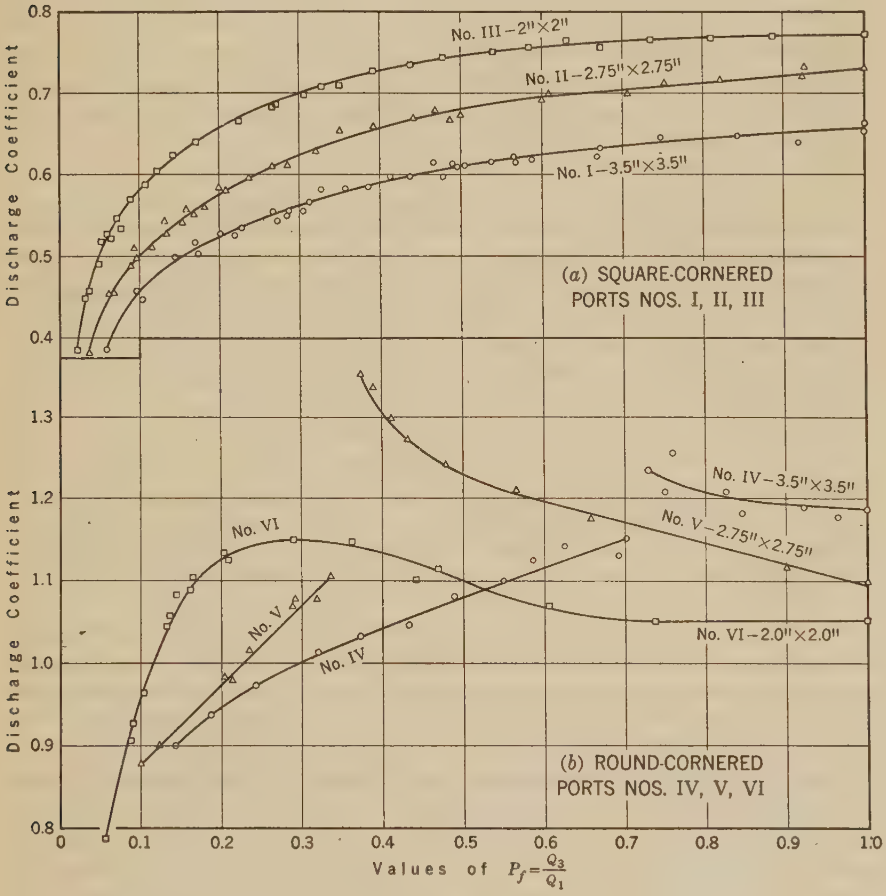

Fig. 21.—Curves of Port Characteristics, Ports I to VI, Inclusive

The orifice coefficients derived by the authors differ from the orifice coefficients ordinarily given in standard textbooks on hydraulics. The former reflect

---

[1] Chf. Design Engr., Water Section, with Cons. Engrs., C. A., Caracas, Venezuela.

the inequality in flow through the ports of a manifold caused by abrupt changes in pressure and velocity of flow along the manifold tube, and by angularity of port discharge. None of these effects can be directly evaluated. Under the heading, "Single Port Tests: Analysis," the authors state that their derived orifice coefficients show no significant dependence upon variables other than P.

Despite the fact that the (C-P)-curves in Figs. 6 and 7 are reduced to a very small scale, it is still possible to observe that these curves assume different relative positions for varying sizes of ports. In Fig. 21 the same data are presented in a form designed for easier comparison. The (C-P)-curves for the square-cornered ports (Fig. 21(a)) indicate a consistent variation of C with the different sizes tested. This variation most likely conforms to the model laws expressed by Froude's criterion of dynamic similitude. However, the (C-P)-curves for round-cornered ports (Fig. 21(b)) show no consistent variation of C with the sizes tested. The shapes of these curves and the juxtaposition probably indicate no conformity with Froude's criterion.

In view of these differences, can one conclude that the geometrical shape of the port, together with variation in size, exercises some influence on the port orifice coefficient? Can tests with model ports of smaller scale provide enough information to permit the formulation of a model law defining the performance of a port of given shape in terms of its size? Discussing a specific example, what values of C for round-cornered ports (Ports IV, V, and VI) would the authors use in calculating the performance of a prototype lock manifold, with ports which should necessarily be much larger than the test ports? (The example shown in the paper is a calculation of the performance of a manifold having ports of the same size as those of the test model.)

To summarize, the writer believes that the authors do not present definite information for solving the practical problem of designing a prototype manifold larger in size than the test models and with port shapes other than square cornered. He must also conclude that, for purposes of practical design, it would be best to conduct tests on ports of prototype dimensions and shapes.

Ralph W. Powell,[22] M. Am. Soc. C. E.—As the authors state, the theoretical treatment of the pressures in manifolds has been very unsatisfactory. As one who, in the past, perhaps has helped to produce this situation, the writer feels moved to make another attempt to clarify the underlying hydraulics of the problem. Discussion will be limited to the case of a single port.

Fig. 22(a) is a diagram of a single manifold port with liquid entering through pipe 1, and leaving through pipe 2 and branch 3. The total pressure on section CD must exceed the total pressure on section AB by the loss of momentum per second, in the axial direction, of the liquid in the space ABCD. Since the liquid flowing into branch 3 will not cross section BC at right angles, it will carry away some of the momentum. The neglect of this condition vitiated the writer's former treatment.[23] Taking this fact into account,

$$\gamma A_e (Z_2 - Z_1) = \frac{\beta_1 Q_1 \gamma V_1}{g} - \frac{\beta_2 Q_2 \gamma V_2}{g} - \frac{\beta_3 Q_3 \gamma V_3 \tan \theta_3}{g} \quad \ldots (21)$$

---

[22] Associate Prof. of Mechanics, Ohio State Univ., Columbus, Ohio.

[23] Discussion by R. W. Powell of "Hydraulics of Sprinkling Systems for Irrigation," by J. E. Christiansen, *Transactions*, Am. Soc. C. E., Vol. 107 (1942), pp. 245–247.

in which θ_3 is the mean angle that the liquid crossing section BC makes with the axis of pipe 3, and β_1, β_2, and β_3 are the momentum factors in the respective pipes for correcting for the nonuniform velocity distribution. The other symbols are defined in the paper.

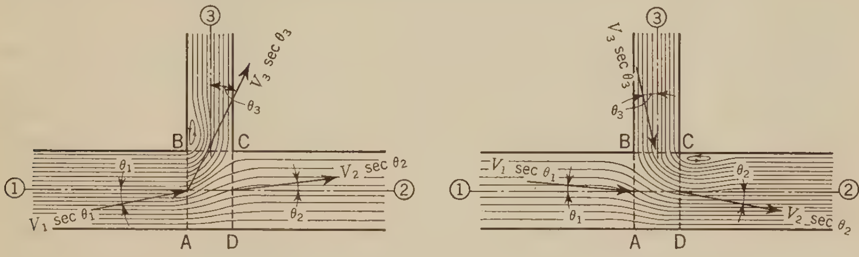
Eq. 21 reduces to

$$\frac{\Delta Z}{(V_1)^2/2\,g} = 2\left[\beta_1 - \beta_2\,(1 - P_d)^2 - (P_d)^2\,\frac{\beta_3\,A_c}{A_p}\tan\theta_3\right] \ldots\ldots (22)$$

Assuming that β_1 and β_2 are both unity, letting $\beta_3\,\frac{A_c}{A_p}\tan\theta_3 = \psi$ and equating to the value given by Eq. 2:

$$\psi = \frac{\beta_3\,A_c}{A_p}\tan\theta_3 = \frac{1 - k_d}{P_d} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

When P_d is small, the foregoing assumptions are probably nearly correct; but, for larger values of P_d, the factor β_2 will be much larger than unity.



(*a*) DISCHARGE PORT (*b*) INTAKE PORT

Fig. 22.—Diagrams of Idealized Flow

Using Eq. 23 and the data given or cited in the paper, the writer attempted to find the value of θ_3. About his only conclusion was that θ_3 approached 90° as P_d approached zero and that it also depended very much on the value of A_c/A_p. In fact, for any given value of P_d, when the side branch was made smaller with respect to the main pipe, θ_3 was increased enough that ψ remained more nearly the same for different values of A_c/A_p than did $\beta_3 \tan\theta_3$. In any given case, assuming a reasonable value of β_3, such as 1.05, an entirely reasonable value of θ_3 could be computed, but no law for forecasting the value could be deduced.

The case of inflow is shown in Fig. 22(*b*). The total pressure on section AB exceeds the total pressure on section CD by the gain in momentum per second, in the axial direction, of the liquid in the space ABCD. Thus:

$$\gamma\,A_c\,(Z_1 - Z_2) = \frac{\beta_2\,Q_2\,\gamma\,V_2}{g} - \frac{\beta_1\,Q_1\,\gamma\,V_1}{g} - \frac{\beta_3\,Q_3\,\gamma\,V_3\tan\theta_3}{g} \ldots (24)$$

which, assuming that β_1 is unity, reduces to

$$\frac{\Delta Z}{(V_2)^2/2\,g} = 2\left[\beta_2 - (1 - P_i)^2 - \beta_3\,(P_i)^2\,\frac{A_c}{A_p}\tan\theta_3\right] \ldots\ldots\ldots (25)$$

or letting $\frac{\Delta Z}{(V_2)^2/2\,g} = J$:

$$\frac{J}{2} = \beta_2 - (1 - P_i)^2 - (P_i)^2\,\psi \ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

In Eqs. 24, 25, and 26, β_2, β_3, and θ_3 are all unknown, and there seems little chance of determining them short of laborious experiments. By plotting J against P_i as in Fig. 7(*d*) and extending the curve back to $P_i = 0$, the value of β_2 can be estimated for small values of P_i. For Port VII the value of β_2 seems to be 1.12 and for the other ports it varies from 1.03 to 1.18. The data of Itaru Naramoto and Taijiro Kasai[24] gives, as nearly as can be estimated: $\beta_2 = 1.06$. The foregoing are for low values of P_i; when P_i becomes large, Ports I, II, III, VI, and VII show that the value of β_2 must increase, because otherwise the values of tan θ_3 become negative.

TABLE 5.—COMPUTATIONS FOR INTAKE PORT I

P_i (1)	J (2)	β_2 (3)	ψ (4)	θ_3 (5)
0.047	0.21	1.040	12.3	76°.6
0.088	0.34	1.040	4.9	59°.0

0.627	1.94	1.130	0.053	1°.0
0.668	2.06	1.170	0.067	1°.3
0.739	2.26	1.245	0.086	1°.7
0.768	2.45	1.290	0.019	0°.4

Table 5 gives a possible set of values for Port I. The values of P_i and J are scaled from the plotted values given in the authors' original paper. Only sixteen of the thirty points have been included, but they are distributed throughout the range of the experiment. Values of β_2 have been assigned arbitrarily, but in such a way as to give a smooth curve when plotted against P_i. The value of β_3 was taken as 1.00, and $A_c/A_p = 36/12.25 = 2.94$. The resulting values of θ_3 seem to be reasonable. Unfortunately, the writer has not been able to devise any equation that will forecast the values of β_2 and ψ or θ_3. For ports of the same proportions as those used by the authors, designs may be based on experimental results. For other proportions, new model tests will be needed.

EDWARD SOUCEK,[25] ASSOC. M. AM. SOC. C. E., AND E. W. ZELNICK,[26] JUN. AM. SOC. C. E.—As the principal conclusions of the paper appear to have been accepted by all who discussed it, this closure will be confined to a brief comment on each discussion and to clearing up a few minor points concerning which some difference of opinion appears to exist.

Mr. Pietrkowski enlarges upon the suggestion that the theoretical treatment adopted in the paper is related to the analysis of flow in side channel spillways. In his problem, the lateral discharge is out of the channel rather than into it. Although the basic principles are the same in the two cases, the direction of flow requires consideration as it appears that the conditions necessary for $k_d = 1$ cannot be obtained whereas $k_i = 1$ is quite possible. This point will be considered further in connection with Professor McNown's discussion. Mr. Pietrkowski's references concerning the conditions under which Bernoulli's theorem may be applied will be valuable to those who wish to explore the limitations of this important principle.

Professor McNown's study of the manifold problem is lucid and comprehensive; for research purposes, it may well supplant the brief theoretical study which appeared in the paper. For use in design, either treatment can be considered merely to support the observation that the characteristics of any port and culvert combination are expressible in terms of P_d and P_i. Professor McNown suggests clarification of the statement that "* * * Bernoulli's theorem is not applicable to the phenomenon under consideration, although a modified energy equation might be used." Bernoulli's theorem with a head-loss term is probably satisfactory for the analysis of discharge manifolds—tests of Boulder Dam penstocks were analyzed in this manner by the U. S. Bureau of Reclamation.[7] In intake manifolds or side channel spillways where flows from sources of differing energy content converge and mix in the culvert or channel as the case may be, Bernoulli's theorem would have to be modified by weighting the head from the two sources in proportion to the respective discharges, even if energy losses did not occur. In the side channel spillway, the energy of the flow received laterally is properly considered to be lost; with vanes to direct the inflow, a large part of the energy could be retained. Closely analogous conditions occur in an intake manifold. In connection with use of the energy principle for discharge manifolds, the Oakey-A curve indicates an energy gain in the direction of flow. The consistency of the A, B, C, and D curves makes experimental error an extremely unlikely explanation of the phenomenon. Professor McNown's other suggestion—that the lateral bleeds away enough low velocity water to increase the energy content of the remainder—seems more logical. However, there is another possibility—that in some manner mechanically similar to that in which water does work on a turbine blade, the lateral discharge actually yields a portion of its energy to the conduit flow. If future research should indicate that this is the correct explanation, it would be preferable to use the momentum principle for both intake and discharge manifolds.

[24] "On the Loss of Energy at Impact of Two Confined Streams of Water," by Itaru Naramoto and Taijiro Kasai, *Memoirs of the College of Engineering*, Kyushu Imperial Univ., Fukuoka, Japan, Vol. VI, 1931–1932, p. 189.

[25] With Office, Chf. of Engrs., Washington, D. C.

[26] With The Panama Canal, Balboa Heights, Canal Zone.

Professor McNown stated that the mention of $k_d = 1$ has no practical significance. The remark in the paper was applied to insertion of values in Eq. 2 and Eq. 3, and consequently no practical significance was indicated. It is clear from the text that values of $k_d = 1$ were not anticipated. Moreover, the statement pertained equally to k_i and k_d; $k_i = 1$ is decidedly significant. It is well, however, that Professor McNown has clarified the matter. Mr. Pietrkowski has used $k_d = 1$ for analysis of a side spillway but, if the weir is constructed with side-walls so as to deflect the flow at right angles to the channel axis as assumed in the derivation, k_d will have a value less than unity. Conversely, if the weir is sharp-edged, the flow will not be diverted at right angles to the channel axis and a basic condition of the derivation—loss of momentum by the lateral flow—will not result. In either case, a rise in water levels substantially less than twice the difference in velocity heads may be anticipated.

It appears that Professor McNown may overestimate the significance of the correspondence of his c (= constant)-curves with the Enger-Levy curve. The theoretical bases for this curve involves flow through a longitudinal slit in a pipe. Although the substantial correctness of the curve is indicated by tests,[10] the agreement is not so close as to warrant adoption of the c (= constant)-curves at this time. The Oakey curves show a more rapid drop in the relative pressure rise for high values of P_d than do the most nearly comparable

c (= constant)-curves. The Bureau of Reclamation curve corresponds quite closely to the curve for $k_d = 0.3$ over a rather wide range. Of course, it is not necessary to determine the mathematical nature of the pressure-change curves, as they may be determined experimentally. Discharge from a longitudinal slit in a pipe—the basis for the Enger-Levy curve—is a phenomenon closely related to flow from a discharge manifold, but there are significant differences. Some of these were revealed in 1931 in discussions of a paper by Jakob Kunz.[27] The jet discharged from a continuous longitudinal slit suffers no loss of momentum in the direction parallel to the pipe axis but each element retains a longitudinal velocity component equal to the pipe velocity at the point of issue. The normal component of velocity appears to take place at the expense of pressure head only (it is assumed that the slit is at an extremity of a horizontal diameter). Shock loss is conspicuously absent. Under these conditions, there is every reason to expect that the pressure changes would occur in accordance with Bernoulli's theorem, although the momentum principle was used in deriving the curve. In a discharging manifold, shock loss (or unbalanced port pressure if the momentum principle is used) is the essence of the problem. Despite these minor differences of opinion, Professor McNown's basic ideas are accepted and endorsed—especially appreciated is his thorough treatment of the energy concept which was merely suggested in the paper. Although it is quite generally realized that the momentum and energy principles are but different statements of Newton's Second Law of Motion, statements that one or the other is exclusively applicable are fairly common. No statement in the paper was intended to suggest exclusion of the energy principle but the clarification suggested and largely supplied by Professor McNown was highly desirable.

Professor Edwards' discussion is most welcome; it was he who initiated the test program in the face of considerable evidence that the theory could not be developed in time for use on the Third Locks Project. As he states, the studies and tests did much to expedite the design and testing of complete lock models. The characteristic curves for Ports I to VI, inclusive, were much better defined than those for Port VII as shown in Fig. 21 by Mr. Berk but the verification tests were made for Port VII only. It is for this reason that Port VII is presented in detail. The port described by Professor Edwards has several desirable characteristics, the foremost of which are its high capacity, a relatively constant discharge coefficient over a considerable range of P_d, and elimination of an undesirable velocity component—lack of the latter characteristic to some extent defeats the purpose of the bottom-filling system of the original Panama locks. The similarity of the ports used in the MacArthur Lock and the one described by Professor Edwards has been noted. There is little doubt that this port shape is largely responsible for the quiet filling conditions in the MacArthur Lock—in addition to its other advantages, the flattened jet has a large surface area which is conducive to a high rate of energy dissipation and tends to minimize surface disturbances.

The curves introduced by Professor Lansford provide some basis for the analysis of flow from a perforated pipe but should eventually be supplemented by tests on a larger scale which will enable calculation of the pressure gradients.

---

[27] "Jets from Manifold Tubes," by Jakob Kunz, *Transactions*, A.S.M.E., 1931, APM-53-14, p. 181.

Although Fig. 18 shows the "great effect the ratio of the kinetic energy to the potential energy has upon the flow through a manifold orifice in a pipe," it is not evident upon inspection that the data corroborate a functional relationship between the discharge coefficient and the ratio P_d. Starting with the basic orifice equation, successive transformations show that such is the case (Z_1 and H_d are equivalent).

$$C_d = \frac{Q_3}{A_p \sqrt{2\,g\,Z_1}} = \frac{P_d\,Q_1}{A_p \sqrt{2\,g\,Z_1}} = \frac{P_d\,A_c\,V_1}{A_p \sqrt{2\,g\,Z_1}} = \sqrt{\left(\frac{A_c}{A_p}\right)^2 (P_d)^2 \frac{(V_1)^2}{2\,g\,Z_1}} \quad \ldots (27)$$

Since A_c/A_p is a constant for any orifice and pipe combination, and as Fig. 18 shows that $(V_1)^2/(2\,g\,Z_1)$ is a function of P_d for each of the orifices tested, it follows that C_d for each orifice is expressible as a function of P_d alone. This experimental support of the theory presented in the paper is greatly appreciated.

The tests reported in the paper would be of little value if they did not lead to a method of designing manifolds. Mr. Kreiss has contributed a very practical means of applying the theory. In Eq. 18, the quantity $N\,A_3$ is the gross area of the ports downstream from the section at which the energy head is determined. In a simple manifold, for example, a lock culvert with wall ports, the energy head producing discharge is simply the gross head minus entrance losses. A few preliminary calculations will indicate whether or not friction losses are significant in any particular case—Fig. 20 serves as a guide for estimating the effect of friction losses. It should not be overlooked that calculations similar to those in Table 2 must be made in the preparation of Table 4. Thanks are due to Mr. Kreiss for undertaking this task and for presenting data on several more ports. It is gratifying to learn that he has made additional tests which tend to confirm the value of single port data in the design of manifolds.

Mr. Berk's comments are particularly interesting because they illustrate an error that is very likely to occur if it is forgotten that the characteristic curves are for a particular port and culvert combination—not for the port alone. Under the heading, "Single Port Tests: Limitations," it was stated that "The data are based on tests of ports of particular sizes, shapes, and lengths—attached to a conduit of a particular size and shape." Elsewhere in the paper, the effects of conduit area and conduit velocity were mentioned. Eq. 27, applicable to Professor Lansford's data, further shows that the culvert size has an important effect upon discharge coefficients.

The concept of a "port and culvert combination" clarifies the questions raised by Mr. Berk. The verification tests were based upon ports of the same size as the one used in single-port tests of Port VII; therefore, as Mr. Berk indicates, scale effects were not investigated. However, the phenomena considered are essentially dynamic in character and there is little question that Froude's law is applicable. The inconsistencies which Mr. Berk believes to exist are entirely due to incomplete geometric similarity in his comparisons. All data are based on a 6-in. square conduit. The values of C which would be used "in calculating the performance of a prototype lock manifold, with ports which should necessarily be much larger than the test ports" are the same as those obtained in small-scale model tests, but the characteristic curves would have to be based on complete geometric similarity. The culvert size and shape must not be ignored. In some cases, allowance for departures from geometric similarity could be determined by interpolation based on diagrams similar to Fig. 21.

Although Mr. Berk's conclusion regarding the value of small-scale tests must be rejected, his sincere discussion goes far toward clarifying the concept of the "port and culvert combination." Table 1 shows that Ports I to VI, inclusive, are all geometrically dissimilar. Even if the lengths of Ports I to III, inclusive, had been proportional to the heights and widths, the fact that all ports were attached to a 6-in. square conduit would prevent correspondence of the characteristic curves. Similar reasoning is applicable to Ports IV to VI, inclusive. Although interpolation in Fig. 21 between the curves for the round-cornered ports would be more difficult and less reliable than for the square-cornered ports, it would suffice for some purposes. For precise results, additional single port tests might be necessary.

The conclusions were limited specifically to the applications of single port test data. Although "definite information for solving the practical problem of designing a prototype manifold larger in size than the test models and with port shapes other than square cornered" is much to be desired, it is far beyond the scope of the paper. Mr. Berk raised the interesting question of scale effects, but this too is beyond the scope of the paper. However, there is much reason to believe, from the ever-increasing number of model-prototype comparisons, that scale effects would be very small in the present case. As explained in the paper, the allowances for conduit friction are independent of scale effect, so one important source of error in model indications has been eliminated.

Professor Powell has extended the analysis to cover momentum coefficients and angularity of velocities. It is unquestionable that a complete understanding of the mechanics of manifold hydraulics must be developed along these lines. Fortunately, design of manifolds need not await the isolation and analysis of these factors as their effects may be grouped together and determined experimentally. Table 5, prepared by Professor Powell, appears to indicate reasonable variation in angles and momentum coefficients for Port I although, as he states, determination of exact values would require "laborious experiments."

In closing, it should be emphasized that the use of characteristic curves for study of any port-and-culvert combination is simply a convenient method of reducing the number of variables. The fact that the characteristic curves may be plotted in terms of P_d and P_i is not a fortunate accident but has the same physical basis as the dimensionless representation of pressure variations in a bend. The ratios P_i and P_d establish the arrangement of stream paths and these patterns remain essentially unchanged by variations in the absolute values of the several variables if proportionality is maintained. One additional point which may merit mention is the fact that an entire lateral in a bottom-filling lock can be treated merely as a port on the longitudinal culvert. The interest shown in the paper is sincerely appreciated.

AMPLIFIED SLOPE DEFLECTION

BY RALPH W. STEWART,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. LEON BESKIN, JOHN E. GOLDBERG, CAMILLO WEISS, WILLIAM C. SPIKER, ARTHUR B. MCGEE, JAROSLAV POLIVKA, A. A. EREMIN, AND RALPH W. STEWART.

SYNOPSIS

Slope deflection, as presented in current textbooks, is encumbered by the necessity of: (*a*) Reversing the signs of certain moments in writing equations; (*b*) Studying the significance of double signs (namely, $\mp$ and $\pm$) which are set up in the standard equations; and (*c*) a set of four standard equations when two are ample.

The purpose of this paper is to eliminate these difficulties, to present a complete physical interpretation of the components of slope-deflection equations, and to show how to use these components in such a manner that, for many problems, the algebraic work required will be only one half that required by the procedure taught in current texts.

DEFINITION OF SYMBOLS AND OTHER DATA

The abbreviation FEM, as used in this paper, denotes "fixed-end moment"—the moment that would exist at an end of a beam if both ends were fixed against rotation. The location of the FEM and the identification of the span to which it pertains are indicated by a subscript. Thus, FEM_{AB} means the FEM at end A of span AB; FEM_{DC}, the FEM at end D in span CD, etc.

The abbreviation FHEM means the fixed-end moment at one end of a beam when the opposite end is hinged, subscripts being used as for FEM.

The symbol Δ is used herein to represent the angle between the end tangents of a beam due to the application of a moment at one end when the other end is hinged. The reason for the selection of this symbol is that it is in common use in treatises on railway curves (notably transition spirals)[2] to indicate the angle between the end tangents of a curve. It measures the amount of curva-

---

NOTE.—Published in September, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

ture in the elastic curve of a flexed beam due solely to the end moment to which it is related.

The symbol θ is used to represent the angular change in direction, due to flexure, of the neutral axis of a beam at a support. Angles Δ and θ are identified as to location by subscripts.

Symbol A_o is the area of the $\frac{M}{E\,I}$-diagram $\left(\text{or } \frac{M}{I}\text{-diagram}\right)$ of a span when the span is considered as simply supported—that is, free from end restraints except simple supports acting at right angles to the beam.

A traverse of the elastic curves of a structure is a series of straight lines which delineate all the θ-angles and Δ-angles, and also, when necessary or desirable, the A_o-angles.[3] The lines of a traverse which pass through supports are tangent to the elastic curve at the supports.

Four important properties of an elastic curve traverse are:

(1) Each Δ-angle and each A_o-angle is located where the center of gravity of the $\frac{M}{E\,I}$-diagram appurtenant to such angle is projected upon the neutral axis of the member.

(2) Each Δ-angle or A_o-angle is numerically equal to the area of its $\frac{M}{E\,I}$-diagram. This follows because the Δ-angle or A_o-angle and the area of the appurtenant $\frac{M}{E\,I}$-diagram each measure the curvature in the beam due to the same moment.

(3) In any triangle formed by the lines of a traverse and the unsprung axis of a beam the angles are proportional to the opposite sides. The altitude of a traverse triangle for any ordinary beam is so small that the angles may be taken as equal to either their sines or their tangents. It is usually convenient in making computations to consider the tangent of an angle as representing its magnitude.

The basic stiffness of a beam is the magnitude of the end moment necessary to produce a unit Δ-angle, or the ratio of an end moment to the Δ-angle it produces. If a Δ-angle can be evaluated from the geometry of an elastic curve traverse it is converted into an end moment by multiplying it by the basic stiffness of the member. A tapered member will have a different basic stiffness for each end.

(4) Property (3) leads to the theorem that any Δ-angle multiplied by the appurtenant beam stiffness equals the adjacent end moment, and any end moment divided by the stiffness equals the appurtenant Δ-angle.

It is probably unnecessary to state that an elastic curve traverse, if correctly used, will close geometrically the same as a land survey. It should be mentioned that with amplified slope deflection, which gives geometrical values to the components of slope-deflection equations, the deflections of a structure are easily computed as a by-product of the stress analysis.

---

[3] "Relative Flexure Factors for Analyzing Continuous Structures," by Ralph W. Stewart, *Transactions*, Am. Soc. C. E., Vol. 104 (1939), p. 521 (see also references therein for demonstrations of the use of the elastic curve traverse).

Signs.—In slope-deflection equations those moments and joint movements which produce or tend to produce clockwise rotation at the joint for which an equation is written are taken as positive; the reverse, negative. In a traverse computation which progresses along a series of angles, the angles which turn the alinement of the traverse toward the right may be taken as positive; and those turning it toward the left, negative.

DEMONSTRATION PROBLEMS

Let member AB in Fig. 1 be a beam of constant section. Its basic stiffness will be $\frac{2\,E\,I}{l}$ since this is the ratio of an end moment to the area of the $\frac{M}{E\,I}$-diagram which it produces. Figs. 1(*a*), (1*b*), and (1*c*) show, respectively, the $\frac{M}{E\,I}$-diagrams for the simply supported condition, the condition of restraint at the left end only, and the condition of restraint at the right end only, each moment acting along the full length of the beam.

FIG. 2

Fig. 1(*d*) represents a traverse of the elastic curves of this beam with both ends fixed so that the θ-angles are zero. From traverse property (3) the angle Δ_1 will be equal to

$$\Delta_1 = \left[\left(g\,l - \frac{l}{3}\right) \div \frac{l}{3}\right] A_o = (3\,g - 1)\,A_o \ldots\ldots\ldots\ldots (1)$$

From traverse property (4) multiply Eq. 1 by the stiffness of the beam $\frac{2\,E\,I}{l}$ and obtain

$$\text{FEM}_\text{A} = \frac{2\,E\,I\,A_o}{l}\,(3\,g - 1)\ldots\ldots(2)$$

Fig. 1(*e*) is the traverse with the left end of the beam fixed and the right end hinged. From traverse property (3),

$$\Delta_1 = (g\,l \div \tfrac{2}{3}\,l)\,A_o = \tfrac{3}{2}\,g\,A_o\ldots\ldots(3)$$

and from property (4) of the traverse

$$\text{FHEM}_\text{A} = \frac{3\,E\,I\,A_o\,g}{l}\ldots\ldots(4)$$

Now consider the beam as one of a series of continuous spans so that the ends are subject to restraint less than fixation and some joint rotation can occur. Also, let the right end deflect a distance *d*. The traverse will then take the form of Fig. 1(*f*), which is drawn for loading and restraint conditions such that both Δ-angles, under slope-deflection sign rules, relate to positive end moments.

From the geometry of Fig. 1(*f*) the following equations may be written:

$$\theta_A + \Delta_1 - A_o - \Delta_2 - \theta_B = 0\ldots\ldots(5a)$$

and

$$\theta_A\,l + \tfrac{2}{3}\,l\,\Delta_1 - g\,l\,A_o - \tfrac{1}{3}\,l\,\Delta_2 = d\ldots\ldots(5b)$$

Solving,

$$\Delta_1 = A_o\,(3\,g - 1) - 2\,\theta_A - \theta_B + 3\,\frac{d}{l}\ldots\ldots(6)$$

Multiplying the Δ-value in Eq. 6 by the beam stiffness and letting $K = \frac{1}{l}$ it is found that

$$M_{AB} = \text{FEM}_\text{AB} - 2\,E\,K\left(2\,\theta_A + \theta_B - 3\,\frac{d}{l}\right)\ldots\ldots(7a)$$

If the beam is hinged at end B the angle Δ_2 will become zero, the traverse showing as a straight line from A_o to the right end. Solving for this condition by a procedure similar to that used to derive Eq. 7*a* it is found that:

$$M_{AB} = \text{FHEM}_\text{AB} - 2\,E\,K\left(1.5\,\theta_A - 1.5\,\frac{d}{l}\right)\ldots\ldots(7b)$$

Note that Eqs. 7 are the conventional slope-deflection equations found in the various textbooks except that all but two[4] of the textbooks, which the writer has consulted, reverse the sign of the fixed-end moments and enter the second term as positive. This leads to considerable confusion in the practical use of the equations. It is well known to all users of the slope-deflection method that the final moment at the end of a beam for which the moments are not dominated by joint movements is less than the fixed-end moment. The form in which Eqs. 7 are written may be expressed by the following rule:

---

[4] "Statically Indeterminate Structures," by John I. Parcel and G. A. Maney, John Wiley & Sons, Inc., New York, N. Y., 2d Ed. 1936; also "Analysis of Statically Indeterminate Structures," by Clifford D. Williams, International Textbook Co., Scranton, Pa., 1943.

> "The moment at A in a beam AB is equal to the moment which would occur at A if the beam were fixed, less the relaxation in the moment due to the joint rotations, plus the moment due to the deflection of a support."

Under this rule the fixed-end moment is entered with its true sign. Note also that if the $\frac{d}{l}$-term is removed from the parentheses it will also have its true sign. This is logical as both the FEM and the deflection d create clockwise moment at end A in Fig. 1(f). The joint rotations θ reduce this moment and are therefore negative. However, amplified slope deflection will operate with either the direct or the reversed use of signs so any analyst can use his own system.

The important feature of amplified slope deflection developed by this paper is that, in any slope-deflection equation written in the form of either Eq. 7*a* or Eq. 7*b*, the expression inside the parentheses is the value of a Δ-angle in an elastic curve traverse. This is true for all special conditions such as tapering members and "semi-rigid" riveted or welded joints at intermediate points along members. The use of this property of the parenthetical expression in a slope-deflection equation offers short-cut solutions for many problems. For convenience in wording this parenthetical term will be called the "Δ-term."

A demonstration of a solution using the geometrical values of Δ-terms is presented in Fig. 2, which shows a symmetrical two-story frame subjected to a lateral force. The numerals in circles near the centers of the members show their relative stiffness values. From property (3) of the traverse the Δ-angles in the beams will be $3\,\theta_A$ and $3\,\theta_D$, as shown. (Note: In the conventional slope-deflection equation for beam AB the parenthetical term is $(2\,\theta_A + \theta_B)$. Since, due to symmetry, θ_A and θ_B are equal, this equals $3\,\theta_A$.) If a conventional slope-deflection formula like Eq. 7*a* were written for member AD, the Δ_1-term would be $2\,\theta_A + \theta_D - 3\,\frac{d}{l}$. This is inconvenient as it contains three unknown quantities. Amplified slope deflection offers a simpler value for Δ_1 containing only one unknown quantity derived as follows:

From traverse property (4)—

$$M_{AB} = 2\,(3\,\theta_A) = 6\,\theta_A \quad \text{(8a)}$$

Balancing moments about A—

$$M_{AD} = 6\,\theta_A \quad \text{(8b)}$$

and from traverse property (4)—

$$\Delta_1 = 6\,\theta_A \quad \text{(8c)}$$

In actual practice this procedure is shortened to

$$\frac{2}{1}\,(3\,\theta_A) = 6\,\theta_A \quad \text{(9)}$$

For joint D the sum of the column moments must balance the beam moment.

The bottom column moment is one half the lateral force times the column height, which is equal to 100. The beam moment is 6 θ_D. Subtracting the lower column moment from M_{DC} and observing that the relative stiffness of the upper column is 1:

$$M_{DA} = \Delta_2 = 6\,\theta_D - 100 \qquad (10)$$

Column AD carries one half the lateral force and the sum of its end moments will be equal to half the lateral force in the structure multiplied by the column height, from which

$$6\,\theta_A + 6\,\theta_D - 100 = 100 \qquad (11)$$

Next, write the equation for traverse angle closure in member AD as follows:

$$\theta_A + 6\,\theta_A - (6\,\theta_D - 100) - \theta_D = 0 \qquad (12)$$

Eqs. 11 and 12 can be solved simultaneously with a little less than half the algebraic work necessary if the conventional slope-deflection equations involving three unknown quantities were used. Solving, $\theta_A = 9.524$; $\theta_D = 23.81$; $M_A = 57.14$; and $M_{DA} = 42.86$; $M_{DC} = 142.86$.

If a pin connection is introduced at one end of a beam DC the unsymmetrical frame so formed will require six simultaneous equations for its solution by conventional slope deflection. Amplified slope deflection will reduce the number of equations to three.

If tapering members are involved the Δ-angle points will not be at the one-third length points. Their locations, and also the basic stiffnesses of the members, must be determined by a method described by the writer elsewhere[5] unless tables, which give coefficients for these beam constants, are available.

FIG. 3

Fig. 3 shows the solution of a symmetrical two-span frame[6] in which the beams are connected to the columns with semi-rigid joints; also the columns have semi-rigid connections to the foundations. This moves the Δ-points away from the one-third length points and alters the basic stiffness of each member. The beam and column properties of Fig. 3 were computed by a method demonstrated elsewhere.[7] Next, the lateral deflection of the tops of the columns was, for convenience, taken as 0.312 which is the coefficient for the distance between the column Δ-angles.

---

[5] *Transactions*, Am. Soc. C. E., Vol. 108 (1943), p. 1200.

[6] *Ibid.*, Vol. 107 (1942), p. 1029, Fig. 19(c).

All beams and column Δ-angles were then computed by the procedure used in discussing Fig. 1. Two slope-deflection equations were then written—one to express the condition of moment balance at the top of an end column and one to balance moments at the top of the center column.

The solution of these two simultaneous equations for the two unknown θ-angles enabled the moments to be evaluated and written on the frame as shown by large numerals.[7]

In conventional slope deflection the number of simultaneous equations required to solve a given problem is definite. In amplified slope deflection the number may be varied some in accordance with the analyst's judgment. In fact, all of the problems presented in this paper can be solved by using the elastic curve traverse in a manner which entirely avoids the use of simultaneous equations and does not use successive approximations.

One caution should be observed in the use of relative stiffness values. If all members have the same E-value and are of constant section the value of its $\frac{I}{l}$-ratio may be used to express the relative stiffness of each member. However, if some of the members in a structure have tapered sections and some have constant sections, it is necessary to use $\frac{2\,I}{l}$ for the stiffness factor of the constant section members. This is why Eq. 7*b* is written in the form shown with the factor 2 outside the parentheses.

CONCLUSIONS

If the slope-deflection equations are considered to be functions of only end slopes and deflections, their usefulness is substantially less than if the fact is recognized that they also are functions of Δ-angles which measure the changes in direction of the elastic curve within the beam. By recognizing and using all the angle components in slope-deflection equations, the computation labor required to use them is reduced by half for certain problems. Simplification of sign rules and a change in form and reduction in the number of standard equations also facilitate the work.

DISCUSSION

Leon Beskin,[8] Assoc. M. Am. Soc. C. E.—In so far as this paper lacks a definite sign convention, it tends to obscure, rather than to clarify, the analysis of rigid frames. For example, the writer has been unable to interpret the sign convention the author has chosen for moments.

In Fig. 2, it seems that at node A, the condition of equilibrium, by Eqs. 8*a* and 8*b*, is

$$M_{AB} = M_{AD} \qquad (13a)$$

whereas, at node D, by Eq. 10,

$$M_{DO} + M_{DA} = M_{DC} \qquad (13b)$$

In Eq. 13*b*, the subscript DO refers to the lower left-hand column of Fig. 2.

A widely adopted sign convention requires that positive moments rotate all nodes in the same direction, with the consequence that the sum of all moments at a node is zero. This is not satisfied by Eqs. 13. In the theory of continuous beams, moments at the two sides of a node are equal. In that case, Eqs. 13 should be written

$$M_{AD} = \pm M_{AB} \qquad (14a)$$

and

$$M_{DO} - M_{DA} = \pm M_{DC} \qquad (14b)$$

the sign in the right-hand quantity being plus or minus depending on whether the member is vertical or horizontal, respectively. Eqs. 13 do not satisfy this second sign convention.

The foregoing remarks apply also to Fig. 3. One may assume that the author's sign convention is: Along columns, positive moments tend to rotate nodes clockwise; and, along beams, positive moments tend to rotate nodes counterclockwise. This convention is consistent with the conditions shown in Figs. 2 and 3, but inconsistent with Fig. 1, in which FEM_A is shown clockwise. Also, on this basis, Eq. 7*a* is inconsistent with Eq. 8*a*.

The comments in the text following Eq. 7*b* are also erroneous:

> "It is well known to all users of the slope-deflection method that the final moment at the end of a beam for which the moments are not dominated by joint movements is less than the fixed-end moment."

The final moment can be greater or smaller than the fixed-end moment, as demonstrated by a continuous beam on three supports for which the moment at the center support has an intermediate value between the fixed-end moments calculated for each span independently—it is greater than one moment, smaller than the other.

The rule following the foregoing quotation is not clear, as its wording seems to apply to absolute values, although the succeeding sentence expresses a contrary opinion. Moreover, the moment due to the deflection may have any sign, independent of the fixed-end moments.

The end-moment formula (Eq. 7*a*), when applied to the end B, can be written either

$$M_{BA} = \mathrm{FEM}_{BA} + 2\,E\,K\left(2\,\theta_B + \theta_A - 3\,\frac{d}{l}\right) \qquad (15a)$$

---

[8] Structures Engr., Consolidated Vultee Aircraft Corp., San Diego, Calif.

or

$$M_{BA} = \mathrm{FEM}_{\mathrm{BA}} - 2\,E\,K\left(2\,\theta_B + \theta_A - 3\,\frac{d}{l}\right) \dots\dots\dots (15b)$$

It has been demonstrated that a minus sign should appear in the expression of M_{BA} which means that Eq. 15*b* must be used. Eqs. 8*b* and 10 tend to confirm this interpretation, although their signs are generally inconsistent with those in Eqs. 7*a* and 15*b*.

The claim for simplicity resulting from the use of the amplified slope deflections is not established, as shown by the following comparison, referring to Fig. 2: Applying Eq. 7*a* to ends A and D of member AD,

$$M_{AD} - M_{DA} = -(\theta_A - \theta_D) \dots\dots\dots (16)$$

Similarly, applying Eq. 7*a* to members AB and CD, and expressing the node equilibriums,

$$-M_{AB} = 2\,(3\,\theta_A) = 6\,\theta_A = M_{AD} \dots\dots\dots (17a)$$

and

$$-M_{DC} - 100 = 6\,\theta_D - 100 = M_{DA} \dots\dots\dots (17b)$$

Adding Eqs. 17*a* and 17*b*, and noting from equilibrium considerations that the total moment in member AD is equal to 100, the resulting equation is identical with Eq. 11. By equating Eqs. 17*a* and 17*b* and substituting the difference in Eq. 16, Eq. 11 becomes identical with Eq. 12. The only difference as compared with the author's calculation is that the foregoing has taken care of sign conventions—namely, all moments that tend to rotate nodes counterclockwise are positive.

Because he eliminates moments, the author asserts that he uses two unknowns. Actually, there are five unknowns, the three additional unknown moments being eliminated rapidly. It is possible to present the calculation with one apparent unknown M_{DA}. Thus, by equilibrium conditions and by deformation considerations:

$$-\frac{\theta_A}{6} = M_{AB} = -M_{AD} = -100 + M_{DA} \dots\dots\dots (18a)$$

and

$$-\frac{\theta_D}{6} = M_{DC} = -M_{DA} - 100 \dots\dots\dots (18b)$$

Substituting in Eq. 16 all quantities expressed as functions of M_{DA}, $100 - M_{DA} - M_{DA} + \frac{100 - M_{DA}}{6} - \frac{M_{DA} + 100}{6} = 0$; and $\frac{14}{6}\,M_{DA} = 100$. This development is even more rapid than that proposed by the author. The author's claim that fewer equations are used and half of the number of operations are necessary, as compared with conventional methods, is doubtful. In the case of the unsymmetrical framework, with a hinge at point D, a straightforward method applying strain energy requires the use of only three unknowns—the shear in the vertical member OD, the shear in member CD, and the axial load in member CD.

Of minor importance are the unjustifiable introduction of the symbol Δ from a technique that bears no remote relation to stress analysis,[2] and the author's adoption of the inaccurate term "tapered beams" to describe "unsymmetrical beams with variable moments of inertia."

In conclusion, it seems to the writer that slope-deflection methods do not require clarification. The author's effort to clarify them is imperfect to the extent that his lack of a precise sign convention has introduced unnecessary confusion.

JOHN E. GOLDBERG,[9] ASSOC. M. AM. SOC. C. E.—An amplification of the slope-deflection method is presented in this concise and excellent paper. The fundamental geometry of slope deflection is combined with the author's concept of the traverse angle as applied to members under flexure. The writer is gratified to perceive that, as this and other interesting papers indicate, the value of slope deflection as a powerful method of analysis is steadily becoming more appreciated.

Several of Mr. Stewart's statements deserve critical consideration. One of these is the sentence (see heading, "Demonstration Problems"): "In conventional slope deflection the number of simultaneous equations required to solve a given problem is definite." This standardization is a distinct advantage of the slope-deflection method from which both the experienced and the inexperienced engineer will benefit since any engineer can see at once the proper direct slope-deflection approach to a given problem. On the other hand, the slope-deflection method is so extremely flexible that it allows much leeway, when desired, in the solution of special problems.

Consider, for example, the problem of Fig. 1. Some years ago the writer developed an extremely simple analysis for problems of this type.[10,11] This method has the advantages of being readily applicable to any number of stories and of being extremely rapid since the basic equations converge very quickly even in extreme cases. Applying the method to Mr. Stewart's first problem, two equations would be set up immediately:

$$\theta_A\,(6 \times 2 + 1) = 0.5\,(20 \times 10) + \theta_D \ldots\ldots\ldots\ldots (19a)$$

and

$$\theta_D\,(6 \times 2 + 1) = 0.5\,(20 \times 10) + 0.5\,(20 \times 20) + \theta_A \ldots\ldots (19b)$$

The solution of Eqs. 19 ($\theta_A = 9.524$ and $\theta_D = 23.81$) agrees exactly with the author's solution. Thus, the method is shown to be simple and direct. Of course, this is merely proof of the fact that the most useful method generally is the one with which the engineer is most familiar.

Mr. Stewart goes on to mention the same frame with the lower girder pinned at one end and states that six simultaneous equations are required by the conventional slope-deflection method. This is absolutely true; but, when these equations are set up (and setting them up is in itself very simple), three of the equations may be eliminated in a very direct manner. Note also that a conventional strain-energy analysis can be made in terms of three redundants.

Mr. Stewart's point concerning sign conventions (see heading, "Definitions of Symbols and Other Data: Signs," and text following Eqs. 7) is well taken. In his original presentation[12] of slope deflection, G. A. Maney, M. Am. Soc. C. E., advanced the sign convention which the author advocates. In subsequent work,[13,14,15,16] both Professor Maney and the writer continued to use that convention, finding it simple and convenient.

[10] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 922.

[11] *Ibid.*, Vol. 110 (1945), p. 1512.

[12] *Engineering Studies No. 1*, by G. A. Maney, Univ. of Minnesota, Minneapolis, 1915.

The author's statement, discussing Eqs. 7, that "* * * the final moment at the end of a beam for which the moments are not dominated by joint movements is less than the fixed-end moment" is likely to be misinterpreted by the reader. The statement would be clarified greatly if the author had written that "the moment is less, algebraically, than the fixed-end moment."

Camillo Weiss,[17] M. Am. Soc. C. E.—The four "properties of an elastic curve traverse" presented in this paper are principles derived in part from "moment areas" and are important enough to be compared with the well-known principles of the moment-area method.

The concept of the Δ-angle is helpful in visualizing the effect of variations in cross sections or end restraints. The author is justified in stating that in many cases the number of simultaneous equations may be reduced by recognizing the significance of the Δ-angles.

The method would seem to deserve a more descriptive designation than "amplified slope deflection." Although related to slope deflection, the unknowns of the author's method consist exclusively of slopes and the method is based on its own distinctive principles.

The author should be commended for his clear and able presentation of these principles and for his skilful derivation and interesting interpretation of the slope-deflection equations.

William C. Spiker,[18] M. Am. Soc. C. E.—The "traverse" method described in this paper is creative and clever. However, because, as acknowledged, it is limited in application and because, in the writer's opinion, it requires more than the average amount of practice and facility for successful use, it should be simplified and amplified, if possible. Then, too, the writer believes that the questions of signs and "unknowns" in the basic slope-deflection method are not as serious as Mr. Stewart states. It is to be remembered, furthermore, that there are other, more simple methods.

As an illustration, the slope-deflection method can be applied to the case in Fig. 2, with perhaps a slight variation from standard routine. The writer prefers the following sign convention: In the setup equations all θ's have plus signs. The signs for the fixed-end moments refer to the moments which resist the fixed-end moments. They are plus when the resisting moments tend to turn the end of the member to the right and minus when the resisting moments tend to turn the end of the member to the left.

The detailed solution is as follows:

[17] Designer, Bethlehem Steel Co., Fabricated Steel Constr., Eng. Dept., Bethlehem, Pa.

[18] Cons. Engr., Mountain View, Ga.

Moment	Computation	Computed moment
M_{AB}	$12\,\theta\,A$	$+\ 57.18$
M_{AD}	$4\,\theta\,A + 2\,\theta\,D - 6\,R$	$-\ 57.15$
....	$16\,\theta\,A = +\,6\,R - 2\,\theta\,D$	....

Adding and transposing,

....	$\theta\,A = +\,0.375\,R - 0.125\,\theta\,D$	....
M_{DA}	$4\,\theta\,D + 2\,\theta\,A\ (= 0.75\,R - 0.25\,\theta\,D) - 6\,R$	$-\ 42.86$
M_{DC}	$12\,\theta\,D$	$+\ 142.8 \pm$
M_{DE}	$3\,\theta\,D - 3\,x\,R$	$-\ 100.00$
....	$18.75\,\theta\,D = +\,5.25\,R + 3\,x\,R$	....
....	$\theta\,D = +\,0.28\,R + 0.16\,x\,R$	$-\ 11.91$
....	$\theta\,A = +\,0.375\,R - (0.035\,R + 0.02\,x\,R)$	
	$= +\,0.34\,R - 0.02\,x\,R$	$-\ 4.765$

Therefore:

M_{AD}	$-\ 4.08\,R + 0.24\,x\,R$	....
M_{DA}	$-\ 4.20\,R + 0.60\,x\,R$	....
....	$-\ 8.28\,R + 0.84\,x\,R$	$-\ 100.00$
M_{DE}	$+\ 0.84\,R - 2.52\,x\,R$	$-\ 100.00$
....	$-\ 9.12\,R + 3.36\,x\,R$	0.00

Therefore, $x = 2.715$; $R = +\ 16.67$; and $x\,R = 45.23$. Then substitute into the basic equations the values of R, $x\,R$, $\theta\,A$, and $\theta\,D$ and add the moments opposite the equations as shown.

Note that, if the sway in both tiers is the same, the problem is as simple as that for two spans on three supports. The x disappears.

ARTHUR B. MCGEE,[19] ESQ.—Amplified slope deflection is in reality the traverse method[3] extended to include the displacement of joints, or sidesway. In a normal traverse solution, joint movement is restricted to rotation only. In general, the traverse of a member consists of three sides of known lengths and four angles—namely, a θ-angle at each end and two intermediate Δ-angles. If there is no joint displacement, any two angles are sufficient to determine the remaining two angles; but, if there is displacement of a joint, three angles are required to determine the fourth one. In the latter case, simultaneous equations are usually required.

Mr. Stewart has shown the relationship between the traverse method and slope deflection. The number of essential unknowns in a given rigid frame is the same regardless of the method used for analysis. However, if a method disposes of any of the unknowns in an easy manner and reduces the number of simultaneous equations necessary for the solution of a problem, it merits consideration.

Fig. 4(a) shows an unsymmetrical frame with members of uniform moments of inertia. The writer's method of procedure assumes a traverse of the deflected frame (Fig. 4(d)). Errors in the direction of deflection angles (Δ-angles) or in the direction of rotation of joints (θ-angles) will not affect the solution. The traverse must be drawn, however, to provide opposing moments at each joint. The assumed traverse is solved and values are found for the Δ-angles. If any angle proves to be negative, the angle was merely assumed in the wrong direction and the numerical value is still correct.

FIG. 4

In Fig. 4(*d*), subscripts have been placed on the θ-angles and Δ-angles in the order of evaluating the angles for ease in following the solution. The Δ-angles are at the third points of the members. The angles of rotation of joint A and joint B are assumed to be θ_1 and θ_2, respectively. By geometry, $\Delta_3 = 2\,\theta_1 + \theta_2$ and $\Delta_4 = 2\,\theta_2 + \theta_1$. Since member AD is half as stiff as member AB, $\Delta_5 = 2\,\Delta_3 = 4\,\theta_1 + 2\,\theta_2$. Likewise, $\Delta_6 = 2\,\Delta_4 = 4\,\theta_2 + 2\,\theta_1$. By assumption, $\Delta_7 = 1$. Then, from joint B to joint C, $\theta_2 + \Delta_6 - \Delta_7 - \theta_8 = 0$; hence, $\theta_8 = 5\,\theta_2 + 2\,\theta_1 - 1$. Since $M_{CB} = M_{CF}$, $\Delta_9 = \Delta_7 = 1$. From joint C to support F, $\theta_8 - \Delta_9 - \Delta_{10} = 0$; therefore, $\Delta_{10} = 5\,\theta_2 + 2\,\theta_1 - 2$. The deflection in member AD must equal the deflection in member BC; so $3\,\theta_1 + 2\,\Delta_5 - \Delta_{11} = 3\,\theta_2 + 2\,\Delta_6 - \Delta_7$, and solving, $\Delta_{11} = 7\,\theta_1 - 7\,\theta_2 + 1$. From joint A to joint D, $\theta_1 + \Delta_5 - \Delta_{11} - \theta_{12} = 0$; and, therefore, $\theta_{12} = -2\,\theta_1 + 9\,\theta_2 - 1$. In the member DC, $\Delta_{13} = \frac{3}{2}\,\theta_{12}$; hence, $\Delta_{13} = -3\,\theta_1 + 13.5\,\theta_2 - 1.5$. The deflection in member DE must equal the deflection in member CF; so $2\,\theta_{12} + \Delta_{14} = 2\,\theta_8 - \Delta_9$ and $\Delta_{14} = -8\,\theta_2 + 8\,\theta_1 - 1$. From joint D to support E, $\theta_{12} + \Delta_{14} - \Delta_{15} = 0$ or $\Delta_{15} = 6\,\theta_1 + \theta_2 - 2$. About joint D, $\Sigma M = 0$; therefore, $\Delta_{14} + \Delta_{11} = 2\Delta_{13}$; and, substituting the values of the Δ-angles in terms of θ_1 and θ_2:

$$7\,\theta_1 - 14\,\theta_2 + 1 = 0 \ldots\ldots\ldots\ldots\ldots\ldots (20a)$$

The shear in the second story equals the shear in the first story; therefore,

$$\frac{\Delta_5 + \Delta_{11} + \Delta_6 + \Delta_7}{10} = \frac{\Delta_{14} + \Delta_{15} - \Delta_9 + \Delta_{10}}{10}$$ or, in terms of θ_1 and θ_2:

$$-3\,\theta_1 + \theta_2 + 8 = 0 \ldots\ldots\ldots\ldots\ldots\ldots (20b)$$

Eqs. 20 are solved simultaneously, and they yield $\theta_1 = \frac{113}{35}$ and $\theta_2 = \frac{59}{35}$.

Substituting these values in the Δ-angles of Fig. 4(*d*) and changing the angles to moments by the relationship $M = K\,\Delta$ give the results shown in Fig. 4(*b*). The shear in each story is $\frac{148}{35}$ which is the applied load producing the moments. Multiplying all the quantities shown in Fig. 4(*b*) by $20 \times \frac{35}{148}$ gives Fig. 4(*c*), which is the solution of the problem. Thus, this problem required two simultaneous equations.

It should be mentioned that, after drawing a logical traverse of the deflected structure, the analyst has numerous choices in starting the evaluation of angles. Some methods are easier than others but no set procedure has to be followed, and, as long as the assumed traverse is solved, the signs will take care of themselves automatically. If the members had had variable moments of inertia, both the stiffnesses and locations of the Δ-angles would have been different, but the procedure would have been the same.

JAROSLAV POLIVKA,[20] M. AM. SOC. C. E.—There are many interesting features in the author's method of simplifying slope deflection by using characteristic properties of a traverse of the elastic curve. Elastic deformation can be visualized more clearly, and automatic procedures can be reduced to a minimum. However, the author's claim that the method reduces by one half the work of computation required by the slope-deflection method, if applied generally, cannot be upheld. The author's procedure is limited to a few problems, such as the one demonstrated in Fig. 2, which was selected to show the usefulness of the method in a case where a symmetrical two-story frame, subjected to a lateral force, has pin connections with the bases.

It is true that, in the usual slope-deflection method, the joint expressions include terms of the unknown deflections; yet it is not difficult to reduce the simultaneous equations to a general form containing only deflection angles and load constants, as has been shown by A. Amirikian,[21] M. Am. Soc. C. E. This reduction is accomplished by substituting deflection values in terms of the deflection angles and the load constants (obtained from the shear equation of each story) for deflections in the joint expressions.

---

[20] Lecturer E. D., Univ. of California, Cons. Engr., Berkeley, Calif.

Applying this principle to the author's example in Fig. 2 and referring to Mr. Amirikian's work, the following equations can be written: For joint A:

$$\left(2 + 1 - \frac{3}{4} \times \frac{1}{2} + 1 - \frac{3}{4 \times 2}\right)\frac{A}{2} + \left(\frac{1}{2} - \frac{2 \times 3}{4 \times 2}\right)\frac{D}{2} = \frac{20 \times 10}{2 \times 2};$$

or

$$13\,A - D = 200 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (21a)$$

Similarly, for joint D, the following equation results:

$$13\,D - A = 600 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (21b)$$

Since, in accordance with Mr. Amirikian's procedure, $A = 4\,\theta_A$ and $D = 4\,\theta_D$, Eqs. 21 become, respectively,

$$13\,\theta'_A - \theta'_D = 50 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (22a)$$

and

$$13\,\theta'_D - \theta'_A = 150 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (22b)$$

Eqs. 22 contain two unknowns and the solution is just as simple as that obtained by the author's method using the properties of the traverse of the elastic curve. The solution is $\theta'_A = \frac{100}{21}$ and $\theta'_D = \frac{250}{21}$, assuming the relative stiffness $K' = \frac{E\,I}{l}$, or, introducing the basic stiffness used in the paper, $K = \frac{2\,E\,I}{l}$ $\left(\text{ratio of an end moment to the area of the } \frac{M}{E\,I}\text{-diagram which it produces}\right)$, $\theta_A = \frac{200}{21}$, and $\theta_D = \frac{500}{21}$. The moments in the horizontal members are computed from the basic equations; thus: $M_{AB} = 2\left(\frac{3}{2}A\right) = 12\,\theta'_A = \frac{400}{7}$; and $M_{DC} = 2\left(\frac{3}{2}D\right) = 12\,\theta'_D = \frac{1{,}000}{7}$. From the shear equation for the symmetrical bent: $M_{AD} + M_{DA} = 100$; and $M_{DA} = \frac{300}{7}$. Finally, from the joint equation at point D: $M_{DA} = M_{DC} - 100 = \frac{300}{7}$.

A. A. Eremin,[22] Assoc. M. Am. Soc. C. E.—An important advantage of the amplified slope-deflection method is that the moments in the members are computed in conjunction with the sketching of the axes of the sloped members, and the moments can be checked simply by inspection. In his illustrative example, Mr. Stewart treats members with constant sections. By application of the simple formulas, the method may be extended to the members with variable sections. In a member AB with variable section, the distances p and q

---

[21] "Analysis of Rigid Frames (An Application of Slope Deflection)," by A. Amirikian, Government Printing Office, Washington, D. C., 1942, p. 88.

[22] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

to the centroids of $\frac{M_{AB}}{E\,I}$ and $\frac{M_{BA}}{E\,I}$ from ends A and B, respectively, are

$$p = c_1\,l \qquad (23a)$$

and

$$q = c_2\,l \qquad (23b)$$

The stiffness factors of beam AB are

$$K_{AB} = \frac{K}{1.5\,e_1} \qquad (24a)$$

and

$$K_{BA} = \frac{K}{1.5\,e_2} \qquad (24b)$$

in which $K = \frac{I}{l}$. The values of the coefficients c and e in Eqs. 23 and 24 may be computed by the moment-area method or may be obtained from diagrams such as those presented elsewhere by the writer.[23]

The sign convention for the algebraic distribution of moments in continuous frames is often a serious source of error. As stated by the author, the interpretation of signs is simplified considerably by sketching the slopes of the axes. However, considerable skill is required. The interpretation of signs can be simplified further by distributing moments graphically. The moment closing line, constructed graphically by "crosslines,"[24] is shown in Fig. 5. Results are automatic and the signs cannot be misinterpreted. The resulting bending-moment diagram may be used directly for the design of the members.

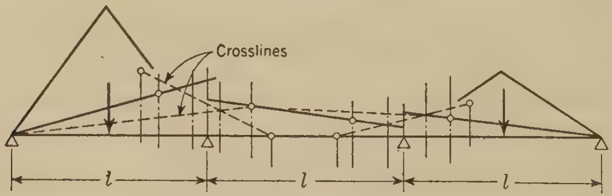

FIG. 5.—GRAPHICAL DISTRIBUTION OF MOMENTS

In the realm of fine arts, the artist's message is broadcast through various mediums—oil, water color, stone, or marble. The artist selects the medium that best agrees with his temperament. Likewise, in the applied art of adapting the science of mechanics to the determination of stresses, various algebraic and graphic procedures of distributing moments are available. All methods based on the elastic theory are equally exact for practical purposes. Mr. Stewart is to be commended highly for his valuable contribution to moment-distribution methods. With the addition of the new concept of the railroad traverse line, the stress analyst has a wider range of choice in selecting a method to satisfy his personal requirements.

---

[23] "Analysis of Continuous Frames by Graphical Distribution of Moments," by A. A. Eremin, Sacramento, Calif., 1943.

[24] *Transactions*, Am. Soc. C. E., Vol. 110 (1945), p. 1543.

Ralph W. Stewart,[25] M. Am. Soc. C. E.—A number of questions about the paper have been raised by Mr. Beskin. His statement concerning the text following Eq. 7*b* has merit. The sentence he quotes should have an additional phrase as is indicated within the brackets:

> "It is well known to all users of the slope-deflection method that the final moment at the end of a beam for which the moments are not dominated by joint movements [or by the flexure of an adjoining span] is less than the fixed-end moment."

The other discussers apparently did not have Mr. Beskin's difficulties in applying signs. The paper states that any analyst can use his own system of signs and still take advantage of the interpretation of angle values—the basic idea of amplified slope deflection. Also, the statements regarding signs in the third and the last paragraphs of Mr. McGee's discussion should be noted.

The method followed by Mr. Beskin in Eqs. 16 and 17*a* involves the algebraic procedure of referring to Eq. 7*a* and transforming it by suitable substitutions. The writer's aim is to avoid such algebraic procedures. The solution of Fig. 2 with one apparent unknown, as developed by Eqs. 18*a*, 18*b*, and a subsequent unnumbered equation, also involves what the writer considers algebraic work of an undesirable type—namely, substituting in Eq. 16 which, in turn, is obtained from Eq. 7*a*. Direct use of the elastic curve traverse offers a solution with one apparent unknown which avoids reference to previously established equations. The elastic curve traverse also reduces the problem to a simple reading of visible geometrical alinement and the direct application of basic mechanical laws. This fact is demonstrated by Fig. 6, in which the values of the Δ-angles are written on each side of joint A in terms of M_A. Each value will be M_A divided by the member stiffness. By geometry, θ_A will be one third of the beam angle Δ. Since the sum of the column moments must be 100 for shear equilibrium, the value of Δ_2 is $100 - M_A$. By simple angle summation from A downward: $\theta_D = -100 + \frac{13\,M_A}{6}$. By geometry the lower beam angle Δ is 3 θ_b as shown in Fig. 6. The lower column moment is known to be 100 since the horizontal footing reaction is 10 and the column height is 10. The equation for equilibrium of moments about joint D is written:

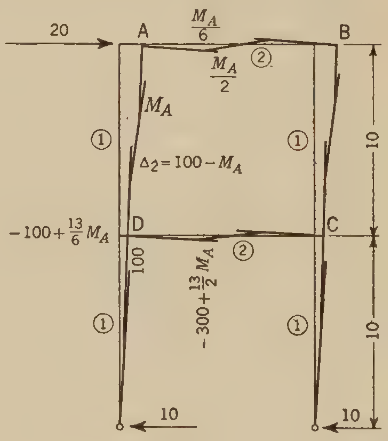

Fig. 6

$$100 + 100 - M_A - 2\left(-300 + \frac{13\,M_A}{2}\right) = 0 \quad \ldots\ldots\ldots\ldots (25)$$

---

[25] Bridge Engr., City of Los Angeles, Los Angeles, Calif.

from which $M_A = 57.14$. Eq. 25 is shorter than the one following Eq. 18*b*; and, as the computation progresses, the physical significance of each term is shown by recording it in Fig. 6. Mr. Spiker has shown another, but longer, solution for Fig. 6.

As minor points, Mr. Beskin criticizes the use of the symbol Δ for angular change due to bending, as well as the use of the term "tapered beams." The term "tapered beams" has an excellent precedent.[26] The symbol Δ was selected because, in a number of treatises, it represents the angle between the tangents to a curve, and it seemed appropriate to extend its use to traverse diagrams which are solved largely as problems in geometrical alinement.

The writer is grateful to Messrs. Goldberg and Weiss for their comments. As Mr. Weiss suggests, the moment-area constants are the basis of the elastic curve traverse. If they are delineated as a traverse, the flexure of the structure can be visualized and the deformations due to flexure become easier to use than when pictured as areas. Such delineation also gives an opportunity to diversify and extend the use of moment-area constants. The object of the paper was to take advantage of this opportunity.

Mr. Polivka commented that "* * * the author's claim that the method reduces by one half the work of computation * * * if applied generally, cannot be upheld." The writer's claim was worded as follows: "* * * for many problems, the algebraic work required will be only one half that required by the procedure taught in current texts." It may be added that slope deflection, as amplified by the elastic curve traverse, will never, for any problem, involve more algebraic work than slope deflection as taught in current college textbooks.

The detailed equation given by Mr. Polivka, which he consolidates into Eq. 21*a*, represents either derivation of a formula by an algebraic procedure involving simultaneous equations as described by A. Amirikian,[21] M. Am. Soc. C. E., or handbook work which the writer wishes to avoid.

An important point which should not be overlooked is that the formulas derived by Mr. Amirikian are for frames composed only of members with constant cross sections. The introduction of tapering members would make no important changes in solutions which use the elastic curve traverse but it would have a serious effect on Mr. Amirikian's algebraic use of slope deflection.

The excellent and constructive work of Mr. McGee in presenting the complete detail of the solution for an unsymmetrical two-story frame with fixed-base columns is helpful. Following this step-by-step solution should clarify most of the situations which can arise in the general use of the method. As shown by Fig. 4(*c*), this problem involves eight unknown moments. The number of geometrical unknowns is six, comprising four joint rotations and two-story deflections. Only two unknowns (θ_1 and θ_2) appear in Fig. 4(*d*), the others having been eliminated in an easy manner so that only two simultaneous equations are needed for the solution.

Mr. Eremin offers suggestions regarding the extension of the method to structures having members of variable section. It is for such structures and also for such complicated conditions as "semirigid" joints that the use of an elastic curve traverse best shows its advantage.[7]

STORAGE AND THE UNIT HYDROGRAPH

By C. O. Clark,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. James S. Sweet, Otto H. Meyer, L. K. Sherman, Gordon R. Williams, Ray K. Linsley, Jr., E. F. Brater, L. C. Crawford, Robert E. Kennedy, Victor H. Cochrane, Franklin F. Snyder, Howard M. Turner, Don Johnstone, and C. O. Clark.

Synopsis

During the period since 1930, study of the flow records of many and various types of streams by the engineers of the United States has resulted in an improved concept and understanding of the physical factors which influence runoff and the flood-producing capacity of streams. Two fundamental tools have emerged from these studies, the unit hydrograph and methods of flood routing (means of modifying a hydrograph by the effects of valley storage), both of which have been the subject of many papers.

The purpose of this paper is to clarify the inherent relationship between these fundamental tools and to show how this relationship may be used to derive accurate unit hydrographs for very short periods of initial runoff which accurately reflect the influence of shape of drainage area upon the shape of the hydrograph, allow the segregation of elements of the hydrograph attributable to particular components of the drainage area, and permit the definition of the calculation procedure to a degree which reduces the dependence of accurate stream flow calculations on intangible factors of personal judgment.

After showing that the constant time units characteristic of unit hydrographs are the characteristics induced by storage capacity of the streams and that storage capacity and discharge capacity are each a limiting factor on the other, the paper illustrates the incorporation of these characteristics in hydrograph calculations.

Definitions

Throughout this paper, the terms "unit hydrograph" and "unitgraph" are used interchangeably to mean a regimen of stream flow for a unit quantity of uniformly distributed runoff originating at a uniform rate during a specified

---

Note.—Published in November, 1943, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Hydr. Engr., U. S. Engr. Office, Winchester, Va.

unit period of time. The time elements of the regimen are independent of the quantity of runoff and the discharge quantities are directly proportional to the quantity of runoff. Included are both the unit hydrograph of L. K. Sherman,[2] M. Am. Soc. C. E., and the distribution graph of Merrill Bernard,[3] M. Am. Soc. C. E. The terms "storage" and "valley storage" are applied to the entire volume of water stored between any two designated points along a river and include both the volume in the channel and on the flood plain. The same terms, expressed in time units, are used to designate the average ratio of storage volume to discharge capacity of the river reach.

The following definition of accuracy will apply to the writer's use of the term in subsequent paragraphs, and at the same time will illustrate some of the problems and aims of incorporating accuracy in stream flow calculations:

> An engineer should learn early to distinguish between the forms of accuracy which sometimes are called absolute, real, and relative. Absolute accuracy is the mathematical precision of correctly manipulated numbers, as used by engineers in computing payments to the cent from earthwork surveys by cross sections or soundings. Real accuracy is an evaluation of the closeness with which a measurement or computation approximates the truth, a quality inherent in the meaning of the engineering term "precision." Relative accuracy is an evaluation of the closeness with which a measurement or computation approximates another measurement or computation, preferably where both determinations are comparable, and frequently is expressed as a ratio or the difference between them, without necessarily giving an absolute value of either. The elevation of one bench mark with respect to another is a value that may have great relative accuracy without any absolute accuracy. The terms with which others designate these qualities of accuracy may differ, but the essential difference between them is acknowledged widely.

In the fields of evaluation and planning of river developments, relative accuracy is attainable at low cost, usually by thoroughly planned systematic analysis; and it is sufficient in the selection of the better of alternative plans. Real accuracy, as in the evaluation of the selected plan of construction, high-order surveys, or field observation and measurement of natural phenomena, such as river stage and discharge, is an elusive value pursued at great cost, with each additional fraction of attainment sometimes costing more than all prior to it. Absolute accuracy in most engineering offices is the product of a calculating machine, useful as a tool in attainment of relative accuracy regarding influences of small variables, but a source of colossal waste of time if confused with real or relative accuracy. One cannot start with an hypothesis having a real accuracy of 80% and develop therefrom conclusions of 95% real accuracy.

By any unmodified references to accuracy which may be made in the body of the paper which follows, the writer means only relative accuracy and the degree to which a computational determination by simplified procedure approximates the result of more laborious, accepted means of computation. No claims of unusual real accuracy are intended.

Investigators entering the field of flood flow analysis will do well to maintain an open mind on the subject of real accuracy, since the difficulties of field observation and measurement under severe flood conditions make it necessary to concede the possibility of errors as large as 20% (or more) in some items of published data. Such possibilities are indicated in many published records by the discussion preceding the tabulations, and in others by subsequent revisions when more reliable data are obtained.

[2] "Stream Flow from Rainfall by the Unit Hydrograph Method," by Leroy K. Sherman, *Engineering News-Record*, Vol. 108, 1932, pp. 501–505.

[3] "An Approach to Determinate Stream Flow," by Merrill Bernard, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 347.

The attainment of a high order of relative accuracy in computation is expedited by concise, precise definition of procedure and the desired result. As an aid to the more rapid attainment of relative accuracy in the computation of flood hydrographs, the paper seeks to define the determination of the unit hydrograph of surface and subsurface runoff in terms of two, large, basic factors —the shape of the watershed from which runoff must come and the storage through which it must come.

The writer does not claim that the determinations will exceed in real accuracy the many excellent ones which have been obtained by trial and error, tried, tested, modified, and retried until they reproduce, well, the hydrographs of record. He does believe that the first determination of the unit hydrographs will prove satisfactory for use without modification in more cases than those determined by any of several other methods with which he is familiar.

INTRODUCTION

Rapid advances in the understanding of floodtime stream flow date from the Report of the Committee on Floods of the Boston Society of Civil Engineers in which it was recognized that, for storms of equal duration, the period of flood runoff was a constant not dependent upon the total volume of runoff and that the maximum rate of discharge was, therefore, a direct function of the total runoff. "For an instantaneous storm, the peak flow will vary directly with the maximum width of the drainage area, all other conditions remaining the same * * * unit peak flows will vary directly with the velocity of flow, all other conditions remaining the same" and "pondage tends to reduce the peak flow in the direct ratio that the volume of pondage bears to the total flood run-off." In these conclusions[4] lie the bases for many current concepts of the unit hydrograph, time-area concentration curves, and valley storage modification of flood flow.

A refinement of theory by Mr. Sherman[2] confirms the conclusion that the flood period is a constant and that the peak flow is proportional to the total volume of runoff, and extends the theory to show that, for a given unit quantity of runoff, uniform over the drainage area, originating in a small unit interval of time, the length of the hydrograph is a constant; that all ordinates will be proportional to the total runoff; and that, by the application of this so-called "unit hydrograph" to successive short periods of uniform runoff throughout the flood-producing storm period, the resulting hydrograph of stream flow could be reproduced with reasonable accuracy. This theory combines sufficient verification in many watersheds with convenience of use to a degree which has made it acceptable to many in the engineering profession and deserving of the status of an original contribution to fundamental hydrologic theory.

---

[4] Report of the Committee on Floods of the Boston Society of Civil Engineers, *Journal*, Boston Soc. of Civ. Engrs., September, 1930.

By the limitation of its definition, as pointed out by Mr. Sherman, the unit hydrograph is correct and applicable only to areas from which the runoff for a given period of time is uniform and therefore to drainage areas for which the rainfall is essentially uniform over the entire basin. The extension of the theory to the areas of such size that this condition is not strictly true is a matter of practical expediency, but one which introduces fundamental discrepancies between theory and fact which are not a fault of the theory but of its application. In its original conception and application, the unit period was taken as one day, and the agreement of computed and observed discharges within that period of time was considered to be confirmation of the theory. The accuracy of the determination of the unit hydrograph was limited by the practical requirement of finding an isolated flood hydrograph resulting from a uniform unit rainfall. This latter requirement, while not a serious limitation on the use of the method for periods of one day, provides an almost insurmountable obstacle to the derivation of the unitgraph for very small drainage areas and very short unit periods of time.

A number of writers[5,6] have shown that the theory is equally applicable to very small drainage areas when the unit period used is sufficiently short to be in proper proportion to the total hydrograph.

In determinations of unit hydrographs for short periods of time, practical difficulties of finding uniform, short-period rainfall, which produced large enough stream flow to be analyzed accurately, make it necessary to determine unitgraphs from multiple periods of runoff. However, such a procedure is indeterminate, as there are always more equations than unknowns and a multiple of possible solutions.[7] For example, in determining a seven-period unitgraph from a flood resulting from three periods of runoff, it is possible to determine thirty-six unit hydrographs which, applied to the three items of runoff, will reproduce the composite hydrograph exactly. The approximate solutions are even more numerous. Consequently, the range of possible solutions by independent investigators is too large—far greater than the range of inaccuracy of stream discharge records. Most methods, graphical and mathematical, of selection of the most probable of these unitgraphs underestimate the capacity of a stream to reach a high instantaneous peak from short, intense rainfall and ignore tendencies toward double peaks which some streams exhibit following intense, short-period rainfall.

The range of possible unitgraph determinations can be reduced by correlating recognized discharge concepts with the physical limitations of valley storage and with the time elements which necessarily result from storage and discharge relations. The correlation can be utilized to develop, from time-area concentration curves of specific drainage areas, unit hydrographs with a small

range of determination variability, independent of assumptions regarding run-off distribution in the flood-producing storm and reflecting influences of drainage area shape and stream pattern. The streams of Virginia and North Carolina, with a wide range of basin shapes, stream slopes, and patterns, present admirable opportunities to prove or disprove some of the theories advanced.

In some respects, the degree of proof or disproof is limited by the quality of records and the means of their interpretation. Although recording stream gages have been installed on many of the streams, few of them are rated to a discharge more than one half of the maximum stage of automatic record. For the very flashy streams it is almost impossible for measuring parties to reach the streams before they have fallen well below peak stage. The greatest limitations on the check of accuracy of the theories, however, are the lack of recording rainfall gages and contour maps. Because of rainfall data limitations, determinations of the time of precipitation without a possible error of 3 to 6 hours were seldom possible. If the reproduced hydrographs agreed with the observed within these limits of time, the theories were regarded as confirmed. In all but a few cases, the agreement was much closer than the allowable error.

The constant time elements which have been indicated as essential to the theory of the unit hydrograph are dictated by valley storage relationships. For that reason, some of the vital elements of valley storage concepts are reviewed.

VALLEY STORAGE

One of the principal characteristics of the passage of a flood wave down an open channel is the time elapsing between passage at one point and at some downstream point—frequently referred to as the time of travel. The concept of this time of travel as a function of the velocity of the water and therefore influenced by the slope of the river, channel friction, and other items which influence the velocity of flow in the river, is deeply rooted in the hydrology of streams. However, time of travel is more closely related to the variable storage capacity of the open channel; dimensionally, time is the ratio of storage to discharge. Flow in pipes is influenced by all the elements of slope, friction factor, etc., which influence velocity of water in an open channel; but there is no time of travel in a closed pipe, which is full at the beginning of the passage of the wave, where an increase in the velocity and discharge at the upstream end is accompanied almost simultaneously by an increase in velocity and a duplication of the waves at the exit end of the pipe. Time of travel is almost nonexistent in rigid pipes, such as cast iron and concrete, and becomes increasingly apparent in pipes which are elastic enough to have some variable capacity for storage, such as rubber hose and the arteries of the human body.

Most methods of taking account of the storage in a river valley involve the solution, either graphically or mathematically, of the storage equation:

$$\frac{I_1 + I_2}{2} t - \frac{O_1 + O_2}{2} t = S_2 - S_1 \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which I is the total inflow rate and O the outflow rate, both in cubic feet per second; S is the total volume in storage in the reach in (cubic feet per second)-hours (12 (cu ft per sec)-hr = 1 acre-ft); and the subscripts 1 and 2 refer to the beginning and the end of the period respectively.[8] This is the arithmetic expression of the storage equation. The calculus equation for the same condition is:

$$dS = (I - O)\,dt \qquad (2a)$$

or

$$\frac{dS}{dt} = I - O \qquad (2b)$$

which is merely a mathematical way of saying that the rate of change of storage is equal to the difference between the inflow and the outflow rates. In Eqs. 2, t is the length of a period of time, in hours.

In general, the quantity of water stored in a short open channel increases with an increase in the flow in the channel, or:

$$S = C\,Q^n \qquad (3)$$

in which Q is the flow in the channel, n is a positive exponent, and C is a constant for the particular channel. Thus the storage in a river is a function of the flow and varies directly with some power of it.

In a short reach of river it may make little difference whether storage is considered as a function of inflow discharge or outflow discharge since there is little difference between them. In long reaches of the length considered practical for flood routing studies or of the length over which appreciable backwater effects may extend in floodtime, there is a great difference.

Methods of accounting for the influence of storage on discharge originally were used in analyzing flood reduction effects of reservoirs, where storage was a function of outflow. The accounting of storage between successive level pool surfaces whose elevation was controlled at the dam was a satisfactory approximation of the total storage. The amount of storage above the slack-water pool level and under the backwater curve was ignored as truly of small consequence.

The backwater storage, however small, existed because of the concurrent existence of inflow to the reservoir. Reduction of the inflow rate necessarily would be accompanied by a decrease in storage and an increase of outflow rate. Rapid inflow shutdown necessarily would be accompanied by a release of the backwater storage and a consequent increase in the slack-water storage or in the outflow discharge or in both. The released volume of water would be free to roll, as a pressure wave, to the lower end of the reservoir. Others have compared the movement to the rotation of saturated soil in a landslide. In either case, the lower end of the reservoir would have to rise slightly and the outflow discharge would have to increase.

The extension of concepts of storage modification to sloping channels and natural streams extended the practise of correlating storage with outflow. In some river reaches, the correlation with inflow is as close as the correlation with outflow. Some current concepts of the action of valley storage in reducing flood peak discharge are faulty because they are in terms of the original, limited theory. The storage which may be treated as a function of outflow reduces flood peak outflow discharge, but the portion which is a function of inflow increases outflow, so that the net decrease or increase of peak discharge depends on which storage portion is the greater.

---

[8] "Flood Routing," by Edward J. Rutter, Quinton B. Graves, and Franklin F. Snyder, *Transactions*, Am. Soc. C. E., Vol. 104 (1939), p. 278.

The idea that there is some valley storage which does not decrease flood peaks is rather new. The nature of the actions is illustrated in Fig. 1, which shows water-surface profiles for a uniform, rectangular channel 500 ft wide, 20 ft deep, and with a fall of 10 ft in its length of 10,000 ft. Line b shows the profile for steady flow of 116,000 cu ft per sec throughout the channel length. Assume that the steady flow into the channel at the upper end is reduced quickly as by the closure of gates on a reservoir or the crevassing of a levee. With discharge reduced at the upper end of the reach and maintained at the lower end by storage release, the distribution of discharge in the reach would be similar to line c to which profile d would apply. The change from profile b to profile d involves the release from storage of 260 acre-ft during the period of inflow reduction and requires the outflow discharge to increase to accommodate such a release. However, as the outflow increases, the discharge distribution in the channel approaches profile e and the water-surface profile approaches that indicated by line f. Storage under profile f is the same as under profile b.

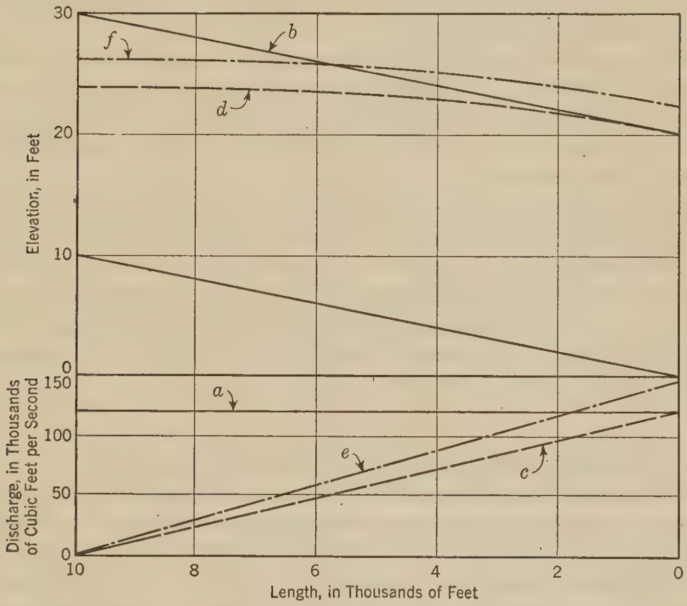

Fig. 1.—Effect of Decreasing Inflow on Flood Profile

A shift of water-surface profile from lines b to f takes place in a natural channel by mass rotation transmitted by means of pressure waves of small amplitude which surge back and forth through the reach, ceasing when the stable profile for the new discharge distribution has been attained. In natural channels under normal flow conditions, the reductions of inflow rates are gradual with the greater changes of discharge distribution occurring near peak stage. The surge of small amplitude transition waves is clearly apparent as a broad trace in many autographic records of stage. Following discharge change, the profile transition takes place in a very short time. The writer has a record of a natural flow reduction, caused by the crevassing of a large levee, in which the effect of the break in transforming the water-surface profile was transmitted 17 miles in as many minutes, whereas a normal flood wave transit of the same distance requires about 15 hours.

In the example of Fig. 1, if the water-surface elevation at the lower end is held constant by opening the gates of a dam, a material increase of outflow rate would be required. To prevent any increase in outflow discharge, a rise of about 3 ft would be required to store the initial volume as it shifted to the lower end of the reservoir.

In an unregulated reservoir of large capacity compared with the inflow to it, the storage may be solely a function of the outflow. In a long and uniform channel, the storage may be almost equally a function of the inflow and the outflow. All during the early stage of rapid increase in discharge in dry channels, such as occurs naturally in the arroyos of the Southwest, the storage is solely a function of the inflow. Thus, Q in Eq. 3 is to be considered as a weighted average value of the inflow and the outflow:

$$Q = x\,I + (1 - x)\,O \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

in which x is a coefficient with a value between 0.0 and 1.0.

According to Eq. 3, storage tends to increase with some power of the stream flow. There seems to be no theoretical reason why the power could not be either greater or less than unity. If it were less than unity, the peaks of large floods would occur earlier than those of small floods; if the power were greater than unity, the reverse would be true. If the power is unity, storage and discharge are in constant direct proportion, and time elements are constant regardless of flood magnitude.

Storage in a river channel does not necessarily increase directly with the discharge, but studies of the variation in a large number of streams indicate that this is the case for most smaller streams and is a condition closely approximated over large ranges of discharge in many large streams. That is, the exponent is 1.0 for small streams, and for many rivers of as much as 10,000 sq miles of drainage area it is less than 1.3. Even for the latter streams, over a large range the true storage may be closely approximated by storage directly proportional to discharge.

Storage which is directly proportional to discharge does not interfere with the accuracy of the unit hydrograph theory, as its characteristically constant time elements are compatible with, and necessary to, the similarly constant time elements of the unit hydrograph. Wherever the unitgraph theory is applicable, or wherever the time elements of flood passage are essentially constant, the storage is proportional to discharge.

There are a great many mathematical and graphical solutions for the storage equations, both for conditions where the storage is considered to vary directly with the discharge and where it is considered to vary directly with some exponential power of the discharge. All but a few of these solutions are for the special case in which the storage is a function of the outflow only and, therefore, are applicable only to routing floods through a very large reservoir. Use of these special solutions for natural channels, or for small reservoirs in which backwater storage is appreciable, leads to undesirable optimism regarding reductions of discharge by storage use.

The scope of this paper is limited to the general conditions in which the storage is considered to vary directly as the discharge, but where the discharge is a weighted value of the inflow and the outflow. Mathematically, these statements resolve to the three equations previously given:

$$dS = (I - O)\,dt \quad \text{(2a)}$$

$$Q = x\,I + (1 - x)\,O \quad \text{(4)}$$

$$S = K\,Q \quad \text{(5)}$$

from which it is evident that:

$$K = \frac{dS}{dQ} = \frac{(I - O)\,dt}{x\,dI + (1 - x)\,dO} \quad \text{(6a)}$$

and

$$O = I - K\,x\,\frac{dI}{dt} - K\,(1 - x)\,\frac{dO}{dt} \quad \text{(6b)}$$

Eq. 6*b* can be solved arithmetically for successive short periods of time, T in length, by designating the flows at the beginning of the short period as O_1 and I_1 and those at the end by O_2 and I_2, thus:

$$\frac{O_1 + O_2}{2} = \frac{I_1 + I_2}{2} - K\,x\,\frac{I_2 - I_1}{T} - K\,(1 - x)\,\frac{O_2 - O_1}{T} \quad \text{(6c)}$$

from which the following simple equation evolves:

$$O_2 = C_0\,I_2 + C_1\,I_1 + C_2\,O_1 \quad \text{(6d)}$$

In Eqs. 6:

$$C_0 = -\frac{K\,x - 0.5\,T}{K - K\,x + 0.5\,T} \quad \text{(7a)}$$

$$C_1 = +\frac{K\,x + 0.5\,T}{K - K\,x + 0.5\,T} \quad \text{(7b)}$$

$$C_2 = \frac{K - K\,x - 0.5\,T}{K - K\,x + 0.5\,T} \quad \text{(7c)}$$

and

$$C_0 + C_1 + C_2 = 1.00 \quad \text{(7d)}$$

This is the Muskingum method of flood routing developed by T. S. Burns and F. B. Harkness, Members, Am. Soc. C. E., and G. T. McCarthy,[7] Assoc. M. Am. Soc. C. E.

To illustrate the action of linear storage upon wave forms, two mathematical curves have been routed through various quantities of storage by the Muskingum method. Fig. 2 illustrates the modification of a cosine-type curve by storage represented by a value of K of four time units, with various values of x from 0.0 to 1.0. For this well-rounded initial wave form, the fundamental effect of the storage modification is to translate the entire wave approximately four time units, and to change the magnitude of the peak. The change of magnitude seems to be more a function of the value of x than of K, because when $x = 0.5$, the modified wave appears to be a close duplication of the initial wave, except for the parts of the curve before initial outflow and after final inflow.

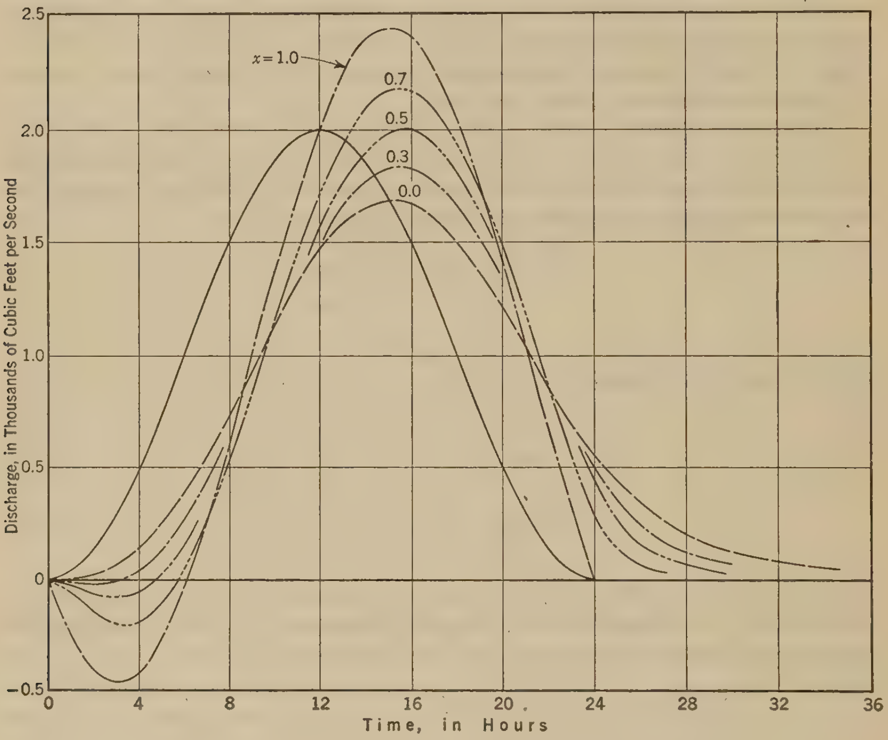

FIG. 2.—MODIFICATION OF COSINE TYPE OF WAVE BY STORAGE

It may be desirable to explain the unorthodox appearance of the modified wave forms (Fig. 2) between the initial inflow and initial outflow. The indicated negative values are partly erroneous and partly correct. A slight error arises in the theory assumption that the average discharge in the reach of river is indicated by a weighted value of the discharge at the ends and, therefore, that the storage prism between successive positions of the rising water surface may be approximated by two wedges of storage extending the length of the reach, one a function of inflow and the other a function of outflow. Considering the real bulbous shape of an advancing wave front in a near-dry channel, the true storage in the reach is less than the full-length wedge during the first part of the initial inflow. During this period, the actual outflow discharge is more than computed. At the instant the wave front reaches the lower end, the actual storage in the reach is somewhat more than that of a full-length wedge. At this time and for a short time after, the actual discharge at the lower end of the reach is less than indicated by the theory and the actual rise is later than that calculated. The inequalities between the theory and fact of wedge storage approximation are ironed out by the time the rates of flow increase at both ends are equal. Since the discharge at the lower end is closely indicated at this time, the true rise at the downstream end is more rapid than computed. The maximum total storage volume in the reach, represented by the area between the inflow and outflow hydrographs, is the same at this time for actual and computed modifications.

In the case of a wave passing into a partly full channel, into which flow is also coming from local streams, much less of the indicated negative discharge is to be regarded as error. The negative values indicate the capacity of the advancing wave not only to store its own waters, but to force the storage of the incoming local flows through the induced backwater effect. Only when the algebraic sum of all components of flow (including the negative values of the routed inflow wave) is less than the flow prior to the flood can the sum be discounted as error. Even then, the appearance of large negative values is an indication of a period of hydraulic instability which in extreme cases results in the formation of a hydraulic bore.

The negative values play an important part in the accuracy of the general storage theory and are to be discounted judiciously. The writer follows the practise of retaining the computed negative values, discounting them only in the drawing of the final hydrograph.

Fig. 3(a) shows the effect of storage that is equally a function of inflow and outflow; that is, $x = 0.5$ on a wave form with an initially very sharp peak. The first wave has been routed through 2 hours of storage in each of five successive reaches. In this case as in the case of the cosine curve, the translation effected by storage is approximately equal to the value of K; but some reduction of peak discharge is effected. However, the reductive influence of the storage decreases as the initial wave approximates the stable, well-rounded form.

The actual progressive modification by storage which is almost equally a function of inflow and outflow rates, illustrated in Fig. 3(a), has about the same effect as the bodily transposition of the initial wave form combined with a final modification of the transposed wave by a small amount of reservoir storage. The difference between the progressive calculation of storage effect, which is probably closer to truth, and the more easily computed transposition and single storage modification calculation is illustrated in Fig. 3(b), in which the wave form (a) has been progressively modified by passage through five reaches, each having 2 hours of storage (2 (cu ft per sec)-hr per cu ft per sec of discharge) to become wave form (b). The approximation wave form (c) was derived by bodily transposition of wave form (a) by 9 hours and routing it through reser-

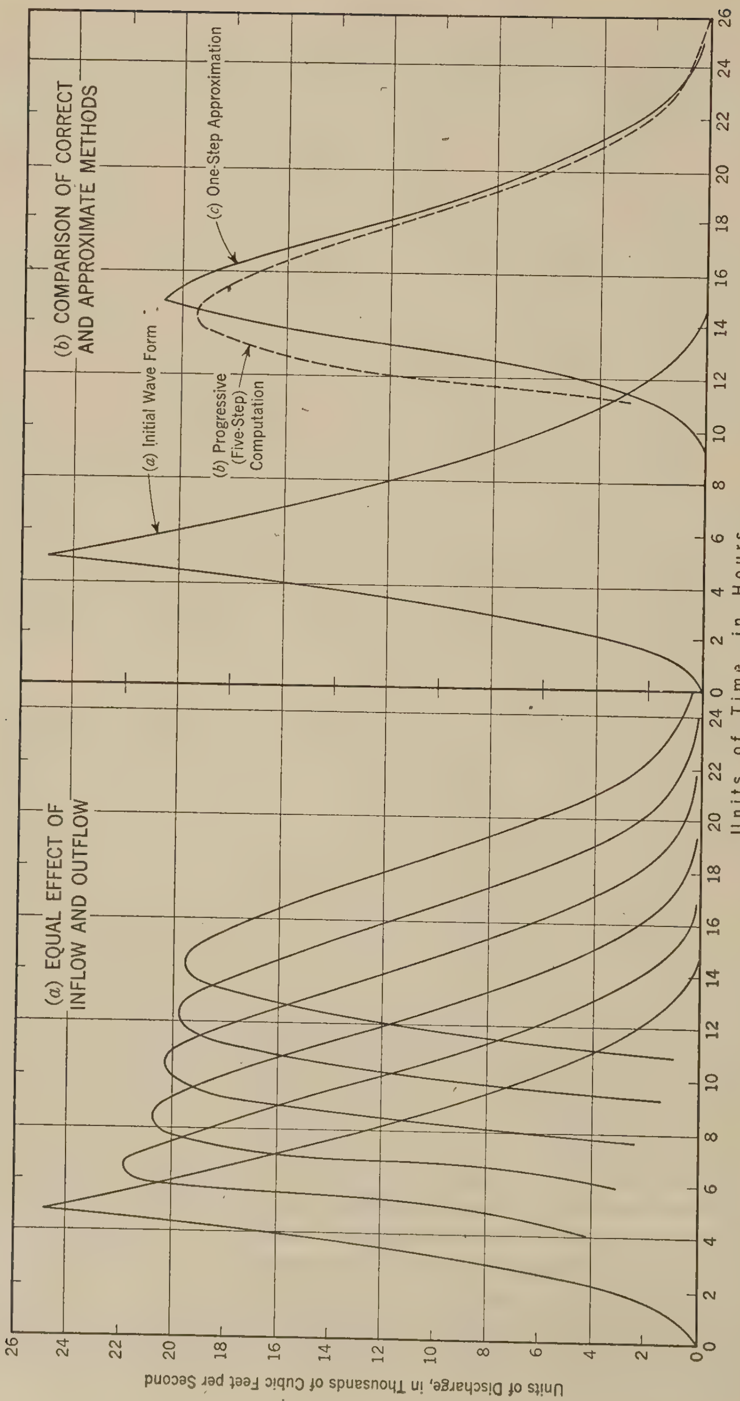

FIG. 3.—MODIFICATION OF A SHARP-CRESTED WAVE BY STORAGE

voir-type storage ($x = 0.0$) of 1 hour. The agreement between curves (b) and (c), far from perfect, is within the degree of accuracy usually attainable in runoff calculations.

This approximate form of storage calculation is used subsequently in the derivation of unit hydrographs; a time-area concentration curve of the drainage area (a composite of all of the transposed, unmodified wave elements of the watershed) is modified by a small amount of storage to form the basic unit-graph. The procedure will be explained in detail.

For many natural streams, the value of x, in Eq. 4, varies from 0.4 to 0.5, but the presence of a large flood plain carrying little flow near the lower end of a reach will cause the storage to be more of a function of outflow than inflow, and will reduce the relative influence of inflow, x, to 0.3 or lower. The back-water effect of a large incoming tributary may act in a similar manner. Conversely, if the large storage is near the upper end of the reach, the value of x may exceed 0.5 and result in an increase of crest discharge rather than the usually assumed decrease (the hydrographs in Fig. 12, introduced subsequently, indicate such an influence).

An understanding of the mechanical process of flow of water through a reach of river or a reservoir in light of the Muskingum routing theory will provide a clearer concept of what can and cannot be accomplished by valley storage. It also will show that, contrary to popular concept:

(*a*) Valley storage does not always decrease flood peaks; and

(*b*) The reservoir pool above a dam may not reduce flood discharges. In fact, if the pool level at the dam is held constant by gate control, the storage becomes the function of inflow solely, and the peak outflow may be larger than the peak inflow. Furthermore, such control, by reducing the effective storage, may decrease the time of travel through the reservoir to almost nothing, with a beneficial or detrimental effect as the case may be.

SIGNIFICANT STORAGE RELATIONSHIPS

The fundamental storage equation for storage which varies directly with a weighted average of the inflow and the outflow is (see Eq. 5*b*):

$$O + (1 - x)\,K\,\frac{dO}{dt} = I - K\,x\,\frac{dI}{dt} \qquad (8)$$

Although the Muskingum equations are easier to use in routing procedure, a knowledge of the following relationships which exist at certain points in the hydrographs of inflow and outflow is of great value in determining the quality and quantity of the storage effect in the reach. The symbols, $\frac{dI}{dt}$ and $\frac{dO}{dt}$, are used to represent the slope of the inflow and outflow hydrographs. When the slope of inflow and outflow hydrographs is equal:

$$\frac{dI}{dt} = \frac{dO}{dt} \qquad (9a)$$

and

$$I - O = K\,\frac{dO}{dt} \qquad (9b)$$

When inflow and outflow are equal:

$$I = O \quad \text{(10}a\text{)}$$

and

$$\frac{dO}{dt} = -K \frac{x}{1-x}\frac{dI}{dt} \quad \text{(10}b\text{)}$$

At peak inflow:

$$O = I - K \frac{dO}{dt}(1-x) \quad \text{(11}a\text{)}$$

At peak outflow:

$$O = I - K x \frac{dI}{dt} \quad \text{(11}b\text{)}$$

When inflow has ceased:

$$O = -\frac{K\,dO}{dt}(1-x) \quad \text{(12}a\text{)}$$

and

$$K = -\frac{O}{\frac{dO}{dt}(1-x)} \quad \text{(12}b\text{)}$$

Volume of runoff remaining in storage is

$$K\,O = -\frac{O^2}{\frac{dO}{dt}(1-x)} \quad \text{(13)}$$

Valley Storage and the Unit Hydrograph

A few years ago, the unit hydrograph was thought to be inapplicable to streams having a great amount of valley storage. However, when valley storage is defined as "all of the volume displaced by water during the passage of a flood wave, including the volume in the river channel," it is evident that no flood wave is unaffected by valley storage.

From a different point of view, the nature of the effect is clear. The essential difference between nonsteady flow in open channels and in pipes is in the time that elapses in the former only between the change of inflow rate and the change of outflow rate. The essential difference between an open channel and a pipe is the variable capacity of the former for storage as compared with the constant capacity of the latter. The time element and the storage capacity are related, for the ratio of storage capacity to discharge capacity is time; that is, $\frac{S}{Q} = T$.

The unit hydrograph theory assumes that the ordinates of any flood hydrograph originating from uniform runoff in the unit period of time will be directly proportional to the quantity of runoff, but that the abscissas, or time elements, will be constant and, therefore, unaffected by magnitude of discharge. Since the time elements are a function of the ratio of storage to discharge but not of discharge alone, it follows that the ratio of storage to discharge must be a constant throughout the entire range of discharge to which the unit hydrograph is to be applied. In other words, the storage-discharge curve for all reaches of river above the point to which the unit hydrograph is to be used must be straight lines when plotted on rectangular coordinate graph paper. This is the simplest of the storage discharge relationships for which methods of solution have been devised—the basis of the Muskingum method outlined by Mr. McCarthy.[9] An understanding of the manner in which it is possible for this type of storage to modify a flood wave will provide an understanding of several significant relationships which must exist in any actual unit hydrograph if the theory is applicable to the drainage area being studied.

THE HYDROGRAPH AS AN INDEX OF STORAGE

Any flood hydrograph is the resultant of all of the factors that have created it. Although no exact determination of the effect of any factor is possible without the segregation of the results of other influences, it is possible to determine the effect between certain limits. The accuracy of the determination will depend on the degree to which other influences can be segregated or discounted as insignificant.

The analysis of the hydrograph, as an index of previous storage effect, is based on the hypothesis that, after inflow to the channel has ceased, all water which will eventually become runoff, but which has not yet passed the gage, is in storage (axiomatic), and that such storage varies directly with the discharge (approximate, approaching truth in very small impervious watersheds). After such a time, the ratio of rate of change of discharge to total discharge reaches its greatest negative value, and remains constant thereafter:

$$\frac{\frac{dO}{dt}}{O} = -\frac{1}{K(1-x)} \qquad (14)$$

If all storage in a stream above a gage has been equally a function of inflow and outflow (that is, if $x = 0.5$), the greatest ratio of decrease of discharge to total discharge will correspond closely to a K-value of the time elapsing since the cessation of inflow. For the same amount of total storage, entirely a function of outflow, the ratio would have only half as large a magnitude, indicating a lesser slope of the depletion curve.

The falling legs of a large number of hydrographs of flood discharge for streams in major drainage basins from New Hampshire to North Carolina exhibit a ratio of decrease of discharge to total discharge which, for a value $x = 0.5$, indicates a value of K closely approximating the time elapsing between termination of runoff producing rainfall and the point of most rapid relative decrease in discharge. The fact that the hydrographs fall so rapidly is highly indicative that the storage affecting the hydrographs is of the balanced variety, and, therefore, chiefly effective in the translation of waves.

The writer has indicated that the effect of such storage may be approximated by (*a*) the bodily transposition of the runoff wave element from its source to the gage, and (*b*) the routing of the element through some amount of storage less than the total with a value of $x = 0$. The summation of all of the transposed elements for an entire drainage area is the same as a time-area concentration curve whose base length is the time between cessation of runoff and the time of most rapid relative decrease in discharge. The value of K selected for the routing of the time-area concentration curve is one corresponding to the ratio of discharge decrease to total discharge for an observed hydrograph (Eq. 12*b* with $x = 0.0$).

---

[9] "The Unit Hydrograph and Flood Routing," by Gerald T. McCarthy, unpublished manuscript presented at the Conference of the North Atlantic Div., Corps of Engrs., U. S. Army, New London, Conn., June 24, 1938; printed by the U. S. Engr. Office, Providence, R. I.

The application of this method to a theoretical drainage area of rectangular shape with uniform instantaneous rainfall over the entire drainage basin is shown in Fig. 4(*a*). If the rainfall were to remain constant for a unit period of time, as is predicated in the theory of unit hydrographs, the flow concentration curve which was the time-area diagram (curve (a), Fig. 4(*a*)) is modified to become the time-flow diagram (curve (a), Fig. 4(*b*)) which, routed through the same storage, becomes curve (b), Fig. 4(*b*). The advantage of an instantaneous hydrograph is that it can be derived from the fundamental characteristics of the basin and then used with any length of unit period to determine the unit hydrograph, in which any ordinate of discharge is the average ordinate of the instantaneous hydrograph for the unit time period previous to time desired. Where the curvature of the instantaneous hydrograph is not excessive, the ordinate can be determined by averaging ordinates of that graph separated by the unit time period desired.

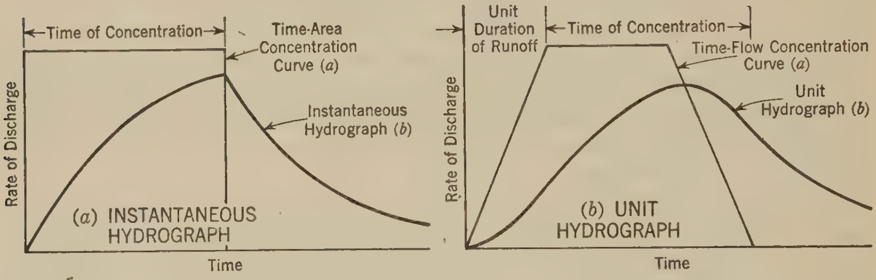

Fig. 4.—Hydrographs for a Rectangular Drainage Area

Determination of the Instantaneous Hydrograph from Stream Flow Records

Where adequate planimetric maps of a stream are provided in which recorder rainfall and discharge records are available, the elements to be determined are the base length of the time-area concentration curve, or the time of concentration, the time-area curve, and the magnitude of the unbalanced storage effect or the amount of valley storage (solely a function of discharge) by which the time-area curve is to be modified.

Referring to Eq. 12*b*, it will be seen that, when the inflow to the storage reach has ceased, the ratio of decrease of discharge to total discharge is a constant; or, as the Muskingum flood routing equation expresses it, the outflow at the end of any period of time bears a constant ratio, C_2, to the outflow at the beginning of the period of time.

Plotting the value of K which is indicated by the rate of decrease of discharge throughout the falling hydrograph, the indicated value should decrease to a minimum at the time that inflow ceased and remain constant thereafter. The time between cessation of runoff-producing rainfall and the minimum indicated value of K is the writer's concept of time of concentration and is so used in the remainder of this paper.

Taking the time of concentration derived in this manner as the time base length, a time-area concentration curve for the drainage area above the gage is prepared. This curve is used as the inflow to the river channel and is routed through an amount of storage represented by the indicated minimum K-value and an x-value of zero.

EXTENSION OF STORAGE THEORY TO GROUND-WATER FLOW

In practise, the indicated value of K does not remain constant after reaching its minimum value. The inflow from ground water continues and does not decrease as rapidly as the storage-controlled surface runoff. Therefore, it becomes an increasingly larger percentage of the total discharge and increases the indicated value of K.

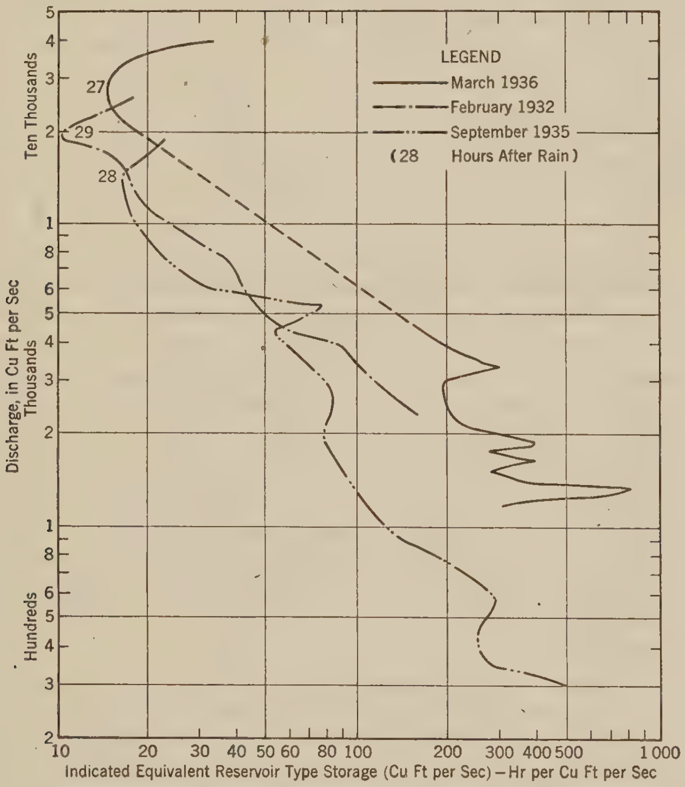

FIG. 5.—DETERMINATION OF EFFECTIVE STORAGE FROM RECESSIONAL HYDROGRAPH; JAMES RIVER AT LICK RUN

Actual curves of the indicated value of K are plotted in Fig. 5 against the discharge rate for the major part of the falling leg of several hydrographs at a stream gaging station at Lick Run, Va., on the James River (drainage area = 1,369 sq miles). The indicated value of K decreases to a certain minimum value which is essentially constant for all hydrographs and then increases from that point as the discharge decreases, becoming very large as the discharge becomes very small.

Application of this theory of runoff would imply a definition of surface runoff as being that quantity of total runoff which, after the cessation of inflow, is discharged in direct proportion to the amount of flow remaining to run off. Ground-water flow would include all other flow.

Since ground water is detained by storage also, it would be convenient for hydrologists if that storage were found to be in direct proportion to the rate of discharge. In analyzing the discharge hydrograph of any stream, it is rare to find one which, after reaching an abnormally high peak, continues to fall without further rainfall until it has reached an abnormally low flow. However, this was the case following the flood of September, 1935, on the James River. In that hydrograph, the discharge at Lick Run increased from 271 cu ft per sec to 19,400 cu ft per sec and then fell steadily to 258 cu ft per sec, the lowest discharge of the year. During the falling period, the rainfall was so small and scattered that it is doubtful if it contributed in any way to the stream flow. The indicated K-curve for this hydrograph is among those shown in Fig. 5.

After studying a large number of hydrographs extending into periods of low flow, both for this station and for several other stations in the James River basin, an approximate value of K of 200 hours was selected as an average representation of the ground-water storage effect in that watershed. For this station and for three others of good record, five hydrographs for each station were separated into the two volumes which could be represented by the channel storage modification outlined and the subsurface (ground-water) flow released from storage of 200 hours. No hydrographs were found in which the subsurface part was less than 30% of the total runoff, and there were no major flood hydrographs in which it exceeded 42%. Using a value of K of 200 hours and of $x = 0.0$, another unitgraph for subsurface flow was derived. Combination of 70% of the surface unitgraph and 30% of the subsurface unitgraph provided an excellent practical unitgraph for this drainage area, which included both surface and subsurface flow.

Thus in the derivation of a unitgraph for instantaneous origin of runoff, by the method proposed by the writer, a unitgraph of surface runoff, derived by routing the time-area concentration curve through an amount of unbalanced storage as outlined herein, is combined with a unitgraph of subsurface runoff determined by routing the same histogram through an appropriate amount of subsurface storage. What the ratio of these components will be in the final hydrograph will depend on the pertinent fact of how much of the water comes from surface runoff and how much from subsurface runoff in the particular watershed. For the streams analyzed along the eastern Appalachian slope, a 70 : 30 ratio seemed quite satisfactory. (If the additional work is justified, separate unitgraphs of surface and subsurface runoff may be utilized. With such use, no assumption of a fixed ratio is necessary.)

Although such a division is arbitrary, it is not as unsatisfactory as the current practise of attributing to ground-water discharge all flow beneath a straight line drawn from a point before the rise to an arbitrary and undefinable point on the descending hydrograph. The volume of flow so neglected frequently contains more than 20% of the total runoff. Any determination of runoff from subsequent storms, to be used in a unitgraph so derived, must be made in the light of such a derivation, with the result that, in times of great floods, the runoff percentage used for the flood-producing precipitation may be less than the average percentage runoff for the month corrected for prior and subsequent ground water.

Derivation of the Instantaneous and Unit Hydrographs

For the purpose of illustrating the method of derivation of unitgraphs, the Appomattox River at Petersburg, Va., was selected. There are several reasons why the drainage basin is not a good location for the application of the unitgraph principle; but, because of its peculiar shape, it is particularly adapted to the illustration of the benefits inherent in the method of unitgraph derivation proposed. Because it was not used in any way in the derivation of any of the data or principles on which this method is predicated and because the writer

had done no work on this stream previous to the present calculation, this basin was used. The calculations in Table 1 show the first computations made and neither the original data, the first interpretations of these data, the calculations, nor the plotting, have been changed or altered in any way to make the computed hydrograph agree more closely with the observed hydrograph. (Only a slight change in estimated time distribution of runoff is necessary to improve the agreement.) This stream has a flatter slope and a longer time of concentration than any other stream of comparable drainage area in its immediate vicinity and therefore is adapted to illustrating some of the faults as well as the good points of the application. Fig. 6 shows the drainage area of the Appomattox River above Petersburg and the manner in which it was divided to provide the data for the time-area concentration curve; Fig. 7 is the profile of the river above the gaging station as taken from the best available U. S. Geological Survey topographic sheets; and Fig. 8, curve (a), shows, in bar diagram form, the time-area concentration curve converted to flow for 1 in. of runoff; and curves (b) and (c) show the time-area curve after routing through 9 hours and 200 hours, respectively, of storage. A combination of 70% of curve (b) and 30% of curve (c) is the instantaneous hydrograph, curve (d), for the Appomattox River at Petersburg. Fig. 9 shows the application of the 12-hr unitgraph derived from the instantaneous hydrograph to the flood of April, 1937. This is the second largest flood for which there is any available record at Petersburg and one of the largest floods that has occurred in the past 100 years. (The largest flood, August, 1940, caused by protracted rainfall, did not exhibit a double peak but is equally well reproduced with the same unitgraph.)

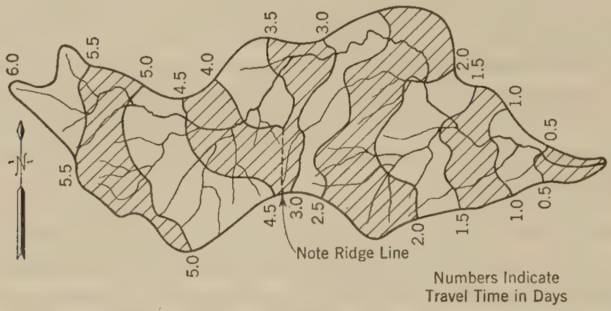

Fig. 6.—Drainage Area of the Appomattox River above Petersburg

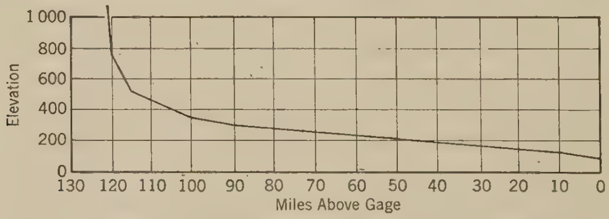

Fig. 7.—Profile of the Appomattox River above Petersburg

The following statements of fact must be taken into consideration in judging the degree of accuracy with which the computed record follows the observed record:

1. The area is too large for the proper application of a single unitgraph (drainage area, 1,335 sq miles). Because of the direction of the stream in comparison with the general east and west travel of storm fronts in this vicinity and because of the long time of concentration, a difference in rainfall both in the quantity and in time on the east part and west part of the drainage area may be considerable as it was in this case. Much better results could be obtained by using separate unitgraphs at the same gaging point for the upper and the lower drainage areas.

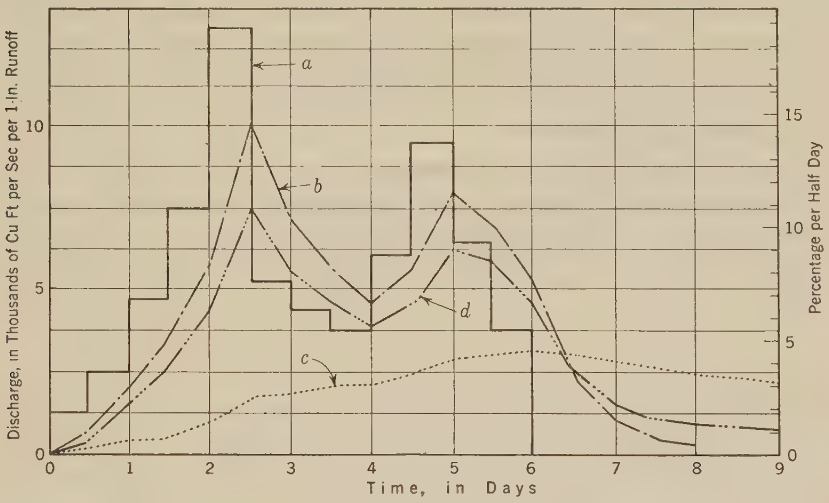

FIG. 8.—TIME-AREA CONCENTRATION CURVE, APPOMATTOX RIVER

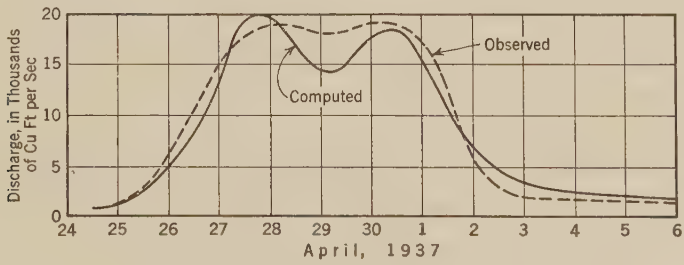

FIG. 9.—APPLICATION OF THE 12-HR UNITGRAPH, DERIVED FROM THE INSTANTANEOUS HYDROGRAPH, TO THE FLOOD OF APRIL, 1937

2. A more than usual degree of doubt as to the actual quantity of total precipitation is present in view of the small number of gaging stations (only one in the drainage basin), the nearest recording rainfall stations being some miles outside. The station in the center of the upper drainage area recorded 5.18 in.

of rain as compared with 2.58 in. recorded at Hopewell, Va., a station several miles east of Petersburg.

3. Observed discharges are from a single-stage discharge curve without slope correction. The gage is on a very flat stream and only 2.5 miles above a power dam. Although the gage is reported to be out of the backwater area in times of low water, the control for high water is thought to be the dam, in which case there is probably a large slope correction to discharges at this gage. If so, the observed stage hydrograph could not reflect the marked discharge decrease on April 29. At peak stage, 1 ft on the stage discharge curve is 3,000 cu ft per sec. This, and other features of the reported record, are sufficiently in doubt to cover the variation between observed and computed hydrographs.

4. On the other hand, the method may be no more accurate than is indicated by the agreement of the curves.

A comparison between the instantaneous unitgraph for the Appomattox River near Petersburg (drainage area, 1,335 sq miles; average slope of the river profile, 2.9 ft per mile; length above gage, 122 miles; and concentration time, 144 hours) and for the James River at Lick Run (drainage area, 1,369 sq miles; average slope 17.3 ft per mile; length, 78 miles; and concentration time, 28 hours) is shown in Fig. 10. Fig. 11(a) shows a similar comparison between the instantaneous hydrographs of the Smith River at Bassetts, Va. (drainage area, 265 sq miles; average slope, 16.6 ft per mile; length, 37 miles; and concentration

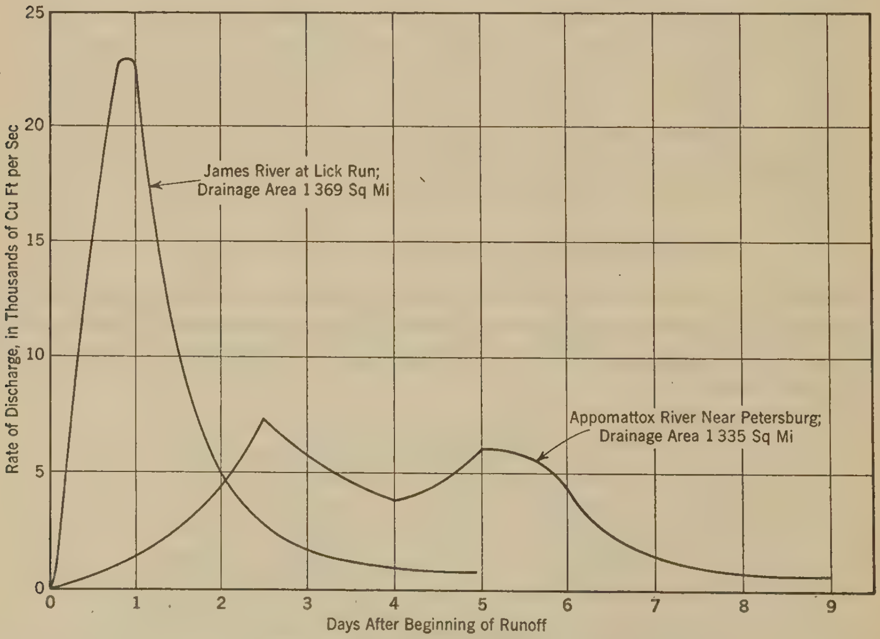

FIG. 10.—INSTANTANEOUS HYDROGRAPHS, APPOMATTOX RIVER NEAR PETERSBURG AND JAMES RIVER AT LICK RUN

time, 7 hours) and for the Meherrin River at Emporia, Va. (drainage area, 750 sq miles; average slope, 2.4 ft per mile; length, 86 miles; and concentration time, 78 hours). Fig. 11(*b*) shows a comparison of observed and computed flood hydrographs at Bassetts for the flood of August 18, 1939, and a similar comparison at Emporia for the flood of March 6, 1932.

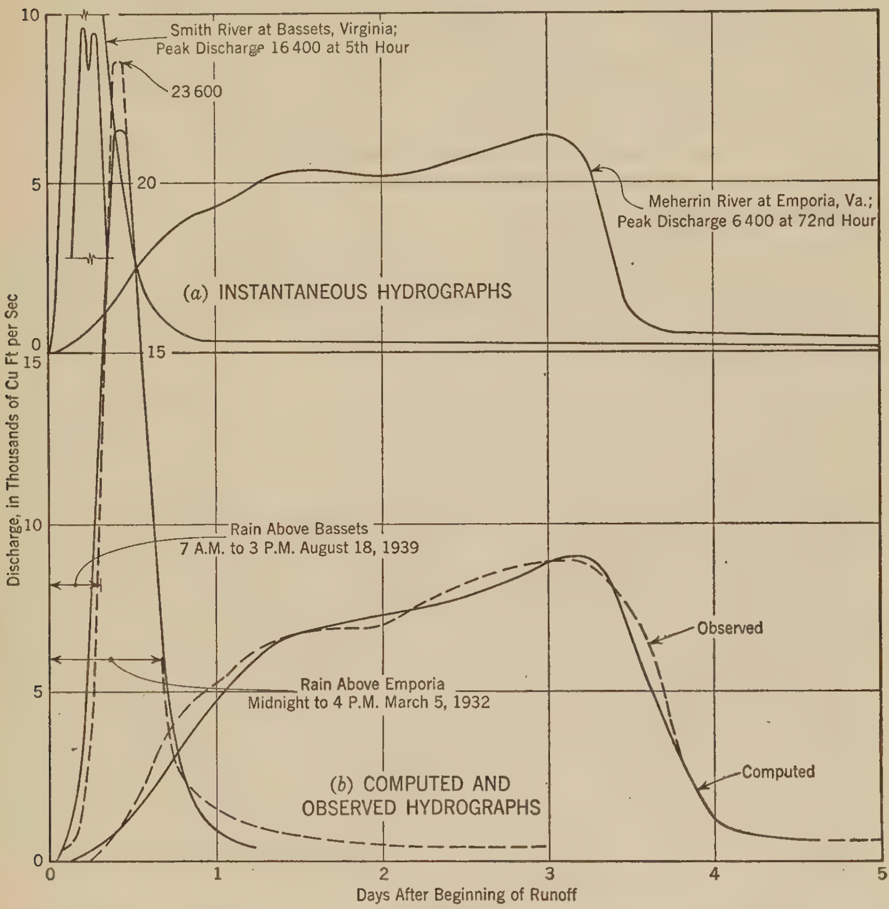

Fig. 11.—Hydrographs for the Smith River at Bassetts and the Meherrin River at Emporia

Determination of the Instantaneous Hydrograph for Streams Without Flow Records

The determination of any kind of unit hydrograph for a stream without records is a hazardous task. In most cases, it will be possible to install river stage recorders temporarily, obtain a record of rise and fall, compute a rating curve, and determine the elements of time of concentration, K and x, with a fair degree of accuracy. Since the record is utilized chiefly to determine the time of concentration, the proposed derivation of a unit hydrograph from a record of a small flood is not subject to the errors incurred by use of similar records in unit hydrograph derivations as originally proposed by Mr. Sherman. However, it is necessary occasionally to approximate the flow characteristics of a stream without records. For such attempts, a correlation of time of concentration or storage capacity with river slope would be adequate.

Attempting to correlate the storage per mile of river expressed as hours per mile (the reciprocal of velocity) with average slope of the stream above the gage, the writer found, as would be expected, that this item increased with the decrease of slope. The average storage in hours per mile was found to be numerically equal to the reciprocal of the square root of the slope in feet per mile from source to gage, when the slope is taken as that of a straight-line profile with the same area below it as the actual profile. For some streams the variation from the average value was large—sometimes as much as 100%. The storage was larger for streams in alluvial beds than for those in rock gorges, although the range in slope for which studies were made overlapped. The average storage above two or more gages on the same stream, although varying with the slope, was more nearly constant than indicated by the aforementioned average criterion.

How much of the variation in storage is to be attributed to the natural causes and how much to limits of data cannot be ascertained. Most of the stream profiles were determined from U. S. Geological Survey sheets of 100-ft contour interval, although some of the flatter streams crossed only two such contours in their entire length. For steeper streams, crossing enough contours to reduce the possible error in slope determination, the time of concentration became so small that the possible error of 6 hours in time of precipitation was a large percentage of the total time. Perhaps someone working in an area for which good maps were available and which contain recording rainfall gages may be able to find a more precise relationship. Also, the writer was unable to find a usable definition of average river slope that could evaluate the influence of local concentration of extreme slope as a truly small influence on flow-time of the entire stream, compared with well distributed fall of the same amount.

The amount of the storage by which the time-area concentration curve should be modified will approximate 10% to 25% of the time of concentration, with the smaller values being used with the longer times of concentration and extremely narrow drainage areas.

UNIT HYDROGRAPHS FOR LARGE DRAINAGE AREAS

By definition the application of the unit hydrograph is limited to areas over which the amount of runoff originating in any unit period may be considered as uniform within the required accuracy of the solution. For the flashy streams of the South Atlantic Coast, this is a drastic limitation, because they drain areas whose principal dimension is west to east, whereas the usual rainfall isohyets run north to south, and complete coverage of a major drainage basin by any storm is the exception rather than the rule. Because the streams are flashy, 6-hr unit periods are too long for component drainage areas, but the shortest practical period for entire principal river systems. Under such conditions, the difference between the theory and fact of uniform origin of runoff may be large even for drainage areas of 500 sq miles or less.

For these streams, the storage-discharge relationship in all reaches of many of the rivers may be approximated closely by a straight line throughout the range of flood discharge. This being the case, the Muskingum method of flood routing is applicable to the translation and storage modification of flood waves. Where the Muskingum method is applicable, the unit hydrograph theory may be used, by deriving the unit hydrograph for the component drainage areas of such size as to approximate the uniformity criterion and by routing the unit hydrographs themselves to the point for which a composite unit hydrograph is desired. The use of the proper amount and distribution of runoff with each routed component unitgraph will reproduce the component of runoff from the drainage area in question, and the sum of all components will be the desired composite flood wave. The degree of accuracy will be the same as though flood hydrographs had been computed for all tributary gages and then routed to the point for which the hydrograph is desired. In flood control work, the advantage of being able to identify individual components of a hydrograph is obvious.

[a] After beginning of runoff. [b] Drainage area above station in square miles. [c] Values beyond 6 days omitted.

For forecast work, it is desirable not only to have a complete breakdown of the drainage area into small parts but also to have a table of summations of these component unit hydrographs in various applicable combinations. If, for any particular storm pattern, practical uniformity of runoff origin over several component drainage areas exists, considerable time may be saved by using the combination graphs rather than the separate components.

Table 2 is a typical arrangement of component unit hydrographs prepared for the James River at Richmond, Va. Illustrating the nonuniformity of occurrence of runoff typical of South Atlantic rivers, the largest known flood (May, 1771) at this city is reported to have occurred without sufficient rain in the city to settle the dust.

Determination of Approximate Routing Constants

There are several ways of determining the storage constants for use in the routing of the unitgraph components. If the inflow between the tributary gage and the outflow is small or if it can be determined with enough accuracy to give proper weight to its influence, the amount of storage effective between the tributary gage and the desired outflow point can be determined from the relationships of Eqs. 9 to 12; or, where the hydrographs are of similar shape, as is frequently the case, by measuring the displacement between the falling leg of the inflow and outflow hydrographs. Thus, in Fig. 12, the storage effect between Danville, Va., and South Boston, Va., on the Dan River, is 32 hours. Although there are 680 sq miles of intervening drainage area, the discharge from that area had decreased to insignificant proportions prior to the time which is used as a criterion.

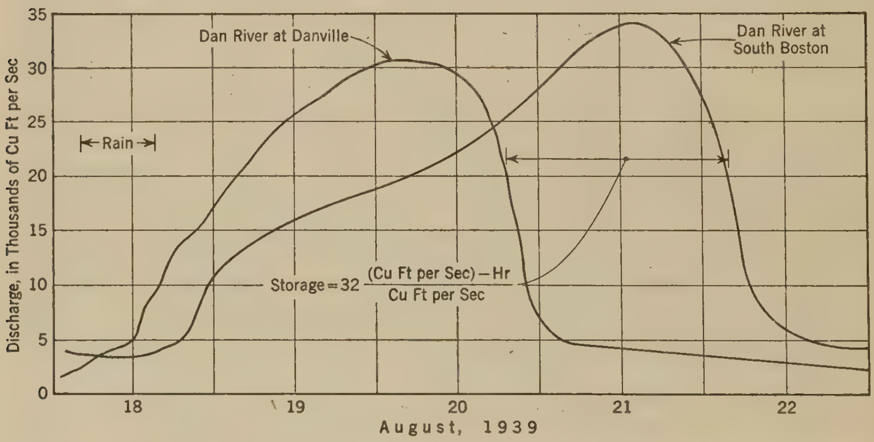

Fig. 12.—Approximate Determination of Storage from Hydrographs

The most accurate method of determining the storage-discharge relation is still from the accumulated differential between inflow and outflow, as outlined by Mr. McCarthy.[9]

SUMMARY

The paper has attempted to show that:

1. The constant time elements essential to the theory of the unit hydrograph, and common in many streams, are attributable to fundamental characteristics of the watersheds which maintain the storage capacities of the stream channels in constant direct proportion to the flows in them.

2. Such a relationship between storage capacity and discharge capacity produces certain characteristics in the rates of rise and fall of the hydrograph which are calculable by a simple established method.

3. These characteristics can be incorporated in a unit hydrograph, without the necessity of making or utilizing any quantitative determination of runoff distribution, in a few steps defined as follows:

(*a*) From a record of flood discharge, determine the time at which the rate of discharge decrease is greatest in relation to the prevailing discharge;
(*b*) The time elapsed between the end of runoff-producing rainfall and the time so determined is the base length (time) of a time-area concentration curve derived by dividing the watershed a long its water courses;
(*c*) The time-area concentration curve is routed as if through a reservoir with storage equal to K times the outflow when K is the time indicated by Eq. 12*b* at the time determined as in step (*a*) when $x = 0.0$;
(*d*) The result expressed in cubic feet per second per inch of runoff depth on the watershed at unit intervals of time is the instantaneous hydrograph; and
(*e*) The instantaneous hydrograph is converted to a unit hydrograph for any desired period of time by subdividing the instantaneous graph into periods of the desired unit length and averaging the ordinates over the preceding periods of time. Thus, in a 6-hr unit hydrograph, the rates of discharge at the end of 6, 12, and 18 hours, respectively, are the average ordinates to the instantaneous hydrograph in the 6-hr periods preceding the sixth, twelfth, and eighteenth hours.

4. A similar procedure may be applied to the determination of a unit hydrograph of subsurface flow, and the two unitgraphs may be combined in the average proportion applicable to the watershed, or used separately if desired.

5. The derivation of the unit hydrograph in this manner has some advantages:

(*a*) The procedure is definable so that all hydrographs derived by different individuals will be identical;
(*b*) The determination is independent of any knowledge of runoff distribution, except the time of ending, and therefore not subject to the errors due to indeterminability of runoff distribution which are factors in other methods known to the author;
(*c*) The influences of shape of drainage area and the capacity to produce large peak flows from concentrated runoff—both factors which are obscured by protracted runoff in other methods of derivation—are well indicated. The method also can be used to indicate the change in hydrograph form which is likely if a natural reach of river is replaced by a reservoir pool; and
(*d*) The unit hydrograph quantities are instantaneous rates of discharge at the time specified, not average values during the preceding unit period as in Mr. Sherman's original method, and the resulting hydro-

graph is properly drawn through all computed points, rather than as a bar diagram, and peaking of the hydrograph is no longer a matter of personal judgment. Hydrographs computed from the same distribution of runoff with 6-hr unitgraphs will agree with those by 1-hr graphs.

6. The derivation of the unit hydrograph in this manner has some disadvantages:

(*a*) Hydrographs are likely to fall a little too low on the receding leg between the point of maximum recession rate and the point where subsurface flow becomes predominant;
(*b*) When applied to too large drainage areas, the hydrograph may have too slow a rise and too rapid a fall, as a result of using the same storage factor for near and remote elements. This fault is corrected easily by subdividing the drainage area and computing separate unitgraphs for the components and combining them in the manner indicated in Table 2;
(*c*) Although this method reflects influence of shape of drainage area and capacity to produce high peaks well—better than any other one known to the author—it is possible that such influences are exaggerated slightly.

DISCUSSION

James S. Sweet,[10] Assoc. M. Am. Soc. C. E.—The relationship between flow and storage in open channels has been demonstrated in this paper. The analysis and the suggested procedures of the flow routing are a definite contribution to flood control design estimates. However, in forecasting work, where time of preparation and issuance of a forecast must necessarily be reduced to a minimum, the procedure must be simplified to effect a quick answer, without sacrificing the limits of relative accuracy. Mr. Clark's method involves time-consuming, laborious computations, and therefore is not adaptable for this type of work. On the James River where stage relationships between the gages along the entire length of the river are not always well defined, due to the nonuniformity of the distribution of the storms over the basin, it is best to use the method of the summation and routing of the discharges. Discharges in the upper reaches of the main stem and the tributaries should be ascertained either through the direct reports from the stations or through the simple rainfall-stage relations and should be routed to a downstream point on the main stem. Adjustments should be made to synchronize the arrival of the discharges at the desired point simultaneously. The discharges from the intervening ungaged areas should be adjusted, taking into consideration the ratio of index areas and rainfall over them and the area coefficient that reflects run-off characteristics and channel storage of the area. Determined empirically, these coefficients for various parts of the basin range from 0.6 to 0.7. Thus, discharge of the James River at Buchanan may be expressed as follows:

$$Q_B = Q_L + Q_P + Q_F + Q_U \qquad (15)$$

in which Q_B = discharge of the James River at Buchanan; Q_L = discharge of the James River at Lick Run, 9 hours previously; Q_P = discharge of Craig Creek at Parr, 7 hours previously; Q_F = discharge of Catawba Creek at Fincastle, 5 hours previously; and Q_U = discharge from the ungaged area (280 sq miles) above Buchanan.

For uniform storms, using the discharge at Lick Run as an index for the ungaged area discharge, Eq. 15 is further simplified:

$$Q_B = 1.123\, Q_L + Q_P + Q_F \qquad (16)$$

Discharges, including peak discharges, can be determined in a similar manner at all desired points along the main stem and converted into stages. With the equations prepared in a simple form such as Eqs. 15 and 16, actual computations take very little time after the headwater discharges become available to the forecaster.

It is regretted that Mr. Clark is introducing a new concept of time of concentration, thus adding another to the multitude of existing definitions. Not in the hope of relieving the confusion, but rather to add another choice for the future selection of an appropriate definition, the writer suggests that consideration be given to the definition of concentration time as time elapsed between the beginning of the effective rainfall (rainfall after the initial loss is satisfied) and the time of the peak rise of the stream.

Otto H. Meyer,[11] Assoc. M. Am. Soc. C. E.—A new tool for synthesizing runoff from rainfall is presented in this paper. It is a good and useful tool, as is shown by the excellent agreement of reconstituted hydrographs with natural hydrographs. Although this method will not replace other accepted techniques of synthesis entirely, it deserves to be used in a large proportion of cases because of both its simplicity and accuracy.

The author does well to emphasize relative accuracy. Estimates have often been condemned for lack of accuracy when they were in fact the best available.

Some conclusions, in the paper, such as increase in outflow following decrease in inflow, mass rotation of water-surface profiles, and negative outflows, are apparently deduced from empirical and approximate formulas. These conclusions should be examined critically. Also, the statement that K is constant (and the derivation of formulas based on that condition) involves rationalizing from an empirical assumption. The value of K can often be assumed constant, with good "relative accuracy" and in many cases with entirely satisfactory results; yet this value usually varies somewhat with S and Q; in fact, it is often so variable as to be unusable. The writer has developed numerous storage-outflow curves for streams in the Sacramento and San Joaquin valleys of California, and for good routing results these curved considerably; in several cases, there were sharp reversals of curvature. The principal effect of using a constant K, instead of a variable K, will probably be the shifting of high peaks in time relative to lower flows.

Mr. Clark mentions storage as "balanced" or "unbalanced." These two types of storage appear to refer to "reach" and "reservoir" storage, respectively.

The division of runoff into surface and ground-water flow, by the criterion that the runoff in direct proportion to storage is surface runoff, is arbitrary. This theory is permissible only for convenience or when no other means of division is practicable. An important part of the runoff other than surface runoff never reaches the true ground-water table, but flows quite near the surface, and responds promptly to rainfall. The writer has found an apparent correlation between this volume in subsurface storage and the infiltration from rainfall; that is, the subsurface storage determines not only the outflow but also the surface runoff factor. Thus, a part of the rainfall may be routed "through the ground"; but as it travels underground a short distance only (at most several hundred yards) the outflow should be added to the "net" pluviograph and synthesized into the hydrograph along with the direct surface runoff. Of course, the inflow into subsurface storage is not total rainfall less direct surface runoff, as evaporation must also be considered; likewise, some of the subsurface storage is lost to the true ground water, and some is lost in transpiration.

---

[11] Maj., Field Artillery, U. S. Army, Corvallis, Ore.

The author constructs a time-area concentration curve, routes it through storage, and averages the outflow over a unit time to form a unitgraph. If the time-area concentration curve were averaged over a unit period, routing of the resulting graph might produce the same unitgraph. To extend this idea further, a summation of the products of a time-area concentration curve with successive parts of a net pluviograph could be routed through the storage with about the same labor as by the author's procedure. Although the suggested method would have the advantage of permitting use of a storage-outflow relation involving a variable K, it would involve more routing. However, there are less laborious procedures than the Muskingum method, such as "lag routing,"[12] or the use of a flood routing machine.

The application of Mr. Clark's technique is not necessarily limited to the Muskingum method of routing, but can be used with any of about a half-dozen methods in current use.

L. K. SHERMAN,[13] M. AM. SOC. C. E.—The definite, but complex, relations that exist between the hydrograph of surface runoff, the procedure of flood routing, and the law of proportionality of certain hydrographs, are presented in this paper.

All the objectives noted in the "Synopsis" have been fulfilled, with one very important exception. That exception is the author's statement, "to derive accurate unit hydrographs." No unit hydrographs or percentage distribution graphs have been derived in this paper.

Col. 10, Table 1, is labeled "12-hr unit hydrograph (cu ft per sec)." This caption is very misleading to a reader. It is not a unit hydrograph. The definition of a unit hydrograph, accepted and used since 1932, is: The hydrograph of surface runoff from a given basin due to a 1-in. depth of net rainfall, applied at a uniform rate in a unit of time. The ordinates of flow of this unit hydrograph (expressed in cubic feet per second) and the ordinates of flow of an observed hydrograph, due to a net rain of X inches in the same unit time, are proportional to their respective volumes of total surface runoff.

Net rain means rainfall minus infiltration and other losses.

The distribution graph is the unit hydrograph with ordinates expressed in percentage of the total volume of the observed hydrograph. The percentage distribution graph is commonly used in practice.

The proportionality of ordinates holds true for any two hydrographs of surface runoff on the same basin, provided the net rains in each case hold a direct relation of intensities, and follows identical sequence of downpours.

Let it be required to apply the foregoing criteria to this Appomattox River basin with a drainage area of 1,335 sq miles. If 1 in. of net rain fell on this basin, and if the rain followed identical times and similar intensities as that of April, 1937 (see Fig. 9), it would produce a hydrograph with the same time base as that observed in Fig. 9. The ordinates of runoff would be proportionate to the ordinates in Fig. 9, and the volume of surface runoff would be 1,335 in.-miles or 36,000 (cu ft per sec)-days or 72,000 (cu ft per sec)-half-days. The total surface runoff (by scaling ordinates in Fig. 9) in the flood of April, 1937, is

---

[12] "Simplified Flood Routing," by Otto H. Meyer, *Civil Engineering*, May, 1941, p. 306.

[13] Cons. Engr., Chicago, Ill.

215,000 (cu ft per sec)-half-days. The base flow (also estimated from Fig. 9) was, approximately, $\frac{1,000 + 2,000}{2} \times 19$ half-days or 29,000 (cu ft per sec)-half-days. Then 216,000 − 29,000 = 187,000 (cu ft per sec)-half-days as the total volume of surface runoff due to the April, 1937, storm.

A similar storm producing 1 in. of runoff from this basin was 72,000 (cu ft per sec)-half-days.

The average depth of net rain, measured from the surface runoff hydrograph, is 187/72 = 2.6 in. of average depth over the Appomattox basin in the flood of April, 1937.

The comparable figures given in Table 1 are: Runoff for 1 in. of net rain = 60,000 (cu ft per sec)-half-days. This is the total of Col. 10. This amount is 87% of the total runoff. Therefore, 100% of 1 in. of net rain is 69,000 (cu ft per sec)-half-days. Accordingly, the depth of net rain utilizing the author's figure is 187/69 = 2.7 in.

This agreement by the author's elaborate routing analysis is an ingenious and possibly very useful accomplishment. It has no value as a derivative of the ratio of 1 in. of net rain to the total runoff from a particular storm. That is found readily in a few minutes from an observed hydrograph and a known size of drainage area. Col. 10, Table 1, is the runoff of 1 in. of net rain over the basin; but it certainly is not 1 in. applied over the basin in one unit of time. Therefore, it is not a unit hydrograph or a distribution graph. It certainly cannot be used to derive the hydrograph of runoff from the Appomattox basin under a storm of entirely different pattern. That is what the unit hydrograph is for. The same criticism applies to all the data in Table 2.

The author states (see heading, "Derivation of the Instantaneous and Unit Hydrographs") that another storm "is equally well reproduced with the same [so-called] unitgraph." He has not demonstrated the truth of this statement.

However, it would seem possible to utilize the methodology of Table 1. In this case the data furnished no record of the amounts of unit-time rainfalls on the basin. The total net rainfall averaged over the basin is simply and readily found as 2.6 in. or 2.7 in. How much of this fell in each of how many half-day periods is unknown. If this were furnished or found, a unit hydrograph could be derived. The unit hydrograph could be derived just as well if the 12-hr rainfalls for the period, April 25–29, were known—by the methods described by Mr. McCarthy[9] or the writer.[14] In deriving a unit hydrograph, the first step is to find the volume or volumes of net rainfall that fell in unit periods of time. These are the volumes that produce the hydrograph of surface runoff.

In the author's example of April, 1937, in Fig. 9, the total runoff was found to be 2.7 in., which is the sum of several unit-time downpours; but, in this case, the number or relative amounts of the unit volumes which total 2.7 in. is not known.

The bar pattern, Fig. 8, curve (a), indicates that the author has discovered that the 2.7-in. runoff was due to 12 unit periods of rain with ordinates proportional, or equal, to this bar pattern. Mr. Clark does not describe how he found this bar pattern. The number of blocks agrees with the number of time units in Table 1, Col. 2. The ordinates or heights of these blocks agree fairly well with Col. 2 averages.

---

[14] "Physics of the Earth," National Research Council, Div. of Physical Sciences, Pt. 9—"Hydrology," by O. E. Meinzer, 1942, p. 521.

The total percentage of Col. 2, however, is not 100%, or even 87%, to correspond with the total of Col. 8, Table 1.

It is hoped that, in his closure, the author will consider this feature of Table 1 and the block pattern (a) of Fig. 8. He may have found a way of determining the unit volumes of net rainfall which created the observed hydrograph, without prior data on rainfall. Astounding as this statement may seem, there is nothing fundamentally impossible about it. The hydrograph of surface runoff reflects, not only the physical characteristics of the basin, but also the pattern or sequence of the creating net rainfall. In other words, with an observed hydrograph of surface runoff, it is possible to derive the unknown unit rains and thus the unit hydrograph. With the unit hydrograph and the observed rainfall, the corresponding hydrograph of runoff is found readily.

If the author presents further consideration of this feature, it is also hoped that he will follow the orthodox procedure of eliminating base flow. The problem is sufficiently complex without including it. In this connection, attention is called to the work of Robert E. Horton, M. Am. Soc. C. E., which includes routing and the derivation of unit hydrographs.[15]

The writer does not agree with the author's statement that 1,000 sq miles is a large basin upon which to apply the unit hydrograph or distribution graph. The distribution graph has been frequently and satisfactorily used for basins of 5,000, 10,000, and even 30,000 sq miles. The theory of the unit hydrograph assumes a uniform rate of rain for a relatively small fraction of the time of runoff. The volume in this unit time is the same volume as the nonuniform rain in this unit time. Each unit volume changes with the storm intensity. If the unit times are taken small enough, the runoff hydrograph will be exactly reproduced.

In practise, whether to use small areas and apply routing, or use large areas without routing, depends altogether upon the available data including the number of stream gages in the basin.

Gordon R. Williams,[16] Assoc. M. Am. Soc. C. E.—Numerous positive statements are made by the author which controvert accepted concepts and experience in the field of river hydraulics. These statements are not substantiated in the paper by experimental evidence or observations of actual conditions.

The most radical theory deals with "pressure" or momentum waves moving downstream through reservoirs and natural river reaches. The author claims that, if the inflow to a reservoir or river reach is decreased abruptly, the slope storage in the upper end of the reservoir or reach moves downstream as a pressure wave and increases the stage and discharge at the lower end of the pool relationship is not disturbed by any manipulation which follows. The relationship is not peculiar to instantaneous hydrographs, however. If two 6-hr unitgraphs are added with a 6-hr lag and the sum is divided by two, a 12-hr unitgraph results. The ordinate of the 12-hr graph at hour 12:00 is the sum of the 6-hr and 12-hr ordinates of the 6-hr graph divided by two, or the average ordinate of the 6-hr graph during the first twelve hours.

[15] "Virtual Channel-Inflow Graphs," by Robert E. Horton, *Transactions*, Section of Hydrology, Am. Geophysical Union, Pt. III, 1941, p. 818 (4).

[16] Senior Engr., Office of the Chf. of Engrs., U. S. Army, Washington, D. C.

The author indicates an attempt to correlate storage with slope in order to devise a method for determining K for basins without adequate data. He found that the relation could be expressed approximately as: $\frac{K}{L} = \frac{1}{\sqrt{s}}$; or,

$$C_1 = \frac{K\sqrt{s}}{L} \qquad (18a)$$

in which L is the length of the stream in miles. Eq. 18*a* considers only the distance along the main stream and the slope. It would seem that other factors of importance would be the storage in tributaries and the comparative magnitude of flood flows to which the streams are subjected. If drainage area were introduced into Eq. 18*a*, it should indicate the effect of these two factors. Then: $\frac{K}{L} = \frac{\sqrt{A}}{\sqrt{s}}$; or,

$$C_2 = \frac{K\sqrt{s}}{L\sqrt{A}} \qquad (18b)$$

The writer has used the square root of A because peak flows tend to vary as the square root of the drainage area, and, in all probability, tributary storage also varies as some power of drainage area less than one.

TABLE 3.—COMPARISON BETWEEN EQS. 18*a* AND 18*b*

Stream	s (ft per mile)	L (miles)	K (hours)	A (sq miles)	C_1 (Eq. 18*a*)	C_2 (Eq. 18*b*)

Table 3 affords a comparison between Eqs. 18*a* and 18*b*. The first four items are from data given by the author, and the last seven are based on data available to the writer. Unfortunately, determinations of K for streams of the Sierra Nevada drainage are complicated by the presence of a snow pack which effectively reduces the drainage area, length of channel, and time of concentration, in addition to the other problems indicated by the author. The criterion of Eq. 18*b* seems to be more nearly a constant than does the value of

$K \sqrt{s}/L$ from Eq. 18*a*. Values of $K \sqrt{s}/L \sqrt{A}$ have somewhat more of tendency to be higher for the California streams than do the values of Eq. 18*a*. This may indicate that a variation must be expected from region to region, but more likely it indicates that some power other than the $\sqrt{s}$ should be used.

Inspection of Fig. 6 indicates that the author divided the drainage area on the basis of equal units of stream mileage. Either Eq. 18*a* or Eq. 18*b* could be used to determine the subareas and should give a time-area concentration graph which more closely approximates the true graph. Eq. 18*a* is the simplest to apply, and, since the problem is merely to divide a basin for which K is already known, should be nearly as satisfactory as Eq. 18*b*. The number of reaches will equal K/T, and the values of $d/\sqrt{s}$ (d is the length of the reach) for all reaches should be equal. The solution is reached easily by approximations if a family of curves showing the variation of $d/\sqrt{s}$ with d, and with s, is plotted. A first approximation to the proper value of $d/\sqrt{s}$ will be the value of $T\,L/K\sqrt{s}$, which, for the Appomattox River, is 6.0. A final value of 5.75 was determined by the writer, which gives ten reaches of 8.6 miles, one reach of 12 miles, and one of 24 miles.

E. F. BRATER,[19] JUN. AM. SOC. C. E.—The unit hydrograph is the most useful tool available for the purpose of converting a quantity of surface water, resulting from precipitation, to a river discharge hydrograph. Since the unit hydrograph concept was introduced, a number of different interpretations and methods of application have been evolved. A description of these various concepts and techniques should be included in technical literature. Such a study and discussions of it should help to unify and improve engineers' understanding of the unit hydrograph. This paper is a valuable step in that direction. However, the engineer who may be desirous of making use of this technique will hope that a more detailed description of the methodology, with examples of the numerical computations, will be included in the author's closing discussion. For instance, the "time-area concentration curve" is an important feature of the method, but the author has not shown how one may be obtained for a given watershed.

In his method of flood routing, Mr. Clark sets up the relationship between storage and discharge in Eqs. 3 and 4. In Eq. 4, x is a term that is allowed to vary from 0 to 1. When $x = 0$, the storage becomes proportional to the outflow from the channel reach; when $x = 1$, the storage must be proportional to the inflow; and, when $x = 0.5$, the storage becomes proportional to both inflow and outflow in equal weight. The third condition assumes trapezoidal or double-wedge storage. Mr. Clark indicates that for most streams x is nearly 0.5. However, he chooses to discuss at considerable length the importance of the case in which x is greater than 0.5. In this connection, the writer does not agree with the author.

In the first place, the case of $x = 1$ is a physical impossibility in a real reach of channel, since, if storage is proportional to inflow, storage must become zero at the same instant that inflow becomes zero. For this to be true, the final portions of flood water would have to travel the length of the reach in-relationship is not disturbed by any manipulation which follows. The relationship is not peculiar to instantaneous hydrographs, however. If two 6-hr unitgraphs are added with a 6-hr lag and the sum is divided by two, a 12-hr unitgraph results. The ordinate of the 12-hr graph at hour 12:00 is the sum of the 6-hr and 12-hr ordinates of the 6-hr graph divided by two, or the average ordinate of the 6-hr graph during the first twelve hours.

---

[19] Asst. Prof., Civ. Eng., Univ. of Michigan, Ann Arbor, Mich.

The author indicates an attempt to correlate storage with slope in order to devise a method for determining K for basins without adequate data. He found that the relation could be expressed approximately as: $\frac{K}{L} = \frac{1}{\sqrt{s}}$; or,

$$C_1 = \frac{K\sqrt{s}}{L} \qquad \text{(18a)}$$

in which L is the length of the stream in miles. Eq. 18*a* considers only the distance along the main stream and the slope. It would seem that other factors of importance would be the storage in tributaries and the comparative magnitude of flood flows to which the streams are subjected. If drainage area were introduced into Eq. 18*a*, it should indicate the effect of these two factors. Then: $\frac{K}{L} = \frac{\sqrt{A}}{\sqrt{s}}$; or,

$$C_2 = \frac{K\sqrt{s}}{L\sqrt{A}} \qquad \text{(18b)}$$

The writer has used the square root of A because peak flows tend to vary as the square root of the drainage area, and, in all probability, tributary storage also varies as some power of drainage area less than one.

TABLE 3.—COMPARISON BETWEEN EQS. 18*a* AND 18*b*

Table 3 affords a comparison between Eqs. 18*a* and 18*b*. The first four items are from data given by the author, and the last seven are based on data available to the writer. Unfortunately, determinations of K for streams of the Sierra Nevada drainage are complicated by the presence of a snow pack which effectively reduces the drainage area, length of channel, and time of concentration, in addition to the other problems indicated by the author. The criterion of Eq. 18*b* seems to be more nearly a constant than does the value of

$K\sqrt{s}/L$ from Eq. 18*a*. Values of $K\sqrt{s}/L\sqrt{A}$ have somewhat more of tendency to be higher for the California streams than do the values of Eq. 18*a*. This may indicate that a variation must be expected from region to region, but more likely it indicates that some power other than the $\sqrt{s}$ should be used.

Inspection of Fig. 6 indicates that the author divided the drainage area on the basis of equal units of stream mileage. Either Eq. 18*a* or Eq. 18*b* could be used to determine the subareas and should give a time-area concentration graph which more closely approximates the true graph. Eq. 18*a* is the simplest to apply, and, since the problem is merely to divide a basin for which K is already known, should be nearly as satisfactory as Eq. 18*b*. The number of reaches will equal K/T, and the values of $d/\sqrt{s}$ (d is the length of the reach) for all reaches should be equal. The solution is reached easily by approximations if a family of curves showing the variation of $d/\sqrt{s}$ with d, and with s, is plotted. A first approximation to the proper value of $d/\sqrt{s}$ will be the value of $T\,L/K\sqrt{s}$, which, for the Appomattox River, is 6.0. A final value of 5.75 was determined by the writer, which gives ten reaches of 8.6 miles, one reach of 12 miles, and one of 24 miles.

E. F. Brater,[19] Jun. Am. Soc. C. E.—The unit hydrograph is the most useful tool available for the purpose of converting a quantity of surface water, resulting from precipitation, to a river discharge hydrograph. Since the unit hydrograph concept was introduced, a number of different interpretations and methods of application have been evolved. A description of these various concepts and techniques should be included in technical literature. Such a study and discussions of it should help to unify and improve engineers' understanding of the unit hydrograph. This paper is a valuable step in that direction. However, the engineer who may be desirous of making use of this technique will hope that a more detailed description of the methodology, with examples of the numerical computations, will be included in the author's closing discussion. For instance, the "time-area concentration curve" is an important feature of the method, but the author has not shown how one may be obtained for a given watershed.

In his method of flood routing, Mr. Clark sets up the relationship between storage and discharge in Eqs. 3 and 4. In Eq. 4, x is a term that is allowed to vary from 0 to 1. When $x = 0$, the storage becomes proportional to the outflow from the channel reach; when $x = 1$, the storage must be proportional to the inflow; and, when $x = 0.5$, the storage becomes proportional to both inflow and outflow in equal weight. The third condition assumes trapezoidal or double-wedge storage. Mr. Clark indicates that for most streams x is nearly 0.5. However, he chooses to discuss at considerable length the importance of the case in which x is greater than 0.5. In this connection, the writer does not agree with the author.

In the first place, the case of $x = 1$ is a physical impossibility in a real reach of channel, since, if storage is proportional to inflow, storage must become zero at the same instant that inflow becomes zero. For this to be true, the final portions of flood water would have to travel the length of the reach instantaneously. This paradox is illustrated by Fig. 2, in which, for $x = 1$, the inflow hydrograph and the routed or outflow hydrograph end at the same time. Thus, if such a graph were routed through successive reaches, the recession side of the graph could not advance in time. The result of several routings of the author's graph is a number of large plus and minus ordinates occurring at the end of the original hydrograph.

---

[19] Asst. Prof., Civ. Eng., Univ. of Michigan, Ann Arbor, Mich.

Mr. Clark is of the opinion that storage of this type does occur and that it may cause outflow rates from a given reach to be greater than the inflow rates even without the addition of inflow from the local drainage area. In the third paragraph following Eq. 3 he states:

> "Reduction of the inflow rate [where backwater exists] necessarily would be accompanied by a decrease in storage and an increase of outflow rate. Rapid inflow shutdown necessarily would be accompanied by a release of the backwater storage and a consequent increase in the slack-water storage or in the outflow discharge or in both."

As an illustration of the nature of this action, the author takes the case of uniform discharge in the rectangular channel shown in Fig. 1. He assumes that the uniform flow of 116,000 cu ft per sec is suddenly stopped at the upper end of the reach and concludes that this will cause an increase in the depth at the lower end because 260 acre-ft of water are released from storage at the upper end. The writer wishes to point out that, since there is no change in the conditions at the lower end of the reach, the normal discharge of 116,000 cu ft per sec will continue there until the effect of this sudden stoppage can be transmitted through the length of the channel. A recession type of wave will be started at the instant of shutoff which, neglecting energy losses, might have a velocity as great as $V_w = \sqrt{g\,d} + V = \sqrt{32.2 \times 20} + 11.6 = 37$ ft per sec. Therefore, the earliest possible time that the effect will reach the lower end is $\frac{10,000}{37} \doteq 270$ sec after stopping inflow. During this time a volume of $\frac{270 \times 116,000}{43,560} = 720$ acre-ft will have passed out of the lower end of the reach. This is more than sufficient to make room for the 260 acre-ft which the author wishes to accommodate. There is in no sense a "release" of stored water, due to a decrease in the discharge at the upper end of the reach, either in a channel such as this or in the backwater above an impounding reservoir. Kinetic storage is held in place solely by the resistance to flow from point to point in the channel. It is already in complete equilibrium—that is, flowing as fast as possible with the energy available. A decrease in depth at the upper end of the channel can only decrease the energy and thus retard, rather than accelerate, flow.

L. C. CRAWFORD,[20] ASSOC. M. AM. SOC. C. E.—One phase of this interesting paper pertains to natural channel or valley storage and the relationship of this volume to discharge or stage. The channel-storage rating has become a valuable tool in flood routing, hydrograph analysis and synthesis, and infiltration studies. The author's comments on real and relative accuracy are very pertinent to unit hydrograph and channel-storage ratings which may be developed by indirect methods through the analysis of records of discharge during past major rises or capital floods.

---

[20] Consultant, Iowa Inst. of Hydr. Research; Dist. Engr., U. S. Geological Survey, Iowa City, Iowa.

The basic stage and discharge records, which are cooperatively collected by the United States Geological Survey and other agencies, give an opportunity for potential channel storage and related studies that probably has not been sufficiently emphasized. Indirect methods of storage determination have been developed and are being further extended through new concepts, such as Mr. Clark presents, and through the use of basic records of stream flow. Thus, it is possible to ascertain with considerable relative accuracy various relations pertaining to natural channel or valley storage that otherwise would be too costly and wholly impracticable without extensive cross-sectional surveys.

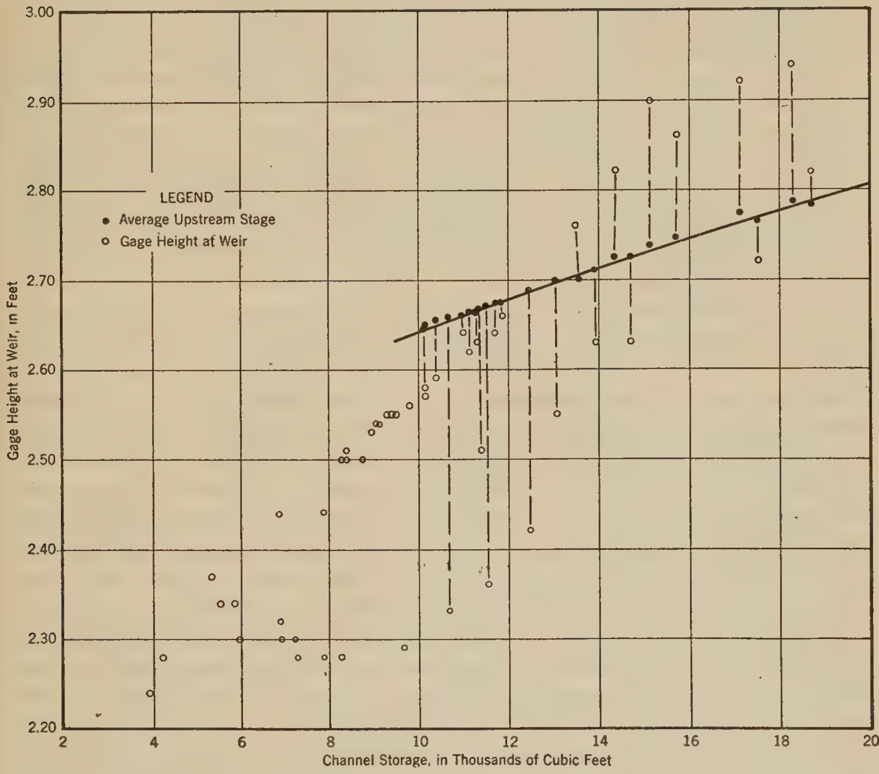

FIG. 13.—CHANNEL-STORAGE RATING CURVE FOR DIFFICULT RUN NEAR FAIRFAX, VA.

Practical experience with recession curves and storage relations have shown, however, that additional refinement in technique may be necessary and desirable. Such refinement is possible if sufficient hydrologic data are collected and correlated with stream flow records.

Fig. 13 shows determinations of gage height and storage in a small headwater area of about 1 sq mile on Difficult Run near Fairfax, Va. The method of channel-storage determinations was presented by O. E. Meinzer and other members of the United States Geological Survey,[21] in the following descriptive discussion:

> "The gaging station is equipped with a V-notch weir and a water-stage recorder. Measurements of channel storage were made by means of 134 secondary gages. The trunk-stream and each of the branches were divided into 100-foot segments, and at the middle of each segment a secondary gage was installed and a profile of the cross section of the channel was made. Each gage consists simply of a 2- by 2-inch stake driven into the bed of the stream so that the depth of water above the top of the stake can be measured with a scale. Secondary gages were installed and cross sections of the channel were made as far upstream on each of the four branches as any stream existed. The volume of water in each segment at any time was computed in cubic feet by multiplying the area of the cross section, in square feet, of the stream at the gaging station for that segment, by 100, and the channel storage in the entire stream system was computed as the sum of the volumes of water in all of the 134 segments. No account was taken, in the computations, of the dead storage below the level of the tops of the 2- by 2-inch stakes."

The observations and calculations of storage were made by V. C. Fishel of the United States Geological Survey in connection with an effluent seepage study.

Despite the probable precision in the determinations of storage volume, the relationship of the gage height at the weir to a storage volume is shown to be somewhat complicated and uncertain. However, if the computed storage is related to an average stage prevailing upstream as calculated from depth measurements from each of the 134 stakes, about two dozen of the storage determinations during appreciable outflow and channel storage may be alined as indicated in Fig. 13. This relationship is interesting in connection with Mr. Clark's discussion of the correlation of storage with discharge.

The measurements on Difficult Run indicate that the stage or discharge at the weir is a very rough index of stages and storage that may prevail in even such an extremely small basin. In addition, it is often presumed that the same relation exists between outflow and storage during rising stages as during the recession. Some methods recognize the existence of this hysteresis effect in connection with channel-storage studies but continue to assume that the net result is small or may be neglected. Some investigators in the field, nevertheless, recognize the inaccuracies in such an approach.

In any event, the study on Difficult Run demonstrates that more exact analysis is possible and probably desirable when the base data are suitable and sufficient. By relating mean upstream stages with channel-storage determinations, evaluations can be made of certain factors whose effect heretofore has been generally given only casual consideration. Moreover, computations involving the volume of channel storage during the rising side of a hydrograph can be made with some increased accuracy from such a storage curve as determined from the recession limb or by other methods.

The use of multiple gages for determining the channel-storage rating also affords a relatively simple method for larger basins. For example, several basins with areas greater than 3,000 sq miles have been examined to explore and demonstrate the procedure presented in this discussion. Fig. 14 shows the orientation of the channel-storage determinations as computed from recession curves for several major rises at the gaging station on the Wabash River at Logansport, Ind. The basin above Logansport comprises 3,760 sq miles and storage takes place in several tributaries with complicated inflow conditions.

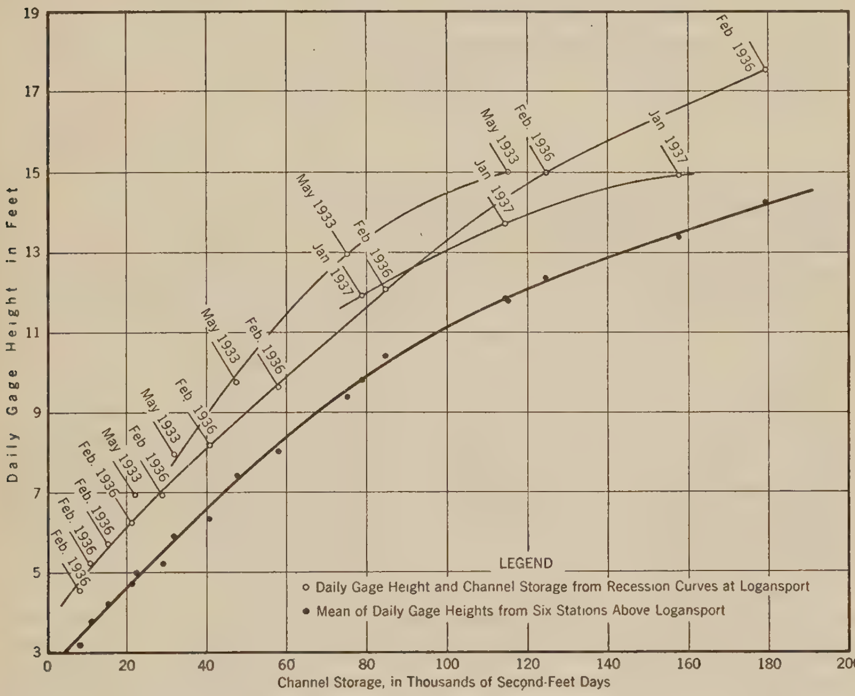

Fig. 14.—Channel-Storage Rating Curve for Wabash River at Logansport, Ind.

Figs. 13 and 14 illustrate important limitations in the assumption of Mr. Clark and others (see heading, "Valley Storage") that "over a large range the true storage may be closely approximated by storage directly proportional to discharge." The method, utilizing an average height or weighted upstream prevailing stage as an index for storage, appears also to provide a somewhat convenient approach for channel-storage determinations during the rising, as well as the falling, stream stages.

The opinions expressed herein are those of the writer and not necessarily those of the organizations with which the writer is identified.

Robert E. Kennedy,[22] M. Am. Soc. C. E.—At the risk of being more or less academic, the writer would like to comment on the old controversy over the basic assumption of the unit hydrograph.

In Fig. 15 the unit hydrograph, as labeled, is the runoff of a net rain of 1 in. over the watershed in a certain time unit—1 hr, 6 hr, or 12 hr—as may be chosen by the investigator. Then the basic assumption of the unit hydrograph idea is that, when a 2-in. net rain, for instance, falls on the watershed in the same length of time as the 1-in. net rain, the ordinates of the new hydrograph will be twice as high as those of the unit hydrograph, but the time of runoff will be the same for both storms. In Fig. 15 the hydrograph of a 2-in. net rain is labeled "Synthetic Hydrograph Computed by Proportional Ordinates of Unitgraph." The time length of both hydrographs, according to the basic definition of the unit hydrograph, is the line AE, for practical purposes. It is not claimed that the base lengths are exactly identical, which opens the question as to how much difference might occur under extreme conditions.

FIG. 15.—COMPARISON OF HYDROGRAPH COMPUTED BY UNITGRAPH METHOD WITH ONE COMPUTED BY CHANNEL HYDRAULICS ON RECESSION SIDE

A glance at the cross section of a stream channel in Fig. 15(*a*) shows that the channel storage of the two storms cannot be emptied in the same time. That would mean that the water stored in the channel at Q_2 and represented by point B on the hydrograph in Fig. 15(*b*) must run out in the same time as that stored at Q_1 in the channel and shown as point C on the smaller hydrograph, Fig. 15(*b*). This cannot occur because the water stored in the channel between Q_2 and Q_1 must go first, and that takes time. No matter how fast it may flow, the water cannot escape in "nothing flat"!

Just how much longer time the larger storage requires to empty is susceptible of mathematical treatment. The writer developed this relation and then found that his labor had been largely anticipated in mathematical analyses published by Robert E. Horton, M. Am. Soc. C. E., in 1936[23] and 1937.[24]

Any two floods can be so compared on the recession side of their respective hydrographs that the discharge at one point, for example, is twice that of the other. Let these two points be points of contraflexure. Two such stages are shown in Fig. 15(*b*) at point B on one hydrograph (dashed line) and point C on the smaller hydrograph below, ignoring for the present that the latter was used to illustrate the unit hydrograph

---

[23] "Natural Stream Channel-Storage," by Robert E. Horton. *Transactions*, Am. Geophysical Union, 1936, Pt. II. pp. 406–416.

[24] "Natural Stream Channel-Storage" (Second Paper), by Robert E. Horton. *ibid.* 1937 Pt. II, pp. 440–456.

The difference in time required by the channel to empty itself of these two floods from this point of contraflexure is computed as $n^{0.20} - 1$ when n is the ratio of the ordinates of the two stages at this point. In Fig. 15, $n = 2$; and $2^{0.20} - 1 = 0.14$. Lines EF and CG, Fig. 15(*b*), are each 14% of line DE.

When the discharge of the larger flood is three times the smaller one at the point of contraflexure the larger flood requires 25% longer time to empty from that point on the hydrograph. If the larger flood discharge is ten times the smaller flood discharge, the larger flood would take 58% longer to empty. However, in practise the last featheredge of the storm water flow is so diluted with ground water or base flow that the end of the hydrograph is entirely indeterminate.

To complete the dashed-line hydrograph, resort was made to the non-mathematical assumption that the larger storm would take as much longer to fill the channel system as it does to empty it when compared to the time required for the smaller storm, so A′A was made 14% of AD. The rising leg of the dashed-line hydrograph was made parallel to that of the smaller flood.

The two areas shown crosshatched in one direction were made equal to the one area crosshatched in the other direction because the two hydrographs bounding these crosshatched areas represent the runoff from the same storm.

In conclusion it appears from the completed figure that the multiple ordinate concept of the unitgraph is not strictly correct because, when two such hydrographs as shown are superimposed, at only one point is the ordinate of the larger one exactly twice that of the smaller one. No matter how much shifting was done, all the ordinates of the larger or dashed-line hydrograph could not be twice those of the smaller one.

Nevertheless the unit hydrograph is a most useful tool in hydrology.

Victor H. Cochrane,[25] M. Am. Soc. C. E.—The relationship between the unit hydrograph and the storage capacity of the drainage system, as well as a simple and practical procedure for calculating hydrographs, is presented in this excellent paper. The author rightly states that the determination of a hydrograph depends upon two, large, basic factors—the shape of the watershed and the storage through which the runoff must come. The influence of these two factors is largely accounted for by the use of what the author calls the time-area concentration curve, and both the accuracy and simplicity of the method are due to this device.

Storage is related to time, and may be expressed in time units. The paper contains a discussion of storage concepts, and some rather surprising conclusions are drawn, but it does not appear that the author's procedure is dependent upon the validity of these conclusions. If the processes by which a hydrograph is built up are viewed from the standpoint of time instead of storage, a different, and perhaps more easily understood, explanation of the basis of the author's method is derived.

If a drainage basin is divided into a number of areas, or zones, such that their downstream boundaries are at equal time intervals of flow from the point of measurement, a bar diagram of these areas would be the time-area diagram for the watershed, the base of each bar being the constant time interval for flow through the zone. This diagram, when converted to flow in cubic feet per second for 1 in. of runoff in one period, becomes the time-area concentration curve.

---

[25] Cons. Engr., Tulsa, Okla.

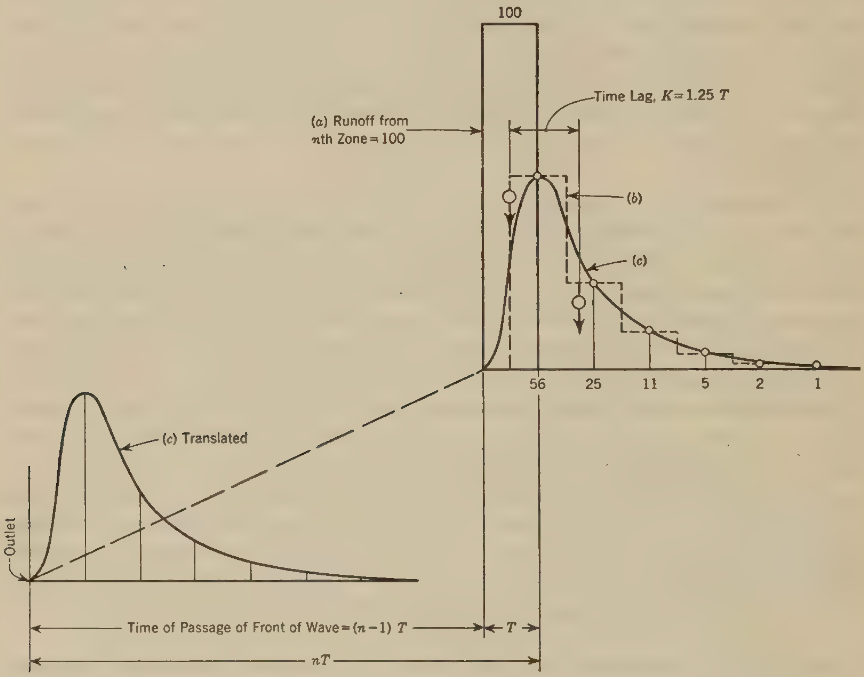

FIG. 16.—TYPICAL ZONE HYDROGRAPH

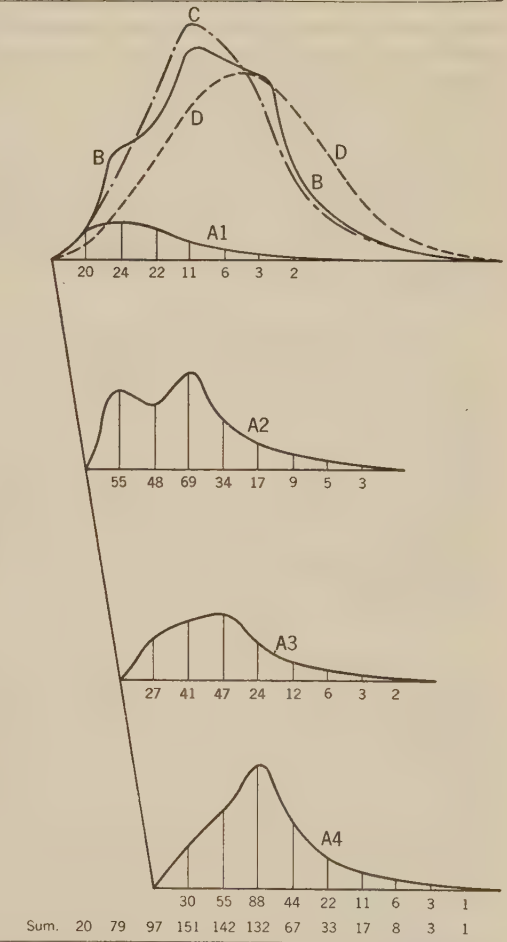
If all the runoff-producing rainfall in a unit period of time could be delivered instantaneously at the outlet (zero storage), the hydrograph would be a single bar with one time unit as the base and a height equal to the combined height of all the bars in the time-area concentration curve. If the net rainfall in each zone could be concentrated instantaneously at the zone outlet, and if the zone concentrations should then flow to the point of measurement at channel velocity and without further modification, the time-area curve would be the hydrograph of flow at the outlet. This latter process accounts for the greater part of the effect of time (or storage), and the time-area diagram resembles the actual hydrograph.

However, the zone contributions do undergo modification within the limits of the zone and during the passage downstream. In Fig. 16 the bar diagram represents the runoff originating in the nth zone above the outlet during the unit time T. By the time it reaches the outlet it is modified to a typical outflow hydrograph, such as curve (c), which is shown in relation to the precipitation and in the translated position. In this connection the author makes the valuable suggestion that the modification (which is in addition to that implicit in the time-area concentration curve) be determined by means of the Muskingum equations with x equal to zero and with K, the time lag in hours between center of mass of net zone rainfall and center of mass of zone runoff, equal to some small amount, such as 1.25 T. The modified hydrograph becomes the bar diagram (b), and if a smooth curve is drawn through the ordinates of (b) it will be the zone hydrograph (c).

TABLE 4.—COMPUTATION OF HYDROGRAPH; $K = 1.5\,T$

Zone Number	Area of Zone, in Square Miles	Net Rainfall: Depth, in Inches	Net Rainfall: Miles² Inches	Distribution to Periods: 1	2	3
1	40	2.2	88	40	28	20
2	100	2.4	240	110	40	90
3	60	2.7	162	54	54	54
4	100	2.6	260	60	80	120
Totals	300		750			



The author's use of a constant value for K seems to be based on the assumption that most of the modification occurs within the limits of the zone. This is a reasonable basis for practical use, for it will be found that the precise shape of the zone hydrograph is of little consequence. However, it is not difficult to make use of variable values of K. The summation of the zone hydrographs for a one-period rain may be used as a unit hydrograph, but it is better to complete each zone hydrograph for its entire runoff and then combine the flows.

The hydrograph is sensitive to the shape of the time-area diagram and to the number of periods of rainfall. Variations in rainfall intensity and distribution, infiltration losses, and other factors may be taken into account zone by zone. The method is simple and flexible. It is based on the same conception of constant time elements that underlies the unit hydrograph theory, but it is more adaptable to a variety of conditions. The hydrograph may be computed for an approximate time interval and then corrected to fit the proper time base. When the time-area diagram and other constants are properly determined, the hydrograph due to any type of storm can be calculated with satisfactory limits of approximation. Conversely, any kind of storm can be employed in deriving the constants.

Table 4 shows the suggested arrangement of data. The calculations are for a four-zone watershed having an area of 300 sq miles. The zones vary considerably in size, and a three-period rainfall is irregularly distributed both with respect to zones and time periods. Constant K equals 1.5 T, so that $C_0 + C_1 = C_2 = 0.50$. The modification of runoff for zone 1 is computed as shown in Table 5.

TABLE 5.—COMPUTATION FOR THE MODIFICATION OF RUNOFF, ZONE 1, TABLE 4

Line No.	Description	Runoff in Mile²-Inches							
		40	28	20	..	..	..	..	Remainder
1	Runoff, in mile²-inches × 0.50	20	14	10	..	..	..	..	..
2	Line 3 (advanced one period) × 0.50	..	10	12	..	..	..	..	..
3	Time-period ordinates	20	24	22	11	5.5	2.75	1.38	1.37
4	Recorded in Table 4, and shown graphically	20	24	22	11	6	3	2	..

The zone hydrographs, A1, A2, A3, and A4, are combined by adding the computed ordinates, resulting in the irregular hydrograph B (see Table 4). The relatively small amount of precipitation in zone 2 during the middle time period is the cause of the dip in A2 and the corresponding flattening of B. The sharp peak in A4 results in a bulge in B. If the same total net rainfall were uniform over the entire drainage area over the three time periods, the resulting hydrograph, C, is much less irregular, but the peak is changed only slightly. The same total rainfall uniformly distributed over five periods would produce hydrograph D, having a considerably lower peak.

If the surface and subsurface flows are separated, the foregoing method may be applied in the case of the Appomattox River (see heading, "Derivation of the Instantaneous and Unit Hydrographs"). Assuming a uniformly distributed net rainfall of 2.35 in. (3,140 mile²-inches), occurring in the three periods ending at noon of April 26, and a time lag (storage) of 15 hours, then adding subsurface flows amounting to 0.57 in. in 10 days in accordance with curve (c), Fig. 8, the results agree substantially with the computed hydrograph shown in Fig. 9.

In the "statement of fact" No. 1, Mr. Clark states that there may have been a considerable variation in rainfall from east to west both in quantity and time. The writer assumed a variation of from 1.7 in. to 3.1 in., with a weighted average of 2.35 in. over the entire basin, and found that, on the whole, the computed curve did not fit the observed hydrograph any better than did the author's hydrograph, Fig. 8. The effect of varying K from a minimum of 9 to a maximum of 20 was found to be negligibly small. It would seem that the time-area diagram is the most important factor in the computation. In all cases there was too much difference between the peaks and the valley between, as compared with the recorded flows. It is likely that the record is at fault, as suggested in the "statement of fact" No. 3, or that the largest zone areas have been somewhat overestimated.

FRANKLIN F. SNYDER,[26] ASSOC. M. AM. SOC. C. E.—Papers dealing with unit hydrograph and flood routing procedures have been quite numerous in recent years and the author is to be complimented for his efforts to clarify the inherent relationship between these hydrologic tools. However, the extent to which that objective has been accomplished is modified by the introduction of a number of confusing and unsupported statements about certain hydrologic phenomena.

In the "Introduction," the author, referring to an article,[7] states that "For example, in determining a seven-period unitgraph from a flood resulting from three periods of runoff, it is possible to determine thirty-six unit hydrographs which, applied to the three items of runoff, will reproduce the composite hydrograph exactly." Theoretically, if the unit hydrograph procedure were exact, there would be one unit hydrograph that would reproduce the composite hydrograph exactly. For illustration, one can assume a unit hydrograph and compute a composite hydrograph. There exists, therefore, a unit hydrograph which will reproduce the composite hydrograph exactly. In actual practice there is no unit hydrograph that will reproduce observed composite hydrographs exactly. However, if the composite hydrograph is not the result of a too complex storm, numerous methods are available for determining a unit hydrograph that will reproduce the observed composite hydrograph with a satisfactory degree of accuracy. The example[7] cited by the author illustrates this theory, as the most probable distribution-graph values obtained by "least squares" for a composite storm do not reproduce exactly the observed hydrograph.

Fig. 3 shows the results of a study of the effect of storage that is equally a function of inflow and outflow on a wave form with an initially very sharp peak. The author has made a common mistake[27] in obtaining an outflow hydrograph different from the inflow hydrograph after assuming that the reach storage is equally a function of inflow and outflow ($x = 0.5$, or that storage varies as the sum of inflow plus outflow).

The fact that the outflow hydrograph should be identical with the inflow hydrograph except for a time shift is readily proved from the general storage equation and is evident from a consideration of the Muskingum formulas,

[27] "A Direct Method of Flood Routing," by C. O. Wisler and E. F. Brater, *Transactions*, Am. Soc. C. E., Vol. 107 (1942), p. 1519.

Eqs. 6*d*, 7*a*, 7*b*, and 7*c*. Another result is obtained when certain basic requirements fundamental to most routing procedures are violated:[8] (1) The routing interval, T, must be small enough to define, satisfactorily, variations in rate of flow; and (2) the reach should be of such length that the time of travel is approximately equal to T. In the example under discussion a 2-hr value of time of travel, K, was assumed by the author for an imaginary reach of a river. The value of T that was used to derive the hydrographs in Fig. 3 is not given, but, according to requirement (2), T should be 2 hours. Then, with x equal to 0.5, $C_0 = 0$, $C_1 = 1.0$, $C_2 = 0$, and $O_2 = I_1$—that is, outflow at the end of the period equals inflow at the beginning. Requirement (1) was violated since a value of T equal to 2 hours is too large to define, adequately, the hydrograph in Fig. 3. However, O_2 will always equal I_1 from Eq. 6*d* as long as T is made equal to K.

On the same basis the outflow curve labeled $x = 0.5$ in Fig. 2 is in error and should be identical to the original curve except for a time shift of 4 hours. The negative values for the curve, $x = 0.5$, and for the other outflow curves, also, are definitely due to the selection of units and the limitations of the routing procedure, and to couple these values with physical phenomena either real or imaginary seems unwise.

Another erroneous result is often obtained when routing a hydrograph such as that for Danville in Fig. 12, through a reach with a value of K considerably greater than a reasonable value of T. The slow prolonged rise and rapid fall coupled with the assumptions of the Muskingum routing procedure result in a peak outflow rate higher than the inflow rate even though a value of x considerably less than 0.5 is assumed. Walter B. Langbein,[28] Assoc. M. Am. Soc. C. E., has suggested an adjustment of the Muskingum procedure to compensate for the inability of the weighted flow to represent storage in the reach adequately when either inflow or outflow is changing rapidly.

To justify the basic assumptions followed in developing the Muskingum routing procedure, the value of T should be made approximately equal to the value of K. If this is not done (and it is seldom possible in practical applications), the value of x is a function of the length of reach, or K, in addition to indicating the portion of the weighted flow that is derived from the inflow.

The attempt to prove that shifting a hydrograph in time and routing it through a small value of storage gives a hydrograph quite similar to that obtained with the Muskingum routing procedure using a value of $x = 0.5$ has resulted in a failure to make clear an important objective of the basic idea. Most flood routing procedures actually provide no time advantage for forecasting purposes—that is, the inflow data must be extended into the future just as far as it is desired to obtain values of outflow. The procedure proposed by the author—namely, shifting the inflow hydrograph in time and routing it through a predetermined amount of reservoir-type storage—does give a time advantage equal to the amount of the time shift.

The writer has been accumulating data in connection with such a routing assumption and, as would be expected from the ease with which routing procedures can be verified, has had little difficulty in obtaining satisfactory results when routing observed hydrographs for various streams in the eastern United States.

---

[28] "Channel Storage and Unit Hydrograph Studies," by Walter B. Langbein, *Transactions*, Am. Geophysical Union, Pt. II, 1940, pp. 620–627.

In analyzing these records a procedure convenient for routing the transposed hydrograph through a certain amount of reservoir-type storage was developed. As stated by the author, where storage, S, and outflow, O, are uniquely defined by the elevation at the outlet such as in a reservoir ($x = 0.0$ in the Muskingum procedure), the ratio of successive increments of storage to increments of discharge, $\frac{\Delta S}{\Delta O}$, has the dimension of time and is represented in this discussion by the symbol T_s. If storage is in acre-feet and O in cubic feet per second, T_s is in units of days and equals (very nearly) $0.5 \frac{\Delta S}{\Delta O}$. Starting with a volumetric expression of the storage equation for some satisfactory routing period, the mean inflow, $\bar{I}$, minus the mean ouftlow, $\bar{O}$, equals the change in storage. For units of cubic feet per second for discharge, acre-feet for storage, and days for time:

$$\bar{I} - \bar{O} = \frac{\Delta S}{2\,t} \quad \text{(19)}$$

With the usual assumption of straight-line variation of inflow and outflow during the routing period, t, and, since $\bar{O}$ then equals $\frac{\Delta O}{2} + O_1$, with the subscript 1 indicating the value of the variable at the beginning of a routing period:

$$\bar{I} - O_1 = \frac{\Delta O}{2} + \frac{\Delta S}{2\,t} = \Delta O \left(0.5 + 0.5 \frac{\Delta S}{t\,\Delta O}\right) \quad \text{(20)}$$

Substituting T_s for $0.5 \frac{\Delta S}{\Delta O}$ and solving for ΔO gives

$$\Delta O = C\,(\bar{I} - O_1) \quad \text{(21)}$$

in which

$$C = \frac{1}{0.5 + \frac{T_s}{t}} \quad \text{(22)}$$

This solution of the storage equation lends itself readily to tabular computation and to the use of variable values of T_s by plotting the variation of C against O. When inflow is zero, ΔO equals $- C\,O_1$ and C equals $1 - C_r$ in which C_r is a recession coefficient of the outflow hydrograph equal to $\frac{O_2}{O_1}$.

Fig. 17 shows graphically some of the time relationships utilized in analyzing observed records. Local inflow has been separated from the outflow hydrograph so that the latter represents the total effect of the transposition, T_t, and the reservoir-type storage, T_s, on the hydrograph of inflow at the upper end of the reach. The total time shift between center of mass of inflow and outflow, T_T, is equal to the sum of T_t and T_s; that is,

$$T_T = T_t + T_s \quad \text{(23)}$$

The value of T_T is also equal to the value of K in the Muskingum routing procedure provided the fundamental routing requirements previously discussed are not violated. However, if the inflow hydrograph, I, of Fig. 17 is routed using the Muskingum coefficients with $K = 24$ hours, $x = 0.40$, and $t = 6$ hours (too long a reach), the time lag between center of mass of inflow and outflow, T_m, will be 21 hours instead of 24 hours. A quite similar outflow hydrograph is obtained by this procedure, using $T_t = 10$, $T_s = 11$, and $T_T = 21$ ($T_m = 21$).

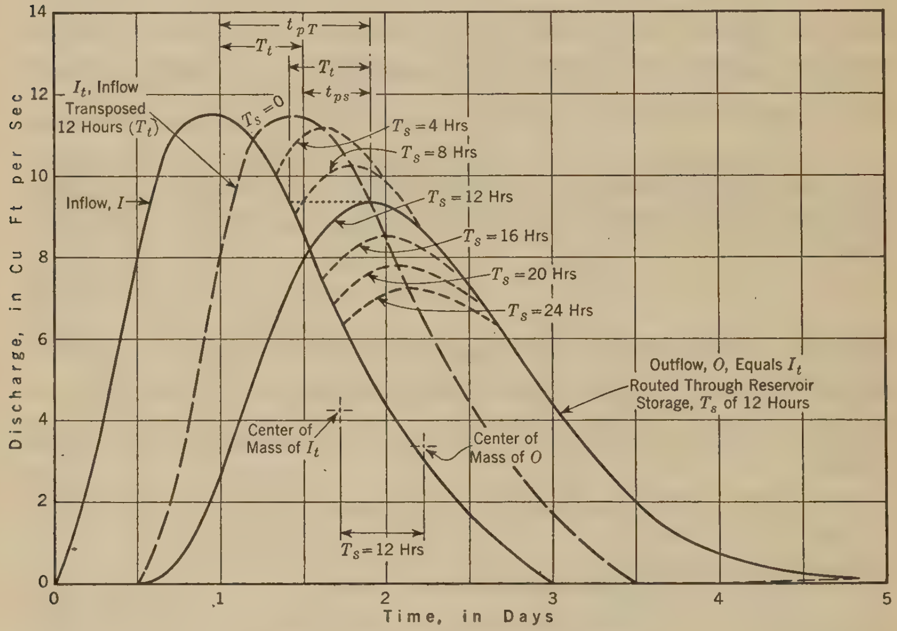

FIG. 17.—TIME AND STORAGE RELATIONSHIPS

The value of T_t in any particular case is available from inspection of the hydrograph and the following relationship is useful in estimating values of T_s: From Fig. 17, t_{pT} equals T_t plus t_{ps}, in which t_{pT} is the total time lag of the crest discharge, T_t is the crest lag due to the transposition, and t_{ps} is the lag of the crest discharge due to reservoir-type storage effect; therefore:

$$t_{pT} = T_t + t_{ps} \tag{24}$$

and, since T_s equals $T_T - T_t$,

$$T_s = T_T - t_{pT} + t_{ps} \tag{25}$$

The time between center of mass of the inflow and outflow hydrographs, T_T or T_m, is readily obtained by transferring the hydrograph shapes with carbon paper to a sheet of stiff paper, cutting out the hydrographs, and locating the centers of area.

In the beginning the writer had hoped that values of T_t and T_s could be assumed constant throughout a wide range of flow conditions, an assumption that is theoretically incorrect but one that is made in most routing procedures.

A variation of T_s can be handled without much difficulty but when both T_t and T_s vary so that their sum also varies, the problem becomes more difficult. As might be expected, observed hydrographs for many streams could be duplicated by assuming constant values of the time and storage factors. However, when a stream with a wide flood plain such as the Missouri River goes overbank, there is a variation of several hundred per cent in the factors.

Under the heading, "Valley Storage," the author states that "The reservoir pool above a dam may not reduce flood discharges." Most engineers will subscribe readily to this generality, and its acceptance is indicated by the fact that considerable attention is given to this problem in the design and operation of reservoirs for hydroelectric projects. The author also states that, " * * * if the pool level at the dam is held constant by gate control, * * * the peak outflow may be larger than the peak inflow." The writer could also agree with this statement if the words "natural peak" discharge at the dam site were substituted for the words "peak inflow"; but it will take considerable more evidence than the Muskingum routing hypothesis to convince him that the peak outflow can be greater than the peak inflow. As a matter of fact, because of backwater storage above a level reservoir pool, the level of the pool at the dam would have to be lowered somewhat to make the peak outflow of a flood as large as the peak inflow. The peak inflow in some cases is larger than the natural peak at the dam site would have been prior to construction of the project because of the elimination of some valley storage but principally because of the change in timing of the concentration of the runoff from the areas draining directly into the reservoir.

The author's extension of storage theory to ground-water flow is quite interesting. The use of a unit hydrograph for distributing ground-water runoff may be quite practicable, but the use of storage values determined from recession curves for deriving the rising part of the runoff hydrograph is subject to more criticism in the case of ground-water runoff than in the case of surface runoff, and the procedure is open to question even for surface runoff.

Other than the use of a constant factor for dividing total runoff into surface and ground-water runoff, the author's procedure probably would be satisfactory for many purposes. However, the writer takes exception to the inference that, in comparison, current practise in treating ground-water discharge is unsatisfactory. Reference is made to a paper[29] discussing this and other phases of runoff phenomena in which both direct runoff and ground-water runoff for the Schuylkill River above Pottstown, Pa. (drainage area, 1,147 sq miles) were computed storm by storm for a year of record using only observed values of precipitation and temperature. This article presents a graphical comparison of the computed ground-water discharge and the observed hydrograph.[30] The accuracy of the ground-water phase of the computations proved more than sufficient for any need of the writer in flood forecasting or hydrologic studies.

The author's use of the quantity, K, and the time of concentration in the development of unit hydrographs is confusing. Under the heading, "The

---

[29] "A Conception of Runoff-Phenomena," by Franklin F. Snyder, *Transactions*, Am. Geophysical Union, Pt. IV, 1939, pp. 725–738.

[30] *Ibid.*, Fig. 4, p. 728.

Hydrograph as an Index of Storage," it is stated that, at the time of most rapid relative rate of decrease of discharge, "The falling legs of a large number of hydrographs of flood discharge for streams in major drainage basins from New Hampshire to North Carolina exhibit a ratio of decrease of discharge to total discharge which, for a value of $x = 0.5$, indicates a value of K closely approximating the time elapsing between termination of runoff producing rainfall and the point of most rapid relative decrease in discharge." With $x = 0.0$ the values of K for these same recessions determined by Eq. 12*b* would be equal to one half the value of time of concentration ($0.5\ T_c$). In the "Summary" it is stated that the time-area concentration curve should be routed through reservoir storage "equal to K times the outflow when K is the time indicated by Eq. 12*b*" at the time of most rapid relative rate of decrease of discharge when $x = 0.0$; that is, $K = 0.5\ T_c$. However, the author states (see heading, "Determination of the Instantaneous Hydrograph for Streams Without Flow Records") "the amount of storage by which the time-area concentration curve should be modified will approximate 10% to 25% of the time of concentration * * *." In the example for the Appomattox River above Petersburg, a value of $K = 0.06\ T_c$ was used ($K = 9$ hours, $T_c = 144$ hours) whereas the average value of K for the James River at Lick Run as determined from the data in Fig. 5 was $0.5\ T_c$ ($K = 14$ hours, $T_c = 28$ hours). With a somewhat similar procedure, which is about the most common and oldest known rational method of determining synthetic hydrographs, the writer has obtained satisfactory unit hydrographs from time-area curves routed through storage values equal to the unit hydrograph "lag" defined as time from center of mass of effective rainfall to peak of the unit hydrograph. Values of "lag" are almost always greater than one half the time of concentration as defined by the author.

Howard M. Turner, M. Am. Soc. C. E., and Allen J. Burdoin,[31] using a similar procedure, obtained fairly good reproduction of observed hydrographs for the Connecticut River at Sunderland, Mass., by routing a time-area or inflow hydrograph through a reservoir storage for which K equals 59 hours with a value of time of concentration equal to 50 hours ($K = 1.2\ T_c$).

The principal purpose of the preceding discussion is to emphasize the fact that there are still two variables in the development of a synthetic unit hydrograph: A time element (time of concentration, T_c, in this paper), and a storage factor (expressed as a percentage of T_c by the author). The use of a slope factor has been introduced by the author as an aid in determining the time factor, but the storage factor has not been correlated directly with any physical features of the drainage basin.

From the writer's experience in attempting to correlate the two variable factors with physical features,[32] he is not too optimistic about the author's use of a slope factor to determine the time variable except in localized areas. The river slope adopted by the author is believed to be a more representative slope factor than the average over-all slope usually obtained by dividing the total fall by the length. However, the data presented in the paper indicate a range of values of C, in which $T_c = C \frac{L}{\sqrt{s}}$, from 0.6 for the Smith River at Bassetts to 2.0 for the Appomattox River near Petersburg. (A value of average slope, as defined by the author, of 11.6 ft per mile for a length of 37 miles was determined from available reports and used for the Smith River at Bassetts instead of the value of 16.6 given in the paper.) Although the writer believes the exponent of the slope factor should be smaller than 0.5, variation of the exponent of s in the expression $T_c = C \frac{L}{\sqrt{s}}$ would have little effect on the relative range of values of C which vary from 0.6 to 2.0 for the Virginia drainage basins discussed in the paper.

[31] "The Flood Hydrograph," by Howard M. Turner and Allen J. Burdoin, *Journal*, Boston Soc. of Civ. Engrs., Vol. XXVIII, No. 3, July, 1941, p. 232.

[32] "Synthetic Unit-Graphs," by Franklin F. Snyder, *Transactions*, Am. Geophysical Union, Pt. I, 1938, pp. 447–454.

The suggestion of the author that the determination of the time and storage factors for streams without records should be based on actual measurements should be emphasized. A time factor such as "lag" [32] can be obtained for any river station where discharge is principally a function of stage, without installing any equipment, by observing the time of crest stage and comparing it with field observations or official records of the rainfall characteristics of the storm. A storage factor is not so easily determined but it is not subject to as great a range in value as the time factor and the time factor provides a partial index of the actual value of the storage factor.

Howard M. Turner,[33] M. Am. Soc. C. E.—The first part of this interesting paper is a discussion of the channel storage in a reach of a river. The author compares the storage in this case with that in a reservoir, indicating the difference in the behavior, due to the fact that the relation between outflow and storage is not clear on account of the slope. The author cites an assumed case showing how a sharp diminution in inflow "requires" an increase in outflow at the outlet end of the reach. The writer has never seen any such effect. There is a sudden decrease in inflow at the outlet of many water power plants at 5 o'clock or 6 o'clock every afternoon for months during the year when there is no waste. The writer has examined many hydrographs taken at gaging stations some distance downstream from such stations and has never seen any evidence of any rise attributable to the cause given by the author. He admits the possibility, but believes that the author's statement is much too categorical in stating that it is "required" under such circumstances. There may be a slightly rising outflow because the high discharge existing at the upper end has not yet become stabilized at the lower end—that is, water is still going into storage and this rise will continue for a period of time after the power station shuts down due to the time lag between the two points. The outflow then drops off in the regular recession curve as the storage drains off. The difficulty in the author's contention is his statement (see heading, "Valley Storage") that the additional storage must be released "during the period of inflow reduction." This increased storage that must flow out may be released over a longer period of time.

---

[33] Cons. Engr., Boston, Mass.; Lecturer on Water Power Eng., Harvard Univ., Cambridge, Mass.

The writer has analyzed several of these conditions and, by using the storage curve determined from the recession side of the hydrograph (that is, the storage as a function of the outflow), he has obtained very satisfactory agreements with an actual hydrograph by routing such power station discharges through this storage with time allowance for travel.[34] In two of the three cases considered, the hydrograph downstream did show higher flow than that upstream, but this was due to the flow from intervening drainage and the inaccuracy of computing the power station discharges from the kilowatt-hour output and the difference disappeared when the inflow hydrograph was adjusted to give the same total runoff. There was no evidence in these cases of any rise which the author states is required by sudden reduction of inflow to the reach. If the author has any actual examples showing this effect, it is hoped that he will present them as it is an extremely interesting and, as he states, a somewhat new conception.

The author then describes his distinction between storage as a function of the outflow and storage as a function of the inflow. The writer believes Mr. Clark has oversimplified this theory. Actually, storage is a function of neither inflow nor outflow alone, depending as it does on topography and the level of the water surface, which in turn are dependent upon slope. Therefore, any difference between the author's two concepts of storage is dependent on a difference in changing slope which with the topography of the banks affects the volume of storage. In this case a more exact statement would be that, in the case of the unsteady flow of a rising or falling river stage, the changing slope affects the storage.

The writer finds it difficult to accept some of the statements made in regard to the storage affected by the inflow. In Fig. 2 the author shows curves for routing a simple sine curve with different storages based entirely on inflow ($x = 1.0$) through to a curve based entirely on outflow ($x = 0.0$). In the case of the former the flow with storage is greater than without storage. Where $x = 0.5$, the hydrograph is very little changed. It is not until x equals less than 0.5 that the storage reduces the inflow, and not until $x = 0$ does the outflow hydrograph intersect the inflow hydrograph at the peak of the former, which is generally held as a basic requirement between inflow and outflow hydrographs.

As would naturally occur if these curves are correct, the curve of outflow with $x = 1.0$ intersects the curve of inflow at the peak of the former and thus the storage increases the peak discharge from the outlet of the reach by a very great amount. The writer gives $x = 0.3$ to 0.5 as the usual range of values. If this condition is valid, there will be many cases in which there will be little if any diminution of peak due to storage. The writer does not question the conclusions reached with the author's equations, but he has never seen any indication of such effects and therefore distrusts the original equation. He believes that it is based on too simple a function of the storage compared to that actually existing in any normal river channel.

The second part of the paper develops a method of constructing a unit hydrograph from an instantaneous hydrograph. In this case the author uses storage as a function of outflow alone ($x = 0$). The writer is not certain whether the author considers the condition to be somewhat different for a given reach than for the storage of the entire river system, since the storage used in this section of the paper does not seem to correspond with his previous statement regarding what he has found to be that on most rivers.

---

[34] "The Flood-Hydrograph and Valley-Storage," by Howard M. Turner, *Transactions*, Am. Geophysical Union, 1943, Pt. II, p. 613.

The author's process consists of using storage based on the actual flood hydrograph at the beginning of the recession curve and routing through it a time-area concentration curve which is in effect an inflow hydrograph built from an analysis of the time required for the water from the different parts of the drainage area to reach the outlet. In doing this the same storage relation is used for the rising stage of the hydrograph as for the falling stage.

The writer was much interested in this procedure as it is based on the same principles that were used by him and Mr. Burdoin.[31] Using their method, a rational inflow hydrograph was constructed from the duration of the rainfall, the concentration time was obtained from the deflection point on the recession curve of the hydrograph, and the total flood volume was routed through storage computed from the recession curve to obtain the outflow or flood hydrograph. The author extends these principles somewhat further adding the feature of the instantaneous hydrograph.

The author's method differs with regard to the storage which he determines from only one point on the hydrograph—the inflection point on the descending limb. This assumes a straight line from this point down to zero, an assumption which may not always be correct. (On the Appomattox River at Petersburg, one of the examples cited, the curve is not a straight line all the way down.) Mr. Clark draws an instantaneous inflow hydrograph for a given river by actually figuring the time-area relation instead of using, as the writer did, a general one based on shape. This makes a much more flexible arrangement than the writer's and gives a more accurate inflow hydrograph. Such accuracy may not always be necessary, however, when the rainfalls over the area for different storms are considered. (For example, the Appomattox River at Petersburg has had other floods which present different characteristics. The one of March, 1932, with a peak of 8,000 cu ft per sec and about the same length of base shows no depression at the top of the hydrograph.) The writer found that an assumption of a rectangular shape gave satisfactory results in many cases that varied considerably from a rectangle.

The author's method, however, would permit extending the time-area concentration inflow not only to cover the shape of a given area with assumed uniform rainfall but also to include varying rates of rainfall on different parts of this area.

The author presents a new treatment of the base flow which, in the particular case of the Appomattox River, gives much better results than would the customary method—that is, a straight line at the base of the hydrograph, which, if used, gives a computed hydrograph less close to the actual one than the author's. This hardly can be taken as a proof that the author's method is any better since the entire matter of the rainfall distribution is unknown, as the author states. (Rainfall at Hopewell amounting to 23% of the total occurred during the two days, April 28 and 29, in the middle of the flood.)

There are many unknowns in the behavior of the ground storage during a flood. Unanswered are such questions as how the water gets into the ground with a rapidly rising river, how far back the rise in ground-water level continues before the river begins to drop again and the storage flows back into the river, and how much of this drainage from storage in the ground may be due to normal ground-water flow backed up by the rising level and thus not originating from the flood rainfall. The outflow hydrograph will also be much affected by the assumption as to the amount of flood appearing as ground-water flow assumed by the author as 30% of the total. The author suggests that this percentage, taken from records of another river, must vary with floods of different magnitude. To use 30% for an instantaneous hydrograph for all floods may lead to error in the case of much greater or much smaller floods. The author should give some examples of the proportion of ground-water runoff which his method discloses in small floods compared to very large floods. The writer has found that with all these possible differences, the simple method of drawing a straight line across the base of the hydrograph is sufficiently accurate for general use in spite of its theoretical limitations.

The author is to be congratulated for devising an additional tool to use in the attempt to analyze the steps between the rainfall, inflow hydrograph, and the flood hydrograph.

DON JOHNSTONE,[35] ASSOC. M. AM. SOC. C. E.—The difficulties of winnowing out the grains of wheat in technical literature are certainly not decreased by inventing new meanings for old phrases. Engineering terms should mean the same thing today as yesterday. If new concepts are introduced, new terms should be invented. The author, in applying the term "unit hydrograph" or "unitgraph" to a hydrograph which includes ground-water flow, is misusing a basic definition. Similarly, in applying the term "concentration time" to the time interval "between cessation of runoff-producing rainfall and the minimum indicated value of *K*" he is tying another time-honored phrase to a new concept. Mr. Bernard's definition of concentration time ("a time interval at the end of which all parts of the watershed are contributing to the flow at the point of observation") gives that particular combination of words a job to do and should pre-empt it from other uses.[36] Other examples of criticizable terminology include the use of "runoff" for "rainfall" in the third and fifth paragraphs of the "Introduction" and in the third paragraph of the section headed "Valley Storage and the Unit Hydrograph," followed by its use in an entirely different sense in the second paragraph of the next section; and the use of "the channel" in that same section without indicating whether reference is to the main stream alone or to any "channel" in the watershed.

Passing to other matters, attention is invited to the statement in the "Introduction" that the determination of unitgraphs from "multiple periods of runoff [sic] * * * is indeterminate, as there are always more equations than unknowns and a multiple of possible solutions." Presumably the author meant "more unknowns than equations," but, waiving that point, the statement is still incorrect. By unitgraph theory, surface runoff in the xth period resulting from a storm of n periods duration is $c_1 f(x) + c_2 f(x-1) + \cdots + c_n f(x-n+1)$, in which $c_1, c_2, \cdots, c_n$ are the net rainfalls for the corresponding periods and $f(x), f(x-1), \cdots, f(x-n+1)$ are the ordinates of the unitgraph for the xth, $(x-1)$th, $\cdots$, $(x-n+1)$th periods. If flow measurements and rainfall measurements were precise, if the base flow (ground-water flow) were known, if the net rainfalls for all periods were determinable, and, finally, if the stream behaved exactly in accordance with unitgraph theory, it would be possible to derive the unitgraph from the hydrograph of a multiple-period storm by successive subtractions. Actually, successive subtractions yield nothing of value, as none of the four "if's" is exactly in accordance with fact and as the process involves the accumulation of error from step to step. The concept is set forth here, however, to demonstrate that there are actually as many equations available as there are unknowns (so far as unitgraph theory is concerned), and that there should therefore be no possibility of multiple solutions from a given set of data if a proper technique of derivation is applied. One such technique has been outlined by William T. Collins,[37] Jun. Am. Soc. C. E.

---

[35] Asst. Prof., Civ. Eng., Ohio State Univ., Columbus, Ohio (on military leave).

[36] "An Approach to Determinate Steam Flow," by Merrill Bernard, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 350.

It follows (see "Introduction") that "the practical requirement of finding an isolated flood hydrograph resulting from a uniform unit rainfall," which the author states "provides an almost insurmountable obstacle to the derivation of the unitgraph for very small [?] drainage areas and very short unit periods [intervals] of time," is no longer a requirement at all. As a matter of fact, a protracted period of heavy rainfall is the ideal period from which to derive the unitgraph, because (*a*) rainfall is more likely to be nearly uniform over the watershed, (*b*) infiltration conditions are more nearly uniform throughout the period of rainfall, and (*c*) the fact that rainfall actually extended over the selected unit time interval is assured. To carry this argument further would be beyond the proper scope of discussion; the writer acknowledges that despite the incorrectness of the quoted statements there is still need for a method that will permit deriving unitgraphs without reference to rainfall records.

The argument under "Valley Storage," down to the introduction of Eq. 4, is confusing. Particularly welcome would be a justification of the statement that "reduction of the inflow rate necessarily would be accompanied by * * * an increase of outflow rate." Fig. 1 and its explanation are unconvincing, and the writer would like to see (here as elsewhere) proof in the form of actual recorded data rather than in the form of a rather casual theoretical analysis.

The argument on the extension of storage theory to ground-water flow appears to "boil down" to this: It would be convenient if unitgraph principles were applicable to ground-water flow; therefore they are applicable. Without further proof, the author proceeds to apply them. There is something about neatly arranged tables of computations that seems to consecrate the result, and it is likely that computing a number of ground-water flow hydrographs by this method would confirm many a budding hydrologist in the belief that the implied relationships had been proved. Actually, the "refinement" attained by treating ground-water flow in this manner (if it be, in fact, a refinement at all) seems scarcely worth the effort; 30% of curve (c) in Fig. 8 could be replaced by the customary sloping straight line and the change in curve (d) would scarcely be noticeable.

---

[37] "Runoff Distribution Graphs from Precipitation Occurring in More than One Time Unit," by William T. Collins, *Civil Engineering*, September, 1939, p. 559.

An even more basic criticism, however, is the inclusion of ground-water flow, by whatever means computed, in the unitgraph. By including it, the range of usefulness of the unitgraph is seriously impaired. Its major function is not—as emphasis in many papers would lead one to believe—to confirm itself repeatedly by reproducing second-rate floods with more or less accuracy. Rather, it is a tool to indicate what will probably happen when a really first-rate rainfall comes along; and it should be left to do that job unhampered by the introduction of ground flow factors that will likely be inapplicable at the big moment. Suppose the maximum storm hits the watershed when the ground is saturated—or frozen. A true unitgraph can handle that situation (compare the "pluviagraph" of Mr. Bernard[38]); a composite graph of surface and subsurface runoff cannot handle it—and it errs on the side of danger.

Passing to the author's example, there is much difficulty in following the detail. Table 1 shows $K = 15$, whereas the text states that $K = 9$. Also, the relationship between the plotted curves of Fig. 8 and the data of Table 1 is obscure. Should not curve (d) be the plotting of Col. 9?

However, the major shortcoming of the example is the failure to explain the construction of Fig. 6. This is the heart of the entire matter—the drawing of lines on a map in such a manner as to define areas that make their contributions to "the channel" in successive intervals of time. How is it done? What factors are taken into account? Why do the area boundaries cross the streams without bending stream-upward, when logic suggests that they should take the form of exaggerated contour lines? (See, for example, Mr. Bernard's statement:[36] "* * * the efficiency of the main channel, through higher velocities, places headwater areas much closer to the outlet in terms of time than extensive areas nearer but less advantageously located.") With a knowledge of how to chart these areas, the operator finds the remainder of the technique to be a matter of measuring areas by planimeter and of running a calculating machine; without it, he is at a loss where to start.

The justification for applying the same value of K to the contributions of all areas is not apparent. It would appear to be reasonable only on the assumption that storage conditions are the same in all areas and that no storage exists in the main channel; but obviously the author does not make any such assumption. Rather, he takes for the value of K the value existing at the moment when all surface runoff is presumed to have reached "the channel." It follows that K for the downstream areas should be smaller, and for the upstream areas larger, than the average.

Since delineating the areas on the map is subject to a wide range of personal choice, and since the use of a single value of K is open to question, the writer suggests that a somewhat different approach might yield equally satisfactory results with less effort. Using "concentration time" as defined by Mr. Bernard, the base length of any hydrograph of surface flow (including the unitgraph as defined by Mr. Sherman) is equal to the duration of runoff-producing rainfall plus the concentration time. This statement includes the instantaneous unitgraph, for which the base length is simply the concentration time itself. Concentration time, by the Bernard definition, can be determined from an inspection of hydrographs, with reasonable accuracy, as readily as concentration time by the Clark definition. Having determined it, divide the watershed map into the corresponding number of time-interval areas and determine the percentage area of each. The tabulation of these percentages, without any further operations, is in itself the instantaneous distribution graph of surface flow for the watershed.

---

[38] "An Approach to Determinate Stream Flow," by Merrill Bernard, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 358.

It cannot be said that the effect of storage is overlooked in this proposed method, for it is reflected in the fact that concentration time (the Bernard definition) takes in the entire period of time required for a particle of water to travel from the hydraulically-most-remote point to the point of observation. Basically, the analysis seems as sound as that of the author's more complex procedure. It would be interesting to determine a unitgraph for the Appomattox River by this proposed method and test it, also, for the flood of April, 1937. Unfortunately, the necessary basic data are not available to the writer. Also, an adequate technique for dividing the watershed map presumably remains to be developed. This should be a fruitful field for further inquiry.

In making such a test, it would be necessary to assume a "reasonable" ground-water flow, and the writer would be content with a straight line joining the point on the observed hydrograph at which rainfall begins, with the point at which surface runoff ceases. Fig. 9 indicates the latter to be at the line marked "April 3."

C. O. CLARK,[39] JUN. AM. SOC. C. E.—The discussions represent much thought and labor at a time when most of the writers are actively engaged in entirely different matters. The expressions which corroborate the paper are gratifying and greatly appreciated. The divergent views outline some fertile fields for further investigation of problems which are still largely dependent on judgment and should stir stimulating and constructive thinking. Some of the queries and counterproposals presented lie beyond the ability of the writer to answer; some have been answered by other discussers; and a few are reviewed in the closing discussion. All are sincerely appreciated.

Mr. Sweet pertinently emphasizes that the labor involved in unit hydrograph and flood-routing techniques is excessive for routine river forecasting. Reduction of this labor by the development of simplified empirical coefficients is necessary and highly desirable. However, the simplification might be based upon a large number of hypothetical floods computed by appropriate methods as well as upon records of past floods. As Mr. Sweet states regarding the James River, nonuniformity of storm distribution may produce variable stage relationships between the gages along the river. If records of only a few large floods are available, it is easy to assume that relationships are fixed, only to be embarrassed when nature proves otherwise. However, unit hydrograph study of hypothetical adverse distributions of storm rainfall will reveal many of the variable possibilities which may serve as guides for good forecasts rather than as alibis for poor ones. The James River, with its two halves on either side of the Blue Ridge Mountains in Virginia, offers opportunities for illuminating study to any one who believes that nonuniformity of runoff distribution on an area is not significant, or that gage-to-gage stage relationships are simple or constant.

---

[39] Hydr. Engr., U. S. Engr. Office, Winchester, Va.

Major Meyer clarifies several points in the paper, and appropriately warns of situations in which K is not a constant. Unit hydrograph theories and constant time elements of flow are convenient oversimplifications of a most complex form of open channel flow. They are by no means universally applicable. The paper treats only the elements common to unit hydrograph theory and to the theories of flood routing based upon constant values of K. "Lag routing," to which both Major Meyer and Mr. Snyder refer, is a very practical and expeditious method of flood routing. Fig. 3 and its supporting discussions demonstrate the essential agreement between this method and the much more laborious application of the Muskingum technique. The construction of the time-area concentration curve of Fig. 8 and its routing modification conform essentially to "lag routing" procedure.

Lag routing is an empirical approximation of some solutions of the storage equation; it is not itself a solution of the storage equation for any fixed relationship between storage capacity and discharge. It is an expedient method for use in a natural state of river development, as in flood forecasting or in computation of past floods. However, the writer would be unable to determine, with it, the effect of improvements which change the storage capacity along a river, such as extensive levee systems—or particularly those improvements which change the relative influence of inflow upon storage, such as a series of dams.

Thus, for solving routing problems which involve a change in storage-discharge relationships, the writer believes that the storage equation will be more reliable than empirical "lag routing." As Major Meyer writes, there are several methods other than the Muskingum method for the solution of Eqs. 2, 4, and 5.

Mr. Sherman—the creator of the unit hydrograph—reviews the underlying theory of this excellent hydrologic tool with masterliness. Possibly through misinterpretation of the bar pattern of Fig. 8 and through the assumption that curve a is a net rainfall pattern of twelve unit periods rather than a representation of shape of drainage area, Mr. Sherman concludes that the resulting derived hydrograph was not a unit hydrograph. In Fig. 8, a bar pattern representing net rainfall would be of infinitesimal duration at zero time. In Fig. 9, rainfall was principally confined to that on April 25 and that early on April 26.

An apology is made to Mr. Sherman and to others who found difficulty in checking the computations in Table 1, particularly the conversion of Col. 8 to Col. 9. The conversion at a rate of 69,000 (cu ft per sec)-half-days per in. is a rounded value appropriate to a drainage area of 1,300 sq miles, rather than to one of 1,335 sq miles. The former area is that for which the first derivation on this stream, determined for a dam site above the gage, was prepared. Intent upon presenting an unretouched, original, routine solution, the writer

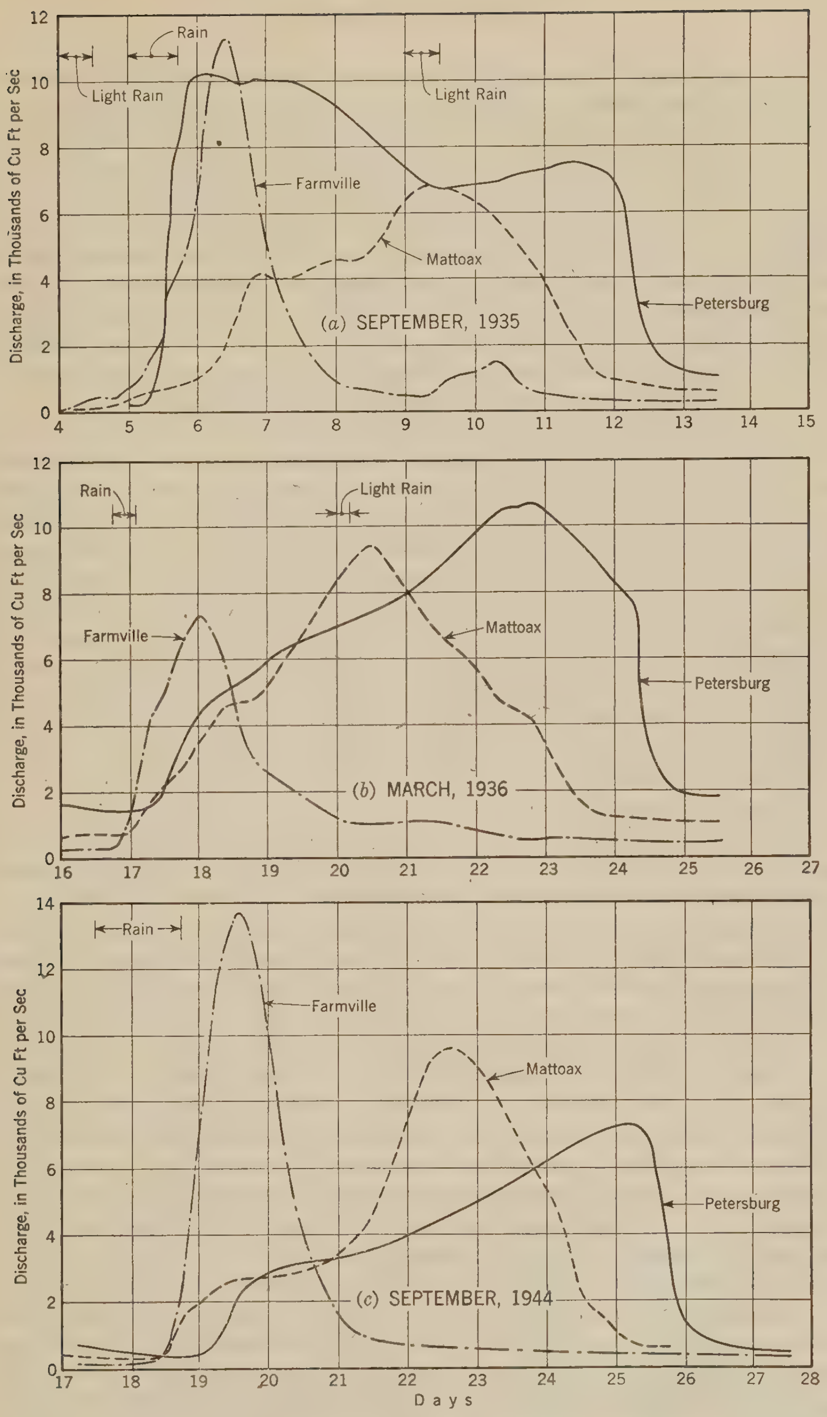

FIG. 18.—HYDROGRAPHS OF THE APPOMATTOX RIVER

failed to notice and properly explain the small difference in drainage area. The routing calculation illustrated is for 15 hours, as stated in Table 1, rather than for 9 hours, as stated in the text. Subsequent investigations indicated the smaller value to be more suitable. There are also some slight errors in Table 1, all well within the range of acceptable routine office practise, and there is much room for improvement in the analysis. The entire original analysis was prepared in 4 hours and was not then intended as a part of a published paper. The presentation of these data was intentional. The real value of a hydrologic tool is much better judged by the rough-hewn original product with its faults, than by the prettier refinements which most investigators possess and ultimately adopt for use.

Mr. Sherman comments on the size of watersheds to which unitgraphs may be applied. He correctly states that size is not a barrier to the adequate treatment of nonuniformity of rainfall with respect to time. On the other hand, nonuniformity with respect to areal distribution of the rainfall creates variations such as those shown in Fig. 18. Each of these hydrographs resulted from a rainfall brief enough to be considered a unit rain. The relative size of hydrographs at the three stations (gaging, respectively, 23%, 55%, and 100% of the Appomattox River above Petersburg) and rainfall records indicate heavier rainfall on one end or the other in each case. Of the hydrographs at Petersburg, none would be suitable for derivation of a unitgraph by any method which assumed that the hydrograph resulted from a uniform distribution of runoff. In the proposed method, which makes no such assumption, an equally suitable unitgraph could be derived from each of the records. However, neither of the hydrographs at Petersburg could be reproduced well by use of a single unit hydrograph, because, although a reproduction would represent flow from uniformly distributed runoff, the record does not. Subdivision of the area and the use of three component unitgraphs like those in Table 2 produce better results. The methodology as extended by Mr. Turner, incorporating both area and runoff depth in the time-area curve, gives much better results.

The possibilities of storage acting to increase outflow drew varied comment from Messrs. Meyer, Williams, Linsley, Brater, Snyder, Turner, and Johnstone, ranging from "controvert[ing] accepted concepts and experience" and "erroneous" to "familiar to all persons who have worked with reservoirs storing appreciable volumes of water under the backwater profile." The writer agrees heartily with those who suggest "These conclusions should be examined critically." The possibility should not be passed over lightly, however, as failure to recognize the possibility leads directly to overoptimism about the effectiveness of certain types of flood control dams, and to underestimation of the importance of avoiding fixed-pool operations at power and navigation dams and unnecessarily rapid gate closures.

The writer's comments about the inflow-controlled storage were intended to be qualitatively explanatory (rather than quantitatively assertive) of the statement (see heading, "Valley Storage"), "Valley storage does not always decrease flood peaks * * *." The excellent discussions reviewing the case against such a viewpoint appear to require some presentation of the data supporting an affirmative case.

The writer's use of a uniform channel in Fig. 1 for the qualitative explanation was ill chosen from a quantitative viewpoint. The uniform channel was selected because of the simple, familiar form of the two backwater profiles. Obviously, however, a uniform rectangular channel would not have an x-value in excess of 0.5. Therefore, Professor Brater's quantitative criticism is well founded. A quantitative demonstration might consider that the rectangular channel possesses a non-water-carrying flood plain several times as wide as the channel at the upper end, converging to the channel limits at the lower end. By appropriate selection of the flood plain width at the upper end of such a channel (which would be quite similar to the channels of many natural streams carrying relatively small flows in their extensive overbank areas), the volume of stored water under the backwater curve could easily be made to exceed 720 acre-ft, which is the volume Professor Brater's analysis indicates as the limiting volume that could be passed without surge.

Channels—the variable cross sections of which effectively converge in the direction of flow—might be expected to possess storage capacities influenced more by inflow than by outflow. Such channels might include:

(*a*) Channels converging in variable depth (such as low-slope channels approaching a steeper channel and thus flowing from a zone of great range in stage to one of small range in stage and at the same time possessing flood plains of about equal width, or such as reservoirs maintaining fixed levels at the dam with pronounced fluctuation at their upper ends, or such as reaches ending in tidal estuaries); and

(*b*) Channels converging in width but of relatively constant range in flood rise.

In the first class may be found certain South Atlantic streams which cross the Piedmont Plateau flowing toward the Fall Line. The Fall Line is a cascade zone which lies between the Piedmont Plateau and the Atlantic Coastal Plain. For example, the Appomattox River, whose drainage area above Petersburg was shown in Fig. 6, lies on the Piedmont Plateau. Two gaging stations are located above the Petersburg gage: Mattoax, Va., with a drainage area of 729 sq miles, is on the 2.0-day isochrone of Fig. 6, and Farmville, Va., with a drainage area of 306 sq miles, is on the 4.3-day isochrone of Fig. 6.

The typical flood rise at Mattoax in feet is much larger than that at either Farmville or Petersburg although flood plain widths are comparable for the three stations. The variable cross section of flood flow can be considered diverging in the direction of flow from Farmville to Mattoax and converging from Mattoax to Petersburg. Hydrographs of flow at these three stations resulting from rainfall of short duration are shown in Fig. 18. (Note that the later portions of the hydrographs at Mattoax and Petersburg must be essentially the flow component from above Farmville.) To occupy such a position in the hydrographs shown, it appears that the flood wave might have undergone flattening from Farmville to Mattoax and then have been built up from Mattoax to Petersburg. A more provable indication of the type of storage influence represented by x-values greater than 0.5 is the increase in recessional slope of the Petersburg hydrograph as compared with the Mattoax hydrograph.

In the second class might be short reaches of many rivers, as most flood plains alternately widen and narrow. Many rivers have long reaches through which flood waves flow without appreciable reduction.[40] It seems a little more rational to interpret such unreduced passage as the result of alternate slight increases and decreases in peak rather than as a passage of an unvaried peak. A record of a wave passage having slightly more increase than decrease was shown in Fig. 12, in which the hydrograph of flow at Danville appears to have built up slightly and shortened to become the later portion of the hydrograph at South Boston. The discharge from the intervening drainage area would have been insignificant on the twenty-first and twenty-second days.

Most rationalizations about the possibility of storage operating to build up peak flow turn upon the question: "Granting that a volumetric differential exists between the equilibrium profiles of flow applicable to flow distributions before and after a change in inflow, can the change from one profile to another take place rapidly enough to cause a surge at the downstream end?" Fig. 19 shows the experimental hydrographs which C. F. Izzard, Assoc. M. Am. Soc. C. E., and M. T. Augustine obtained by sprinkling a pavement.[41] In this case, the change from one flow distribution profile to another did take place rapidly enough to cause a surge. How fast does the change take place in rivers? How fast does storage volume react to a change in flow?

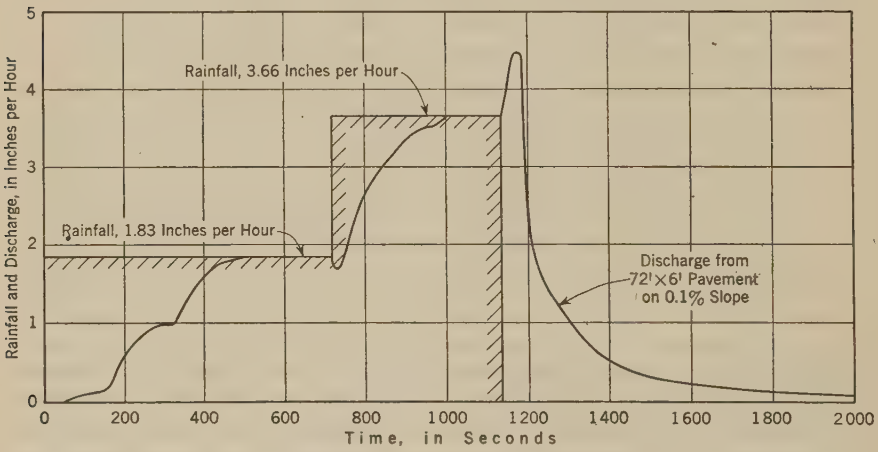

FIG. 19.—HYDROGRAPHS FROM EXPERIMENTS BY C. F. IZZARD AND M. T. AUGUSTINE

Several discussers mention the assumed instantaneous reaction of storage to a change in flow (which is characteristic of most flood-routing techniques and favorable to reduction of peak flow in the method discussed when x is less than 0.5) as the error which leads to the author's conclusion. The formula for reaction time presented by Messrs. Williams and Brater is quite favorably regarded by many, whereas Mr. Snyder appears to regard any value less than K as inadequate. Several intermediate viewpoints have some adherents. The time elements indicated by Eq. 17, first discussed by Mr. Williams, vary from very long values for a shallow depth at the beginning of a flood to crest-depth values which are very short in relation to the time elements of mean flood-wave travel. Thus, in the reach of river to which Mr. Williams applied the formula, the channel depth was more than 50 ft at the time of crevassing. For this depth, the formula discussed would indicate less than 40 min. (Neither the methods of observing stage, nor those of defining the time of crevassing of a levee are sufficiently reliable to distinguish between the time of transit as originally stated and that given by the formula.) This value would be insignificant in flood routing over a reach involving flood-wave travel time of 15 hours.

[41] "Preliminary Report on Analysis of Runoff Resulting from Simulated Rainfall on a Paved Plot," by C. F. Izzard and M. T. Augustine, *Transactions*, Am. Geophysical Union, Vol. 24, 1943, Pt. I, p. 500.

The writer does not claim that the upgrading of flood crests by storage action has been proved, but merely offers the explanation and the examples of the paper in support of the statement, "There is some valley storage which does not decrease flood peaks." The upgrading of hydrographs does appear possible, however, and should be investigated. A closely analogous situation exists in electrical circuits, and the upgrading (in height, not discharge) of hydraulic waves in converging channels is a recognized phenomenon in tidal hydraulics.

Mr. Linsley clarifies several ideas in the paper by his discussion. The formula he presents for determining time of concentration in watersheds without records shows better correlation with data in the paper than the author's formula. To aid in further study by others, additional data are presented in the same manner in Table 6. The majority of values were developed from records available prior to 1938. The variation in the constants suggests judicious local application. Attention is again directed to the first two sentences under the heading, "Determination of the Instantaneous Hydrograph for Streams Without Flow Records," and to Mr. Snyder's closing two paragraphs.

Messrs. Linsley and Johnstone properly question the writer's use of uniform velocity in establishing time contours along the watercourses and suggest variations based on slope and efficiency of watercourses. These refinements were considered, but investigation showed their use to be unaccompanied by superior results. This may be a case of two wrongs making a right, as the likewise neglected principle of using greater storage values, K, on flows from more remote areas instead of a single average value is a logical refinement of opposite effect. In general, the use of a varied velocity of channel flow and a single value of K tends to increase the fault originally recognized by the writer in item 6(*b*) of the "Summary."

Messrs. Brater and Johnstone voice an interest in a more detailed description of the time-area concentration curve. As Mr. Snyder states, the curve is an old device[42,43] for calculating flow. It has fallen into disuse because its theory assumes the reductive influence of storage to be negligible. A storage correction factor was included in the paper to revitalize this useful tool. The time-area concentration curve is derived by marking time contours along the

watercourses, the time to the most remote point being equal to the "time of concentration." For the latter term, a standard definition such as that quoted by Professor Johnstone is intended. Fig. 4 illustrates why the terminus of this time is not at the end of the hydrograph (theoretically infinite in length) but well up on the recessional leg.

[a] Time of concentration, not reductive storage factor.

Mr. Crawford presents interesting analyses of channel-storage correlation with stages at the discharge point and upstream from it, and shows the superiority of correlations which give weight to upstream values of inflow and stage. He calls attention to the potential possibilities of determining from discharge records other storage relations which would be too costly by cross-sectional surveys. The writer has seen area-capacity curves for small dam sites so developed which would require very detailed field surveys for equal accuracy.

Mr. Kennedy emphasizes the fallacy of constant base length in a unit hydrograph. Much of this fallacy may originate in the assumption of a finite base length. If storage theories and unit hydrograph theories are to be correlated, the concept of finite base length in a unit hydrograph must give way to a concept of an infinite length, a characteristic possessed by the writer's instantaneous hydrographs and their derivatives. Nevertheless, the practical differences, as shown by Fig. 15, are within the range of usually acceptable hydrograph computations. This is probably the reason that the practical simplicity of finite constant base length has so long outweighed the theoretical superiority of infinite base length.

Mr. Cochrane has very thoroughly examined the procedure for deriving unitgraphs utilizing storage concepts, and presents some explanations which should be helpful to those who were mystified by the writer's presentation. In a simple manner, he clarifies the twofold effect of storage: First, the greater effect of storage in creating time lags between flows from different zones, or the time-area diagram; and, second, the further modification of hydrograph shape accomplished by storage.

The order in which these steps have been utilized is the reverse of that in Fig. 8, but the result is the same regardless of order. The order in Fig. 16 gives a clear picture of the mechanical effects, and would be necessary if one wished to use variable values of K for different zones. At the sacrifice of this possibility, the order of Fig. 8 involves less work. However, a unit hydrograph for an entire area may produce very disappointing results if applied to a storm characterized by great nonuniformity of runoff distribution. Mr. Cochrane presents a very practical application of storage principles which considers both nonuniformity of runoff distribution and some variation in storage effect.

Another method of accounting for nonuniformity, suggested by Mr. Turner, is to extend the time-area concentration curve to express not only shape but also different runoff distribution—that is, multiply the zone areas by the depth of runoff in each zone before embarking on the routing procedure of Table 1. This procedure takes care of distribution with respect to area and is a fine tool for studying the magnitude of the effect of areal nonuniformity of runoff distribution.

Both procedures abandon the unit hydrograph and require complete recalculation of each flood with attendant increased labor. Other less logical, but extremely useful techniques to account rapidly for nonuniformity include adjustments of chronological sequences of runoff used with the unit hydrograph. Thus, concentration of volume on more remote parts of a simple watershed can be simulated in some degree by using an effective runoff volume for a later time than actually was the case. Extreme intensity of rainfall within a unit period can be simulated by increasing the computational amount in that period and decreasing the values on either side of the period. The most flexible technique yet utilized by the writer is the development of unit hydrographs for very small zones, which are routed downstream to gaging stations and tabulated in the manner of Table 2. This procedure is followed for as small areas as desired to express nonuniformity to the necessary degree. These subunitgraphs can always be added together for use on areas as large as justified by the uniformity of any storm and can be used separately if necessary. Although this procedure was discussed under the heading, "Unit Hydrographs for Large Drainage Areas," any watershed is large from the viewpoint of detailed, exacting hydrograph computation.

Refined techniques are necessary and desirable to establish more suitably correct procedures and to confirm academic viewpoints as to the effect of certain qualitative variables. However, a computation is only a guide to judgment. After a hydrograph is computed with a unitgraph or other appropriate tool, judgment demands some modification of the answer if the premises of the methods and the facts of the occurrence are not in accord. At times a wide line, a small scale, or a little freehand "artistic license" may have as much merit as hours of computing. In their proper place, these too are proper tools.

Mr. Snyder presents several of the practical aspects of hydrograph calculation and the mathematical basis for a very simple and useful method of routing over long reaches of river where storage-discharge relationships are such as to produce essentially constant time elements. He calls attention to elements of logical and mathematical fallacy which may appear small to some investigators, but which must be faced squarely and solved before the hydrograph computations can be considered accurate enough to prove or disprove some of the questions raised in this paper.

As Mr. Snyder states, the Muskingum method of flood routing loses its usefulness when applied to too long reaches. However, this may also occur because the storage-discharge relationship for a long reach of river is much less closely approximated by a straight line than is the relationship for short reaches. The storage item in flood-routing formulas such as Eq. 5 deals with the volume stored in a reach at any instant of time, whereas the storage capacity of channels having nearly constant elements of flow time ($n = 1.0$ in Eq. 3) refers more closely to the volume under the high-water profile. Although this latter volume is the total storage volume utilized in the reach of river during flood passage, it is more than is used at any instant during that time. The difference becomes a material one in long reaches. Nevertheless, if storage solutions are confined to the length of reach for which Eq. 5 would be applicable, Eq. 6*b* is a correct solution. The Muskingum method is a correct solution of Eq. 6*b* only to the extent that a finite value of T is a satisfactory approximation of dt. Mr. Snyder expresses the opinion that values of T used in the preparation of Figs. 2 and 3 were too short.

The inadequacies of methods of mathematical solution receive too little recognition. Most engineers find it necessary to adopt arithmetic approximations, such as Eqs. 1 and 6*c*, for the solution of calculus equations, such as Eqs. 2*a* and 6*b*.[44] The practises are so common that they escape much comment. The simplicity of the Muskingum method encourages these procedures, since it depends first on the substitution of a finite value of time T for the infinitesimal time dt. Then, too, many convenient, quick solutions evolve from various lengths of time T which make one or more of the constants either 1.0 or 0. Values of T as large as K or larger conveniently obscure some of the effects of the inadequacy of the theory recognized by the writer in his discussion of Fig. 2, and have been accepted by some as a basic requirement. The differences are as given by Mr. Snyder. In an effort to prove whether such a basic requirement added anything to the over-all accuracy of hydrograph solutions, the writer has for several years assumed that the shortest practical time element, T, was the most appropriate. In general, practical applications have been no more faulty, and in some cases apparently better, whereas the practical benefits of greater mathematical consistency and rapid checking procedures accrue to (or result from) closer adherence to the mathematical premises.

---

[44] "Graphical Integration of the Flood-Wave Equations," by Harold A. Thomas, *Transactions*, Am. Geophysical Union, Vol. 21, 1940, Pt. I, p. 597.

Mr. Snyder's presentation of the mathematics of a simple method of lag routing should increase the practical appeal and use of this simple procedure. To be completely general, the solution may need some provision (1) to cover the flow conditions in which the lag of the crest discharge is greater than the lag between the centers of mass of the inflow and outflow, and (2) to cover the conditions in which the recession rate of outflow exceeds the recession rate of inflow. Flow conditions requiring this modification are evident in Fig. 18, in which the hydrographs of the Appomattox River at Mattoax are shown to have a materially smaller rate of recession than does that portion of the hydrograph at Petersburg which encompasses the flow volume from above Mattoax.

Inspection of Fig. 17 and Eq. 25 suggests the applicability of a negative value of T_s. The writer finds the mathematics of a solution evasive, however, and doubts that this is a practical solution. Nevertheless, it is explanatory of a relationship between K and time of concentration (T_c), which still baffles him. However, it is assumed for the purpose of the next paragraph that negative values of T_s are applicable.

The failure of the writer to solve this possible adaptation of lag routing is the source of his confusion in statements under the heading, "The Hydrograph as an Index of Storage," about which Mr. Snyder rightfully comments. The values of K applicable to smaller watersheds appear to be as large as 0.5 of the time of concentration (T_c); yet those for larger watersheds have a much smaller ratio of T_c and occasionally a smaller dimensional quantity. Obviously this is possible if T_s could have a negative value. For the three gages on the Appomattox River—Farmville, Mattoax, and Petersburg, each site being downstream from the preceding site—the values of K which the writer regards as most appropriate are, respectively, 9 hours, 12 hours, and 9 hours, whereas the most acceptable times of concentration, T_c, are 32 hours, 114 hours, and 168 hours. (These values for Petersburg differ from values in Table 1, which were the very first computations made for that stream. The difference between the values of T_c equal to 144 hours and 168 hours is dimensionally large, but the same percentage difference in the more usual range of the writer's application, 24 hours or less, would represent but 4 hours, which is close to the limiting error fixed by rainfall data. Furthermore, that percentage difference is quite comparable with the expected difference due to seasonal variation in flow conditions, a factor usually ignored, but by no means absent.)

The Appomattox River presents the most perplexing flow conditions to which the writer has yet applied the unit hydrograph theory and the longest time of concentration for comparable drainage area that he has ever encountered, as well as a unique shape. Although the illustrated hydrographs for the Smith River at Bassetts and the James River at Lick Run are certainly the more common type, exceptions, like the illustrated hydrographs of Appomattox River and Meherrin River, are necessary to prove the rule. Judging from records of rounded and tree-shaped watersheds typical of the glaciated and alluvial streams of the Midwest, it would appear illogical that a stream could rise for a longer period than it fell, or that streams could have unit hydrographs like those presented for the Appomattox and Meherrin rivers. Mr. Sherman's doubt that any unit hydrographs were presented in the paper is therefore very understandable.

Mr. Turner provides a well-balanced discussion of the paper, confirming statements and expressing appropriate reserve and doubt where his experience and understanding of conventional concepts and procedures do not justify presented conclusions. His comparison of results obtained from the outlined unitgraph procedure and from his similar procedure[31] encourages confidence in the principles applied. His extension of the method to include varying rates of rainfall on different parts of the area is quite practical.

Professor Johnstone outlines some logical elements of greater and lesser refinement whose merit would depend on the extent of the use for them. He expresses several views in sharp conflict with those of the paper. The propriety of defining a unitgraph to include nonsurface runoff is basicly criticized Granting that some investigators have presented hydrographs attributed to surface runoff, the writer questions whether such a claim can be substantiated or disproved, since there is no feasible method of distinction, no acceptable specific definition of either kind of runoff, or any impervious boundary between the flow channels utilized by each. Practise in the application of the terms seems to justify distinctions satisfactory to the user and determinable only to the extent of their compatibility with a preferred theory. The writer indicated that separate unitgraphs could be used for surface and subsurface flow, if warranted, and that there was nothing fixed about the 70:30 ratio. However, in computations of subsurface flow there seems little reason to reject that definable quality which the use of the unit hydrograph theory has provided in surface flow analysis.

In his demonstration that there "* * * should * * * be no possibility of multiple solutions" of conventional unit hydrograph derivations from rainfall and stream flow data only, Professor Johnstone adequately presents the reasons why an investigator who uses all the data available can secure: (*a*) A distressingly large number of different solutions if he assumes he is able to determine runoff from rainfall; or (*b*) no solution if he admits inability to determine runoff from rainfall. In the storage concepts presented in the paper, there are additional considerations which eliminate the necessity for dependence on rainfall and runoff determinations. Until runoff determinations become more reliable, however, the real accuracy of the method must remain partly shrouded in unproved hope.

ANALYSIS OF RIGID FRAMES BY SUPERPOSITION

By David M. Wilson,[1] M. Am. Soc. C. E.

With Discussion by Messrs. F. S. Merritt, Ralph W. Stewart, John E. Goldberg, A. W. Fischer, Leon Blog, Arthur B. McGee, Jaroslav Polivka, Odd Albert, W. C. Spiker, David B. Hall, A. A. Eremin, Victor R. Bergman, and David M. Wilson.

Synopsis

The purpose of this paper is to demonstrate the usefulness of the principle of superposition in the analysis of rigid frames by the slope-deflection and moment distribution methods. A number of examples are presented to show how the principle may be used to advantage in attacking a variety of problems. The principle of superposition is usually stated in textbooks on structural analysis; but, in the writer's opinion, its application is not emphasized to the extent that its importance warrants. In the study of continuous structures, in particular, a thorough working knowledge of the principle is indispensable.

It will be noted that no new method of analysis is proposed. Instead, a method of procedure is outlined which coordinates the principle of superposition with existing methods and, at the same time, places emphasis where it properly belongs.

Preliminary Considerations

The scope of the paper is limited to the analysis of frames in which applied loads cause linear displacements of the joints, in addition to angular displacements (rotations), and consequent angular displacements of the members. It is assumed that each member of any frame considered has constant section throughout its length. However, the method of procedure which is presented is general, since it is based upon fundamental principles, and can be applied with little additional labor to the analysis of frames having members of varying section after fixed-end moments, carry-over factors, and stiffness values have been evaluated.

Notation.—The following letter symbols, used in this paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials,[2] prepared by a Committee of the American

[2] ASA—Z10a—1932.

Standards Association, with Society representation, and approved by the Association in 1932:

C = a moment symbol commonly used in slope-deflection analyses; for example, C_{AB} = a fixed-end moment at end A of any member AB, caused by transverse loads on the member (see also M);

E = modulus of elasticity;

K = a ratio of moment of inertia of a section to the length of the member $= \frac{I}{L}$;

L = length of any member;

M = bending moment; for example, M_{AB} = resisting moment of end A of any member AB; M'_{AB} = fixed-end moment, caused by the angular displacement of the member (see also C);

R = angular displacement, in radians, of the straight line connecting the ends of the member $= \frac{\Delta}{L}$ (referred to as the angular displacement of the member);

Δ = relative linear displacement of one end of any member with respect to its other end, measured perpendicularly to the initial position of the member;

θ = angular distance or rotation; for example, θ_A = the rotation angle at joint A of any frame, or of end A of any member framing into joint A.

Convention of Signs.—The signs of the quantities used in the problems of this paper are determined by the following conventional rules:

The rotation angle, θ, is positive when it occurs in a clockwise direction and negative when it occurs in a counterclockwise direction.

The linear displacement, Δ, and the angular displacement, R, are both positive when the straight line connecting the ends of the member under consideration rotates in a clockwise direction and negative when this line rotates in a counterclockwise direction.

The resisting moment, M_{AB}, and the fixed-end moments, M'_{AB} and C_{AB}, are positive when they act in a clockwise direction and negative when they act in a counterclockwise direction.

Lengths of Members.—In the solutions of subsequent problems, the lengths of members are taken between axial intersections of members. Therefore, the moments obtained represent the moments at these intersections, not the moments at the faces of supporting members. The latter may be computed without difficulty, however, after the moments and shears at intersections have been determined.

Fixed-End Moments Induced by Angular Displacement, R.—The resisting moments at ends A and B, respectively, of any member AB are defined by the slope-deflection equations:

$$M_{AB} = 2\,E\,K\,(2\,\theta_A + \theta_B - 3\,R) + C_{AB} \qquad \text{(1a)}$$

and

$$M_{BA} = 2\,E\,K\,(2\,\theta_B + \theta_A - 3\,R) + C_{BA} \qquad \text{(1b)}$$

These equations may be expressed in the form:

$$M_{AB} = 2\,E\,K\,(2\,\theta_A + \theta_B) + (C_{AB} - 6\,E\,K\,R) \text{..........} (2a)$$

and

$$M_{BA} = 2\,E\,K\,(2\,\theta_B + \theta_A) + (C_{BA} - 6\,E\,K\,R) \text{..........} (2b)$$

Now, if both ends of the member are fixed against rotation so that $\theta_A = \theta_B = 0$, the fixed-end moments at A and B are obviously equal to $(C_{AB} - 6\,E\,K\,R)$ and $(C_{BA} - 6\,E\,K\,R)$, respectively. Furthermore, if the member carries no transverse loads so that $C_{AB} = C_{BA} = 0$, the fixed-end moments at A and B are each equal to $(-\,6\,E\,K\,R)$. Therefore,

$$M'_{AB} = M'_{BA} = -\,6\,E\,K\,R = -\,6\,E\,K\,\frac{\Delta}{L} \text{............} (3)$$

If one end (say, B) of the member is free to rotate and A is fixed against rotation so that $M_{BA} = 0$ and $\theta_A = 0$, it may be readily shown that the fixed-end moment at A, if the member carries no transverse loads, is equal to $(-\,3\,E\,K\,R)$. Under this condition, the rotational stiffness at A of the member is equal to three fourths the rotational stiffness at A when B is fixed against rotation.

Outline of Method of Procedure.—In the problems herein considered, the key to analysis in each case consists in the consideration of all possible conditions of deformation of the given frame. In accordance with the principle of superposition the resultant effects on the frame will be equal to the sum of the component effects produced by these separate deformations. The following outline of method of procedure presents, in logical order, the steps required for the solution of any rigid frame problem:

Step 1. Sketches showing all possible conditions of deformation of the frame are made. If transverse loads act on any member of the frame, these sketches will include one of the undeflected frame with any transverse loads that may be acting.

Step 2. Fixed-end moments set up by the transverse loads and unknown angular displacements of the members, before rotations of the joints are permitted, are determined and recorded on the appropriate sketches of step 1. These moments will be numerical values for the condition of transverse loads on members of the frame, and functions of the unknown angular displacements (or unknown joint displacements) for all other conditions of deformation (see Eq. 3).

Step 3. The joints are balanced for each condition of deformation in step 1 by either the slope-deflection or moment distribution method, and the final moments are shown on the deformation sketches.

Step 4. Equilibrium equations are written for the frame with the given loads; and, after proper substitutions, the unknown displacements are evaluated. These substitutions are determined from a consideration of appropriate free bodies on which the moments found in step 3 and all forces are shown acting. The moment at the end of any member in a free body must equal the sum of the moments obtained at the end of that member for the several deformation conditions. It will include a numerical value, if transverse loads act on any member, and additional values that are functions of the unknown displacements.

Step 5. With all displacements known, the moments in step 3 which are functions of these displacements are evaluated, and the final numerical values of the moments at the ends of all members are determined by summation.

It is important to observe that simultaneous equations obtained in the foregoing procedure will usually be the type which may conveniently be solved by successive approximations (method of iteration). This is of particular significance in problems involving more than three unknowns.

Rectangular Frames

Most frames in practice are rectangular in shape. In general, they must be designed to resist both vertical and horizontal loads. The following examples will illustrate the analysis of rectangular frames with different types of loading.

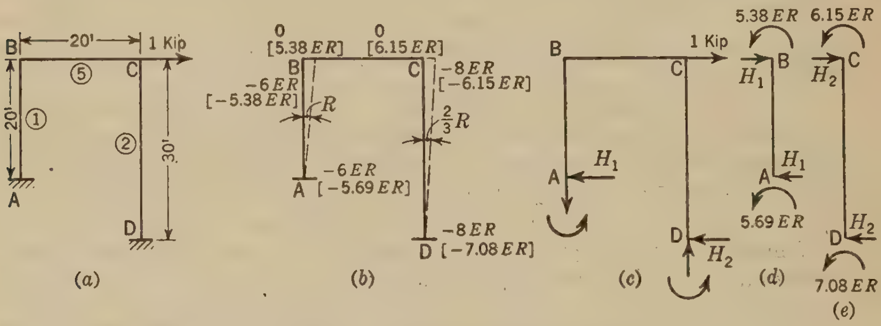

Fig. 1.—Bent with Legs of Unequal Length

Example 1. Bent with Legs of Unequal Length.—Fig. 1(*a*) represents a bent with legs of unequal length, subjected to a horizontal force of 1,000 lb at C. The relative *K*-values of all members are shown in circles. It is desired to compute the values of the moments at the ends of all members of the bent.

Step 1. The only possible condition of deformation of the bent is shown in Fig. 1(*b*). It is obvious that $R_{CD} = \frac{2}{3} R_{AB}$.

Step 2. The fixed-end moments at the ends of all members are determined by use of Eq. 3 as functions of $E\,R$ and are recorded in Fig. 1(*b*).

Step 3. In this problem, the joints in Fig. 1(*b*) are balanced by the slope-deflection method.

The moments at the ends of all members are defined by the slope-deflection equations as follows:

$$\left.\begin{aligned} M_{AB} &= 2\,E\,\theta_B - 6\,E\,R \\ M_{BA} &= 4\,E\,\theta_B - 6\,E\,R \\ M_{BC} &= 20\,E\,\theta_B + 10\,E\,\theta_C \\ M_{CB} &= 20\,E\,\theta_C + 10\,E\,\theta_B \\ M_{CD} &= 8\,E\,\theta_C - 8\,E\,R \\ M_{DC} &= 4\,E\,\theta_C - 8\,E\,R \end{aligned}\right\} \cdots\cdots\cdots\cdots (4)$$

At joint B: $M_{BA} + M_{BC} = 0$. Therefore,

$$24\,E\,\theta_B + 10\,E\,\theta_C = 6\,E\,R \qquad (5a)$$

Also, at joint C: $M_{CB} + M_{CD} = 0$; and

$$10\,E\,\theta_B + 28\,E\,\theta_C = 8\,E\,R \qquad (5b)$$

Solving Eqs. 5 simultaneously,

$$E\,\theta_B = 0.154\,E\,R \qquad (6a)$$

and

$$E\,\theta_C = 0.231\,E\,R \qquad (6b)$$

Substituting Eqs. 6 in Eqs. 4, the following values of the moments are obtained in terms of $E\,R$: $M_{AB} = -5.69\,E\,R$; $M_{BA} = -5.38\,E\,R$; $M_{BC} = 5.38\,E\,R$; $M_{CB} = 6.15\,E\,R$; $M_{CD} = -6.15\,E\,R$; and $M_{DC} = -7.08\,E\,R$. These moments are shown in brackets in Fig. 1(*b*).

Step 4. To determine the value of $E\,R$, an equilibrium equation for the bent must be written.

In Fig. 1(*c*), from $\Sigma F_x = 0$,

$$H_1 + H_2 = 1{,}000 \qquad (7)$$

In Fig. 1(*d*), from $\Sigma M = 0$,

$$H_1 = \frac{11.07\,E\,R}{20} \qquad (8a)$$

Similarly, in Fig. 1(*e*),

$$H_2 = \frac{13.23\,E\,R}{30} \qquad (8b)$$

Substituting Eqs. 8 in Eq. 7, the value of $E\,R$ may be found: $\frac{11.07\,E\,R}{20} + \frac{13.23\,E\,R}{30} = 1{,}000$. Solving, $E\,R = 1{,}005$.

Step 5. The final numerical values of the moments in foot-pounds are: $M_{AB} = -(5.69)(1{,}005) = -5{,}720$; $M_{BA} = -(5.38)(1{,}005) = -5{,}410$; $M_{BC} = (5.38)(1{,}005) = 5{,}410$; $M_{CB} = (6.15)(1{,}005) = 6{,}180$; $M_{CD} = -(6.15) \times (1{,}005) = -6{,}180$; and $M_{DC} = -(7.08)(1{,}005) = -7{,}110$.

Example 2. Unsymmetrical Three-Column Bent.—Fig. 2(*a*) represents an unsymmetrical three-column bent with a vertical load of 1,000 lb acting at the center of BC.

Step 1. Two possible conditions of deformation exist—one for the transverse load on BC, and the other for lateral deflection (sidesway) of the frame. These are shown in Figs. 2(*b*) and 2(*c*).

Step 2. Fixed-end moments are computed for the deformation conditions of Figs. 2(*b*) and 2(*c*) and recorded as shown.

Step 3. In this problem, and in subsequent problems, the joints are balanced by the moment distribution method. Fig. 3 shows the distributions of the fixed-end moments shown in Figs. 2(*b*) and 2(*c*). The final moments obtained from these distributions are shown in brackets in Figs. 2(*b*) and 2(*c*).

Step 4. To determine the value of $E\,R$, an equilibrium equation for the bent must be written.

In Fig. 2(d), from $\Sigma F_x = 0$,

$$H_1 + H_2 + H_3 = 0 \qquad (9)$$

Fig. 2.—Unsymmetrical Three-Column Bent

In Fig. 2(e), from $\Sigma M = 0$, $15\,H_1 + 4.21\,E\,R + 5.11\,E\,R - 1{,}090 - 545 = 0$; and

$$H_1 = \frac{1{,}635 - 9.32\,E\,R}{15} \qquad (10a)$$

Similarly, in Fig. 2(f),

$$H_2 = \frac{-\,1{,}159 - 10.94\,E\,R}{15} \qquad (10b)$$

and, in Fig. 2(g),

$$H_3 = \frac{208 - 2.36\,E\,R}{15} \qquad (10c)$$

Substituting Eqs. 10 in Eq. 9, the value of $E\,R$ may be found; thus, $684 - 22.62\,E\,R = 0$ and $E\,R = 30.2$.

Step 5. The numerical values of the moments caused by lateral deflection are determined by substituting the value of $E\,R$ in the moment terms shown

FIG. 4.—TWO-STORY BENT WITH HORIZONTAL LOADS

Step 1. Two possible conditions exist—one for deformation of the first story, and the other for deformation of the second story of the frame. These are shown in Figs. 4(*b*) and 4(*c*).

Step 2. Fixed-end moments are computed as functions of $E\,R_1$ and $E\,R_2$ for the deformation conditions of Figs. 4(*b*) and 4(*c*) and recorded as shown.

Step 3. The joints in Fig. 4(*b*) and 4(*c*) are balanced by the moment distribution method, and the final moments, in terms of $E\,R_1$ and $E\,R_2$, respectively, are shown in brackets. The actual work of distribution is not shown in this or in subsequent examples, inasmuch as routine computations only are involved.

Step 4. To determine the values of $E\,R_1$ and $E\,R_2$, two equilibrium equations for the bent must be written. In Fig. 4(*d*), from $\Sigma F_x = 0$,

$$H_1 + H_2 = 20 \qquad (11a)$$

and, in Fig. 4(*e*), from $\Sigma F_x = 0$,

$$H_3 + H_4 = 10 \qquad (11b)$$

In Figs. 4(*g*) and 4(*h*), from $\Sigma M = 0$,

$$H_1 = H_2 = \frac{9.34\,E\,R_1 - 2.14\,E\,R_2}{20} \qquad (12a)$$

Similarly, in Figs. 4(*i*) and 4(*f*),

$$H_3 = H_4 = \frac{-\,2.11\,E\,R_1 + 6.71\,E\,R_2}{20} \qquad (12b)$$

Substituting Eqs. 12 in Eqs. 11.

$$18.68\,E\,R_1 - 4.28\,E\,R_2 = 400 \qquad (13a)$$

and

$$-\,4.22\,E\,R_1 + 13.42\,E\,R_2 = 200 \qquad (13b)$$

Solving Eqs. 13 simultaneously, $E\,R_1 = 26.7$; and $E\,R_2 = 23.4$.

Step 5. The numerical values of the moments caused by each deformation are determined by substituting the values of $E\,R_1$ and $E\,R_2$ in the moment terms shown in brackets in Figs. 4(*b*) and 4(*c*), and the final moments at the ends of all members in foot-pounds are computed by summation of these values: $M_{AB} = -\,120$; $M_{BA} = -\,80$; $M_{BE} = 120$; $M_{BC} = -\,40$; and $M_{CB} = -\,60$.

Example 4. Complex Three-Column Bent.—Fig. 5(*a*) represents a complex three-column bent (5*a*)[3] with a horizontal load of 500 lb applied at joint B.

Step 1. Two possible conditions of deformation exist—one for the part ABCD of the bent, and the other for primary deformation of part EDFG which in turn causes secondary deformation of part ABCD. These are shown in Figs. 5(*b*) and 5(*c*), respectively.

Step 2. Fixed-end moments are computed for the deformation conditions of Figs. 5(*b*) and 5(*c*) and recorded as shown. In this problem, the fixed-end moments are expressed in terms of the unknown linear displacements Δ instead of the angular displacements R as in previous problems. The method of solution, however, is not changed in any way.

Step 3. The joints in Figs. 5(*b*) and 5(*c*) are balanced by the moment distribution method, and the final moments, in terms of $E\,\Delta_1$ and $E\,\Delta_2$, respectively, are shown in brackets.

Step 4. To determine the values of $E\,\Delta_1$ and $E\,\Delta_2$, two equilibrium equations must be written for the bent. In Fig. 5(*d*), from $\Sigma F_x = 0$,

$$H_1 + H_2 = 500 \qquad (14a)$$

---

[3] Numerals in parentheses, thus: (5*a*), refer to corresponding items in the Bibliography (see Appendix).

and in Fig. 5(*e*), from $\Sigma F_x = 0$,

$$H_1 + H_3 + H_4 = 500 \qquad (14b)$$

In Fig. 5(*f*), from $\Sigma M = 0$,

$$H_1 = 0.359\ E\,\Delta_1 + 0.269\ E\,\Delta_2 \qquad (15a)$$

FIG. 5.—COMPLEX THREE-COLUMN BENT

Similarly, in Fig. 5(*g*),

$$H_2 = 1.311\ E\,\Delta_1 - 0.075\ E\,\Delta_2 \qquad (15b)$$

In Fig. 5(*h*),

$$H_3 = -\ 0.193\ E\,\Delta_1 + 0.316\ E\,\Delta_2 \qquad (15c)$$

and, in Fig. 5(*i*),

$$H_4 = 0.032\ E\,\Delta_1 + 0.100\ E\,\Delta_2 \qquad (15d)$$

Substituting Eqs. 15 in Eqs. 14,

$$1.670\ E\,\Delta_1 + 0.194\ E\,\Delta_2 = 500 \qquad (16a)$$

and

$$0.198\ E\,\Delta_1 + 0.685\ E\,\Delta_2 = 500 \qquad (16b)$$

Solving Eqs. 16 simultaneously, $E\,\Delta_1 = 222$, and $E\,\Delta_2 = 666$.
